Anæsthetic	85%	45%	38%
Forceps	38%	16%	10%
Neonatal asphyxia ..	97%	21%	0%

These results will be reported in greater detail elsewhere, but it is difficult to avoid the conclusion that cerebral anoxia is closely connected with the occurrence of athetosis, while one must accept Freud's (1897) and Collier's (1899, 1924) view that an early defect of neuronal development is probably the cause of spastic paraplegia and quadriplegia.

CLINICAL PICTURE

Characteristically the condition is not diagnosed until the age of 9 months or 1 year. This is partly because the first thing the parents notice to be wrong with the child is that he does not sit up at the right age, and perhaps partly because we use for the examination of these infants a technique which has been designed to show up abnormalities of the adult nervous system.

There may be an early history of a spastic limb or an abnormal posture, of icterus gravis, of atelectasis or cerebral hæmorrhage, of convulsions in the first two weeks of life, but the story is often merely one of delay in the acquisition of motor and postural skills. The child does not sit at the usual age of 6 or 8 months, at 10 months he is seen by a doctor who can find nothing much wrong with him and counsels patience. The first birthday brings comments from the relatives and causes reflection. The infant is taken again to the doctor who advises a consultation or a visit to hospital where the diagnosis is made. Adductor spasm will have developed at this time, and will be apparent when the child is lifted up, but in athetoid cases the characteristic serpentine movements may not be clearly distinguishable from infantile and physiological inco-ordination until the age of two years.

Table VI shows the delay in sitting, walking, feeding, talking and acquiring control of the excretions in the first six years. These figures are taken from examination of the records of 59 children who were being considered for admission to a special school and who were preselected as being the more promising cases of those who were too severely affected to go to an ordinary school.

one where the child is brought daily by his mother. The former is probably best for the very young, and for those where the home environment is bad, or the parents unintelligent. The day institution is good in that the child leads a normal home life, and the mother gets thorough instruction in the management of her child. In fact, in this type of centre the mother rather than the child, is taught, and this is very important, because, in order to prevent relapses, treatment programmes must continue for years. These day centres are doing very well in Australia. Whatever the type of centre, it must provide full facilities for mental education as well as physical rehabilitation, and it should bear as little resemblance to a hospital as possible, one of the key-notes being that the child must not be looked upon as sick in the ordinarily accepted sense of that word.

As has been said, treatment must continue for years in most cases, and so a great deal devolves upon parents. All that centres can do is to correct the worst of the defects, to provide the correct management programme, to give the right appliances, and to instruct the parents how to carry on, the child being brought back every six months or so for review and change of programme where necessary.

Before proceeding to a more detailed treatment of any specific type of cerebral palsy there are some general points which are applicable to all.

The earlier treatment can commence the better, and an age of 1 year is certainly not too young. There are obvious risks of maldagnosis in starting at this age, and it is not easy to determine whether the child be intelligent or not, but there is one very great advantage in that the child does not develop bad movement patterns in the endeavour to overcome his handicap himself, and further the right environment can be ensured. In the older child these bad habits of movement superimposed upon the original handicap are very difficult to deal with and make the best results almost impossible of attainment.

These children must be enabled to sit up in a chair as soon as possible. Many, if not all of them, cannot sit unsupported at the age they would normally be able to do so, and they are too often allowed to lie on their backs all day staring at the ceiling or the sky. They thus are unable to gain normal childish experience by observing their surroundings. Such a chair is specially made so that the child can sit well into it and be completely supported as to the back and head, and he may be strapped in if necessary.

Where there is not gross athetoid movement, the child should be encouraged to roll and kick on the floor, and he may be allowed to crawl, but he should not be allowed to stand or walk until his reablement programme is well advanced.

Respiration is often irregular or of a faulty pattern, and steps must be taken as early as possible to correct this since without correct movements of breathing a child will have difficulty in swallowing and in speaking.

Proper feeding is often overlooked. In addition to poor respiration the movements of tongue and palate are often restricted or irregular. Swallowing is therefore difficult and slow and these children often do not get sufficient to eat. Thus, great patience must be shown, and the child should be given plenty of time to deal with small mouthfuls. Again, it is often not realized that some of these children have impaired palatal sensation, and the spoon is often placed too far into their mouths, with the result that they choke and may refuse their food.

As treatment programmes are long and may continue for months at a time, it is most important that the child's interest in his treatment should be aroused and maintained. To this end his rehabilitation must be made as attractive as possible, and one good plan is to teach him his exercises, &c., to the sound of an easily learnt tune preferably sung to him in order that he may get the sense of the words as well.

Due to the natural enthusiasm of teachers and therapists there is a danger of overworking the child and overtaxing his powers of concentration. Programmes must therefore be carefully worked out with this in mind, and adequate rest periods provided.

Passing to the spastic type of cerebral palsy, it will be found that these children are often extremely fearful. They must therefore, at all times, feel perfectly secure. Treatment tables must be wide enough to give them this feeling of security, and they must be handled firmly and competently. In contradistinction to the athetoid child they often need a considerable amount of urging. They should be carefully examined in an effort to discover exactly which muscles and muscle groups are involved in the disease, which are hypotonic and which have become weakened due to their being stretched by the affected antagonist. They should not be allowed to stand or walk until their abdominal and back muscles have been given sufficient strength by exercise to give them proper pelvic control, since it may be found that tight hamstrings and adductors may be due to weak abdominals allowing the pelvis an exaggerated tilt. At the same time a scheme of exercises is made out for the re-education of their limb muscles, and when as much improvement in pelvic control as possible has been obtained they can pass to practise in sitting unsupported, kneeling, standing, and finally walking. It is always useful to get as much aid from gravity as possible by posturing the child in his

as other boys have, to the patients in a hospital school. I must mention the danger of overstimulating athetoid children, stressed by Carlson (1937). They cannot stand a lot of treatment in a day, the journey to the hospital may by itself make them so tense and inco-ordinate that treatment is impossible. It is well to remember that they are at their worst when they are taken to see the doctor.

On intelligence testing, I can do no more than repeat the warning that ordinary testing is unfair to these children with motor, sensory, and speech defects, and that it may be impossible to assess the intelligence without some weeks of observation. The response to treatment is thus more useful than a single psychometric session. E. S. Evans (1946) found over 60% of spastics and under 10% of athetoids ineducable.

Selection of cases.—In selecting cases the following general points should be taken as favourable: Age 1 to 12 years, but especially 1 to 5 years; normal or high intelligence; perseverance and ability to concentrate, which may compensate for an inferior intelligence; sociability; no epilepsy; no sign of progressive nervous deterioration.

If facilities for treatment are limited, it is better to concentrate on the mildly and moderately affected, for the severe cases take an immense amount of the time of therapists, teachers, nurses and porters.

Some Points in Management of Infantile Cerebral Palsy

By JOHN H. CROSLAND, M.R.C.S., L.R.C.P.

THE management of a case of cerebral palsy differs in many respects from that of infantile paralysis or from that where the defect is purely sensory, e.g. blindness or deafness. In poliomyelitis there is a motor disability which can arise at almost any age, but there are no sensory defects, and there is usually no brain damage. In blindness and deafness there is usually one specific sensory disability, all other aspects of the case being relatively normal. In cerebral palsy, however, there is a motor disability of greatly varying severity, there may be sensory loss, such as partial or total deafness, and sight may be adversely affected. In addition, there may be such damage to the brain as to produce a subnormal intelligence, and one may be confronted with a psychological problem to make things even more difficult.

Thus, at the outset, one must try to get a picture of the total disability of any particular child, and try to assess the effect of one defect on the other. One must also get an idea of the child's background and his home conditions so that a composite picture forms in the mind. In the first instance the child is examined physically and placed in one or other of the five types of cerebral palsy according to Phelps. This may not always be possible at the first examination, though usually it can be done. Next, he must be seen by a child psychologist, and an estimation made of his intelligence. Here it must be said that only a psychologist used to making proper allowance for the motor disability and the usual lack of normal childish experience will be able to give a correct assessment of the I.Q. Defects of sight and hearing should be attended to by the appropriate specialist, and external aids provided where necessary.

It is not yet clear which type of treatment centre is the better, the purely residential or the

[January 22, 1948]

DISCUSSION ON ADVANCES IN THE TREATMENT OF URÆMIA

Mr. Ronald Reid

ABSTRACT.—Uræmia is common, little is known of its actual nature and treatment has therefore been unsatisfactory. The kidney is not only an organ of excretion but guards the chemical and physical constitution of the extracellular fluids.

In uræmia, urea and other products of metabolism including the toxic phenols accumulate. That the physical and chemical composition of the extracellular fluids, excluding protein, can be influenced by contact across a semi-permeable membrane is the basic concept of the treatment of uræmia by dialysis, whether by means of the artificial kidney or by peritoneal lavage.

The principles of treatment of uræmia are: (1) To remove the cause. (2) Reduce the load on the kidney. (3) Assist or take over the function of the failing kidney in the hope that it may recover. (4) To relieve symptoms without thereby prejudicing recovery.

Dialysis can be effected by peritoneal lavage or by conducting the circulating blood through a tube of semi-permeable membrane. The composition of the dialysing fluid is of the utmost importance the aim being to keep the physical and chemical balance of the extracellular fluid within the normal range and to encourage the diffusion of toxic metabolic products. The excessive use of parenteral fluids and diuretics in uræmia may be harmful. A number of cases of peritoneal dialysis are described.

RÉSUMÉ.—L'urémie est fréquente, et sa vraie nature est peu connue, par conséquent, son traitement est resté peu satisfaisant. Le rein est non seulement un organe excrétoire, mais protège aussi la constitution chimique et physique des liquides extra-cellulaires.

Dans l'urémie l'urée et d'autres produits du métabolisme, y compris les phénols toxiques, s'accumulent. Le principe fondamental du traitement de l'urémie par la dialyse, soit par un rein artificiel ou par le lavage péritonéal, est la possibilité d'influencer la constitution physique et chimique des liquides extra-cellulaires par le contact à travers une membrane semi-perméable.

Les principes du traitement de l'urémie sont 1° l'élimination de la cause, 2° la diminution de la charge sur le rein, 3° aider ou remplacer la fonction du rein défaillant, dans l'espoir qu'il guérisse, 4° le soulagement des symptômes sans empêcher la guérison.

La dialyse peut être effectuée par le lavage péritonéal ou par le passage du sang circulant par un tube de membrane semi-perméable. La composition du liquide dialysant est de la plus haute importance. Le but est de maintenir l'équilibre chimique et physique du liquide dans les limites normales, et de favoriser la diffusion des produits toxiques du métabolisme.

L'emploi exagéré de liquides parentéraux et de diurétiques dans les urémies peut être nuisible.

L'auteur décrit plusieurs cas de dialyse péritonéale.

Прогресс в лечении уремии

Доктор Р. Рид.

КОНСПЕКТ.—Уремия хотя и частое явление, но о ее существенном свойстве мало известно и оттого лечение не удовлетворительное. Почка не только орган для выделения, но она также охраняет химический и физический состав экстрацеллюлярных жидкостей.

При уремии накапливаются мочевины и другие продукты метаболизма, включая токсические фенолы. Лечение уремии диализом, будь то при помощи искусственной почки или же перитонеальным промыванием, основывается на том, что контакт через полу-проницаемую перепонку влияет на физический и химический состав экстрацеллюлярных жидкостей, за исключением белков.

Принципы лечения уремии: 1/ устранить причину; 2/ уменьшить нагрузку почки; 3/ помочь или перенять функцию слабеющей почки в надежде на излечение, и 4/ облегчить симптомы, не мешая излечению.

July—UROL. 1

exercises. Thus he may be placed head downwards on a tilted table where the pectoral muscles are spastic. Again, where the dorsiflexors of the foot are weak, as they often are, he may be placed on his abdomen with his legs at right angles to the table.

In the child with athetosis the key-note of management is relaxation. If he can be taught to relax efficiently, he can lose a great deal of his unwanted movements. It is very important that these children should have really adequate rest periods because of the greatly increased amount of energy consumed by this uncontrolled movement. When relaxation has been achieved as well as may be, he must be taught new movements of the affected limbs which are purposive movements under his own volitional control.

Relaxation must first be taught in the prone position. At first a child may find it easier to relax on one or other side, but eventually he must be taught in all lying positions. When this has been acquired, he must be taught to relax in the sitting position, using a properly constructed chair. After this, sitting balance and then standing balance must be taught, and not until these have been achieved should he be allowed to walk.

Many cases of athetosis develop a "tension" which is thought to be a voluntary effort to control the unwanted movements. In these cases the teaching of relaxation will at first increase the unwanted movement, but a great deal of this should be lost if the child follows the regime outlined. It should be said, however, that, particularly in older children, this tension may be extremely difficult to overcome, and it may be necessary to proceed with training in spite of it.

Occupational therapy is an important part of the management of most types of cerebral palsy. It has, of course, little part where the arms are unaffected. Its main sphere is to teach the child to carry over into every day actions what has been taught him by the physiotherapist. That is to say, he is taught to feed himself, and to dress himself, and this is carried out by practice with various feeding aids, such as drinking straws, special plates, spoons, &c. In learning to dress, the child will first practise buttoning, lacing, &c., on models held immovably in frames. He is also taught the movements of writing, and, if it is thought he will not be able to achieve this legibly, he is taught to use a typewriter. While the athetoid child is being taught these skills the occupational therapist must see that the rest of his body is maintained in the relaxed position.

As most of these children have a speech defect they will need the services of a speech therapist. One of the most important parts of this person's job, apart from speech training, is to ensure that the child's facial expression is as normal as possible, in order to increase the child's subsequent social chances and his value in the labour market.

Appliances of various kinds are used. Space forbids any detailed description, but a word should be said concerning leg braces. These are used to a very great extent in the pioneer schools in America. Their use must be regarded as corrective rather than as mere props, and it should always be remembered that it is a great psychological boost to get a child on his feet as soon as possible.

At present no unduly optimistic views as to the results of treatment should be entertained. Practically all children who are educable benefit from treatment, but the amount of such benefit varies enormously. The lowest aim is to make the child self-sufficient as far as dressing, feeding, and amusing himself is concerned. Even this will take an intolerable burden from parents. A small percentage will benefit to the extent of being able to take their places in normal life from the intellectual point of view. A somewhat larger percentage can be trained to craft standard, and thus be enabled to earn their own living, but it must be emphasized that both these latter percentages add up to a small proportion of the whole.

The President (Dr. W. S. Tegner) said that the subject was most important, and one was forcibly reminded that many of these children have been regarded as mentally deficient and condemned to a life in institutions when subsequent experience has shown that they are often educable.

Dr. J. Euan Dawson asked what could be done for the spastic child who suffered from bad athetoid movements, for he had known several cases where the anguish suffered from the perpetual movement was such as to undermine the child's general health, and no conservative treatment had in these cases been of any avail.

Dr. J. Shulman stated that the optimum age to begin treatment appeared to be the age-group 1 to 4 years, but in view of the wide interest now being taken in this problem, many applications for treatment were made on behalf of patients of much older age-groups. Was there any age at which one could definitely say it is useless to begin treatment?

Dr. Crosland, in reply to Dr. Dawson, stated that each case must be taught individually how to relax.

In reply to Dr. Shulman he said that there was a sharp fall in the progress charts if treatment was delayed to the later age-groups.

В нашей машине это более усовершенствовано и установлен тщательный контроль над втечением и вытечением крови, которые совершенно синхронизированы. Для улучшения анализа насос, контролирующий течение крови, присоединен к барабану таким образом, что 10 миллилитров крови входит и выходит из машины на каждое полное вращение барабана. Производимое таким образом движение дает удовлетворительный анализ, но машина слишком громоздкая и несмотря на точный контроль кровяного течения, целлофановая трубка может растянуться и допустить накопление крови.

Оттого мы изобрели вторую, более компактную, машину, в которой целлофановая трубка проходит через серию пластинок, а анализирующая жидкость выпускается через серию отверстий в центре пластинок. Таким образом, анализирующая поверхность того же размера может быть смата в машину 18 дюймов длины и 9 дюймов вышины и вместе с тем объем крови в машине не может быть увеличен.

Конечный успех анализа будет зависеть от состава анализирующей жидкости. Опыт показал, что жидкости одинакового электролитического состава, хотя и изотоничны, не остаются изоосмотическими. Это зависит от того, что глюкоза, которая употребляется для поддержания осмотического давления, быстро всасывается в больного. Это производит перегружение кровообращения больного и ввиду этого вода в анализирующей жидкости не может быть задержана. Потому очень важно найти нетоксичное, не-анализирующее вещество, которое было бы способно поддерживать изо-осмотическое давление.

EXTRACTO.—En el método de Kolff de diálisis sanguínea se usa un tambor giratorio para extender una fina película de sangre sobre la extensa superficie de un tubo de celofana, que actúa de membrana dializadora.

En nuestro aparato esto ha sido ventajosamente desarrollado, pero además, un control exacto permite que el aflujo y salida de sangre sean exactamente sincronizados. Para mejorar la diálisis, las bombas que regulan la corriente sanguínea están conectadas con el tambor, de modo que 10 c.c. de sangre entran y salen de la máquina en el transcurso de una rotación completa del tambor. La agitación así producida mejora considerablemente la diálisis, pero el aparato en conjunto es voluminoso y a pesar del cuidadoso control de la corriente sanguínea, el tubo de celofana puede distenderse permitiendo cierta acumulación de sangre.

Para evitar este inconveniente, hemos construido una segunda máquina, mucho más compacta, en la cual el tubo de celofana atraviesa una serie de placas que presentan unos orificios en el centro, a través de los cuales es inyectado el líquido dializable. De este modo, la misma extensión de superficie dializante es comprimida en una máquina de 45 centímetros de longitud por 22 centímetros de altura, con la particularidad de que el volumen de sangre dentro de ella no puede ser aumentado.

El éxito final de las diálisis dependerá de la composición del líquido dializable. La experiencia ha demostrado que los de un mismo carácter electrolítico, aunque isotónicos, no permanecen iso-osmóticos. Esto es debido a que la glucosa usada para mantener la presión osmótica, se difunde rápidamente al interior del paciente, con lo que el líquido dializable es incapaz de retener el agua, resultando de ello una sobrecarga de la circulación del paciente. Es por tanto esencial la búsqueda de una sustancia no tóxica e indializable, que sea capaz de mantener una presión iso-osmótica.

Dr. E. G. L. Bywaters and Dr. A. M. Joekes

ABSTRACT.—Two recently evolved methods of dealing with uræmia (a) by dialysis through cellophane (the Kolff artificial kidney), and (b) through the peritoneal membrane, were described.

Dr. E. G. L. Bywaters and Dr. Joekes described the results obtained over a period of fifteen months using the Kolff artificial kidney. It consisted of a cellophane tube rotating in a Ringer bath, through which blood flowed from an artery and back to a vein. The bath water (100 l.) contained glucose 1.5-2.0 grammes % and chloride, sodium, bicarbonate and potassium in physiological concentrations. The most suitable type of case was one of tubular or "lower nephron" disease (e.g. pigment nephrosis), since complete recovery was possible. 12 cases had been dialysed, including 2 complete recoveries, detailed in full. The maximum amount removed was 92 grammes urea in seven and a half hours, at a blood flow through the cellophane tube of about 60 ml./min. This reduced the blood urea to about half its previous level. Factors working against recovery included pre-existing pneumonia, widespread oedema and sepsis; one subdural hæmorrhage occurred, but no other bleeding complications due to heparin were seen. 0.5-1.0 grammes heparin was used per patient. The pump was used to fill a gravity-feed burette for returning blood to the patient, and in the later patients right auricular pressure obtained by cardiac catheterization was used to control flow. Amidopyrine, penicillin, nembutal and calcium gluconate were also given. A high-caloric non-protein diet was prescribed afterwards in an effort to obviate nitrogen accumulation due to endogenous protein catabolism.

RÉSUMÉ.—Description de deux méthodes de traitement de l'urémie récemment développées:

(a) La dialyse à travers le cellophane (rein artificiel de Kolff).

(b) La dialyse à travers la membrane péritonéale.

Les Drs. E. G. L. Bywaters et Joekes rapportent les résultats obtenus pendant 15 mois par l'emploi

Диализ можно совершить или же перитональным промыванием, или же пропускаем обращаемой крови через трубку с полу-проницаемой перепонкой. Состав диализирующей жидкости весьма важен, так как нужно удерживать физическое и химическое равновесие экстрацеллюлярной жидкости в пределах нормы и поощрять диффузию токсических продуктов метаболизма. Чрезмерное употребление подкожных инъекций и мочегонных средств может быть вредным.

Описаны несколько случаев перитонального диализа.

EXTRACTO.—A pesar de ser la uremia un síndrome común, su naturaleza es muy poco conocida y su tratamiento, por consiguiente, insatisfactorio. El riñón no es solamente un órgano de excreción: mantiene además la composición físico-química de los fluidos extracelulares.

En la uremia, hay un acúmulo de urea y otros productos del metabolismo, inclusión hecha de fenoles tóxicos. El hecho de que, exceptuando las proteínas, la composición físico-química de los líquidos extracelulares pueda ser influenciada por contacto a través de una membrana semipermeable, constituye la base del tratamiento de la uremia por diálisis, ya sea mediante el riñón artificial o por lavado peritoneal.

Los principios para el tratamiento de la uremia son: (1) Eliminar la causa; (2) Disminuir la sobrecarga renal; (3) Asistir o hacerse cargo de la función del riñón claudicante con la esperanza de que pueda todavía recuperarse; (4) Tratar los síntomas sin que con ello se comprometa la recuperación.

La diálisis puede efectuarse por lavado peritoneal o bien conduciendo la sangre circulante a través de un tubo de membrana semipermeable. La composición de los fluidos dializables es de la más alta importancia, ya que la finalidad es el conservar el equilibrio físico-químico de los líquidos extracelulares dentro de los límites normales y favorecer al propio tiempo la difusión de los productos tóxicos del metabolismo. El uso excesivo de fluidos parenterales y diuréticos en la uremia puede ser peligroso. Se describen además una serie de casos de diálisis peritoneal.

Dr. E. M. Darmady

ABSTRACT.—Kolff's method of dialysing blood makes use of a rotating drum to spread a thin film of blood over large dialysing surface (a cellophane tube).

In our machine, this has been further developed, but a strict control is kept on the inflow and outflow of blood, which are exactly synchronized. To improve dialysis, the pumps controlling the flow of blood are geared to the drum so that 10 ml. of blood enters and leaves the machine for every complete rotation of the drum. The agitation thus produced results in successful dialysis, but the machine is bulky and, in spite of this careful control of blood flow, the cellophane tube may expand and allow accumulation of blood.

We have, therefore, developed a second and more compact machine, in which the cellophane tube is run through a series of plates, the dialysing fluid being injected by a series of ports in the centre of the plates. In this way, the same sized dialysing surface can be compressed into a machine 18 inches long and 9 inches high, and at the same time the volume of blood in the machine cannot be increased.

The ultimate success of dialysis will depend on the composition of the dialysing fluid. Experience has shown that those of a similar electrolytic pattern, although isotonic, do not remain iso-osmotic. This is because the glucose used to maintain the osmotic pressure diffuses rapidly into the patient. This results in overloading the patient's circulation, because water can no longer be held in the dialysing fluid. A search for non-toxic, non-dialysing material capable of maintaining an iso-osmotic pressure is therefore essential.

RÉSUMÉ.—La méthode de Kolff pour la dialyse du sang consiste en l'emploi d'un cylindre tournant pour étendre une couche mince de sang sur une grande surface dialysante (tube de cellophane).

Dans notre machine cette idée a été développée plus loin, mais l'arrivée et le débit sont strictement réglés et synchronisés exactement. Pour améliorer la dialyse les pompes réglant la circulation sont engrenées avec le cylindre de telle façon que 10 ml. de sang entrent et sortent de la machine à chaque tour complet du cylindre. L'agitation ainsi produite donne une dialyse satisfaisante, mais la machine est volumineuse, et malgré le réglage soigneux de la circulation, le tube de cellophane peut se dilater et permettre au sang de s'accumuler.

Nous avons donc inventé une seconde machine, plus compacte, dans laquelle le tube de cellophane passe entre une série de plaques, le liquide dialysant étant injecté par une série d'orifices au centre des plaques. De cette façon une surface de la même grandeur peut être incluse dans une machine longue de 18 pouces (45 cm.) et haute de 9 pouces (22 cm.), et d'autre part, il est impossible d'augmenter le volume de sang dans l'appareil.

En fin de compte, le succès de la dialyse dépend de la composition du liquide dialysant. L'expérience a montré que des liquides de composition électrolytique semblable, même s'ils sont isotoniques, ne restent pas iso-osmotiques, parce que le glucose employé pour maintenir la pression osmotique se diffuse rapidement dans le malade. Ceci surcharge la circulation du malade, parce que le liquide dialysant ne peut plus tenir l'eau. Il est donc essentiel de chercher une substance non toxique et non dialysable capable de maintenir une pression iso-osmotique.

Доктор Дармади.

КОНСПЕКТ.—При Методе Кольфа для диализирования крови применяется вращающийся барабан для распространения токой фильмы крови на большой диализирующей поверхности /целлофановая трубка/.

Transperitoneal Dialysis

By RONALD W. REID, F.R.C.S.

URÆMIA is a symptom which is easily recognized and is a common cause of death, and yet little is known of the actual nature of the condition. It follows that treatment, not being based on sound knowledge, has been unsatisfactory. There is little doubt that many factors are involved including: (1) The accumulation of toxic products of metabolism. (2) Alterations in the osmotic pressure of the body fluids. (3) Dehydration or its opposite. (4) Alterations in the balance of electrolytes. (5) Changes in the acid-base balance.

Professor Gamble of Harvard, to whom all interested in this subject owe a debt for his magnificent work on the extracellular fluids, states that the kidney is very inadequately described as an organ of excretion. He states: "Were removal of waste products its only function a much simpler mechanism would suffice. Its complexity of design and intricacy of function are required for the construction and accurate defence of extracellular fluid, on the chemical consistency of which depends the successful operation of intracellular processes."

I like to look upon the kidney as a guardian of the environment of the body cells, as responsive and delicate as the most sensitive thermostat in the maintenance of a constant temperature, but infinitely more comprehensive in its action.

The composition of the body fluids is shown in Gamble's famous diagram (fig. 1). The body fluids amounting to about three-quarters of the body-weight can be looked upon as

FIG. 1.—Body fluids compartments (after Gamble).

FIG. 2.—Diagram of kidney in action.

existing in three compartments, although interchange is constantly going on: (1) The intracellular fluid, 35 litres in an 11-stone man. (2) The interstitial fluid, 11 litres. (3) The intravascular fluid, 3 litres.

Potassium and phosphorus are the ions concerned in the composition of the intracellular fluid, and it seems certain that the cell membrane in contrast to the capillary is impervious to most electrolytes.

The relationship of the kidney to the fluid in the vascular system which is in the closest and most sympathetic contact with the rest of the extracellular fluid in the interstitial compartment is shown in fig. 2.

The functions of the kidney are to maintain the physical and chemical constancy of the body fluids and to eliminate waste products of metabolism. As its function fails from disease, lack of water or salt or some other essential factor to its proper action, so the composition of the body fluids changes and waste products accumulate. The exact nature of the changes is in some doubt but it is known that a number of products of metabolism appear in increased quantities in the blood stream, including urea and phenols. Urea is not toxic to man in the concentration found in the blood in many cases of profound uræmia, but generally speaking, the amount of urea in the blood is a rough index to the severity of the uræmic state. Harrison and Mason have shown that free phenols accumulate in the body fluids in uræmia and that their concentration rises as toxæmia progresses.

Although the nature of the metabolic toxins remains obscure there is reason to believe that they are dialysable, that is to say, pass freely across a semi-permeable membrane such as the capillary wall or the peritoneum. I have confirmed the observation made years ago that the urea content of the blood and of natural ascitic fluid are almost identical.

That the physical and chemical composition of the extracellular fluids, excluding protein, can be influenced by contact across a semipermeable membrane is the basic concept of the treatment of uræmia by dialysis, whether by means of the artificial kidney or by peritoneal lavage.

du rein artificiel de Kolff. Il consiste en un tube de cellophane tournant dans un bain de solution de Ringer, ou circule du sang venant d'une artère et rentrant dans une veine. Le liquide dans le bain (100 litres) contient de 1.5 à 2.0 grammes pour cent de glucose et des concentrations physiologiques de chlorure, de sodium, de bicarbonate et de potassium.

Les cas qui bénéficient le plus de ce traitement sont ceux de maladie tubulaire ou du "néphron inférieur" (les néphroses pigmentaires par exemple), car la guérison complète est possible. Douze cas ont été traités par la dialyse, avec deux guérisons complètes. Ces cas sont rapportés en détail. La plus grande quantité d'urée éliminée fut 92 grammes en sept heures et demie, le courant de sang passant par le tube étant d'à peu près 60 ml. par minute. De cette façon l'urée sanguine fut réduite à environ la moitié de son taux original. Les facteurs opérant contre la guérison étaient, entre autres, des pneumonies existant d'avance, des œdèmes extensifs et la sepsie. Une hémorragie sous-durale fut observée, mais aucune autre complication hémorragique due à l'héparine, dont 0.5 à 1.0 gramme fut employé pour chaque malade. Une pompe fut employée pour remplir une burette à gravitation pour rendre le sang au malade, et chez les derniers cas la pression auriculaire droite fut contrôlée par la cathétérisation du cœur pour permettre d'ajuster la circulation. L'amidopyrine, la pénicilline, le nembutal et le gluconate de calcium furent employés comme médicaments additionnels. Un régime riche en calories et sans protéine fut prescrit après le traitement, pour éviter l'accumulation de protéine due au catabolisme de la protéine endogène.

доктор Байвотерс и Доктор Джекс.

КОНСПЕКТ.—Описаны два недавно испытанных способа для лечения уремии: 1/ путем диализа через целлофан /искусственная почка Кольфа/ и 2/ через перитонеальную оболочку.

Доктор Байвотерс и доктор Джекс описывают результаты полученные в применении искусственной почки Кольфа в течение 15 месяцев. Для опыта употреблялась целлофанная трубка, вращающаяся в ванне Рингера, через которую протекала кровь из артерии и обратно в вену. 100 литров воды в ванне содержало 1.5 - 2.0% глюкозы и хлористый натрий, сода и калий в физиологических концентрациях. Наиболее подходящий случай оказалась болезнь трубок или нижнего нефрона, т.е. пигментозный нефроз/ ввиду того, что в этом случае полное выздоровление было возможно. Было продиализировано 12 случаев, причем два из них дали полное выздоровление. Автор дает полные детали. Максимальное количество удаленной мочевины было 92 грамма в 7½ часов, причем количество протекаемой крови через целлофанную трубку было приблизительно 60 миллилитров в минуту. Это уменьшило количество мочевины в крови приблизительно на половину предыдущего уровня. Факторы предупреждающие выздоровление включали: заранее существующую пневмонию, обширные отеки и сепсис. В одном случае появилось субдуральное кровоотечение, но в общем гепарин не вызывал никаких других кровоотечений. Для возвращения крови больному автор пользовался насосом, который нагонял бюретку путем тяжести. У некоторых больных для контроля течения употреблялось правое предсердечное давление путем сердечной катетеризации. Амидопирин, пенициллин, нембутал и глюкозный кальций тоже были применены.

После опыта была прописана диета, содержащая большое количество калорий с полным отсутствием белков с намерением предупредить накопление азота вследствие эндогенного белкового катаболизма.

EXTRACTO.—Se describen dos métodos recientemente desarrollados para tratar la uremia: (a) por diálisis a través de un tubo de celofana (el riñón artificial de Kolff) y (b) por diálisis a través de la membrana peritoneal.

Los doctores E. G. L. Bywaters y Joeques reseñan los resultados obtenidos con el empleo del riñón artificial de Kolff durante un período de quince meses. El aparato de Kolff consiste en un tubo de celofana giratorio a través del cual la sangre procedente de una arteria circula en dirección a una vena. Este tubo gira sumergido en un baño de solución de Ringer (100 litros), conteniendo de 1.5 a 2 gramos por % de glucosa y cloruros sódico y potásico y bicarbonato, en concentraciones fisiológicas. El caso más adecuado fue uno de lesión tubular (nefrosis pigmentaria), con el que fue posible obtener la curación completa. Doce casos dializados, incluyendo dos curaciones completas, son minuciosamente detallados. La cantidad máxima de urea separada fue 92 gramos en 7½ horas, con una corriente sanguínea de 0.060 litros por minuto pasando a través del tubo. Con esto se logró reducir a la mitad la cantidad de urea en sangre. Entre los factores que pudieron comprometer el completo restablecimiento, mencionan un caso de neumonía preexistente, otro con extenso edema y otro con sepsis; se presentó una hemorragia subdural pero no se vio ninguna otra complicación hemorrágica a consecuencia del empleo de la heparina, que en dosis de 0.5 a 1 gramo fue administrada a cada paciente. La sangre era devuelta al paciente desde una bureta que se llenaba por medio de una bomba y en los últimos casos el flujo sanguíneo se reguló de acuerdo con la presión auricular obtenida por cateterización cardíaca. Fueron administradas amidopirina, penicilina, nembutal y gluconato cálcico. Una dieta no proteica, rica en calorías, fue prescrita a continuación, al objeto de evitar la acumulación de nitrógeno debida al catabolismo de las proteínas endógenas.

William Abbott of Detroit and his collaborators have studied peritoneal dialysis in the last few years and have shown that urea nitrogen diffuses quite rapidly into fluid which has been injected into the peritoneum, and that nephrectomized animals can be kept alive in a relatively normal state for over a week by intermittent peritoneal lavage.

Fine, Frank and Seligman of Boston have studied peritoneal perfusion for the treatment of uræmia during the last few years, and have shown that continuous peritoneal irrigation with the proper fluid is a satisfactory method of treating uræmia, and they point out that the control of electrolyte and fluid balance is at least as important as the elimination of toxins.

In peritoneal dialysis I have, as far as possible, used the method when I felt there was some hope of recovery. I have only used intermittent peritoneal lavage which I have held to be more satisfactory for reasons which I will discuss later.

CASE I.—Our first case was that of a woman aged 37 who had anuria following an incompatible blood transfusion. She was treated by vast quantities of fluid intravenously and admitted to our hospital with anuria of nine days' duration. She was œdematous and drowsy, with a blood urea of 253 mg.%. The kidneys were washed out by cystoscopy. A high spinal anæsthetic was given to no avail, and as the patient's condition was rapidly deteriorating and renal tenderness was very marked on both sides, it was decided to decapsulate the kidneys, and this was done on the tenth day. Œdema of the skin, muscle and perinephric tissues was pronounced. Both kidneys were so firm that on decapsulation the renal substances burst. After the operation a rubber catheter was inserted into the peritoneal cavity and 2,000 c.c. of twice normal saline dripped in slowly. Only 1,100 c.c. were recovered and by this time the patient had begun to pass urine, and there was also an escape of urine from the renal wounds. The next day 1,000 c.c. of double strength saline was run into the peritoneal cavity and only 205 recovered, and the process was further repeated. In all 6,000 c.c. of twice normal saline were put into the peritoneal cavity slowly and allowed to escape, and 2,500 c.c. were recovered containing just over 6 grammes of urea in all, but a great deal of fluid escaped into the dressings. The woman began to pass urine freely after decapsulation and there is no doubt that peritoneal dialysis had little to do with her recovery, but we were satisfied with our experience because first, the woman recovered, and secondly, we had shown that urea could be recovered by peritoneal dialysis. The patient has been followed up since and is normal in all respects.

CASE II.—The second suitable case did not appear for six months. In September 1946 a man, aged 57, was admitted to hospital semi-comatose. Twenty years previously he had undergone a right nephrectomy and about ten days before admission he was seized with nausea and vomiting and gradually his urine output had declined. For twelve hours before admission he had passed no urine whatever. He had a tender, palpable and slightly enlarged left kidney and a blood urea of 268 mg.%. It was thought he had an obstruction of the pelvo-ureteric junction and catheter drainage up the ureter was unsatisfactory. The patient went downhill rapidly, was completely comatose and vomiting copiously. A rapid nephrostomy was performed through the cortex of the greatly distended kidney. A rubber catheter was introduced into the peritoneal cavity and twice normal saline was run in slowly for twelve hours and then allowed to escape naturally. Peritoneal dialysis was continued in all for seventy-two hours, a total of 6,350 c.c. double-strength saline being run into the peritoneal cavity, but only 1,600 c.c. were recovered containing 6·7 grammes of urea. In the meantime the decompressed kidney began to function freely and in twenty-four hours produced 10 litres of urine. The blood urea fell from 268 to 57 mg.%, and a week later the kidney was explored at leisure and obstruction due to aberrant vessels relieved.

In this case again peritoneal dialysis had little to do with the patient's recovery. We lost very little fluid by leakage, and as we put over 6,000 c.c. into the peritoneal cavity and recovered only 1,600 a great deal of the saline was absorbed and excreted by the kidney.

An interesting feature is that the concentration of urea in the peritoneal efflux was higher than that of the blood (fig. 5), and another interesting point is that the chloride concentration of the dialysing fluid which was 0·18 grammes to begin with, rose to 0·26 grammes at the end of dialysis. It seems that there was a selective absorption of water which accounted for the high level of urea and chlorides in the peritoneal washings.

CASE III.—The third case was a man of 62 who had a carcinoma of the prostate for which a resection was done in March 1945, followed by treatment with stilbæstrol. In October 1946 the patient was admitted with the pelvic floor infiltrated with growth. He was uræmic with a blood urea of 262 mg.%. It was considered that the lower ends of the ureters were blocked by growth. Forced fluids were employed without improvement and it was decided that the man might be tided over the crisis by peritoneal dialysis.

We considered that in the last cases there was evidence that too much chloride had been used in the peritoneal wash, and so in this man normal saline was used. 4,000 c.c. were run into the peritoneal cavity and only 650 c.c. recovered.

2,000 c.c. were used for each dialysis and the efflux contained 450 mg.% of urea in the first specimen and 360 mg.% in the second. It is interesting to note that during this time the blood-urea readings were 203 and 195 mg.% (fig. 6).

Eventually the man died quite suddenly and the post-mortem examination showed massive prostatic carcinoma blocking the ureters and multiple secondaries in the lungs.

CASE IV.—The next case was that of a male aged 58, who was admitted in November 1946 in a semi-comatose condition with an offensive dark brown vomit and diarrhoea, he was in a collapsed condition with a blood-pressure of 70/50. He was treated on general principles for shock and given continuous 5% dextrose saline intravenously and very slowly. He improved slightly and by the

Fig. 3 indicates diagrammatically the contact with the extracellular fluids achieved by means of the artificial kidney.

Fig. 4 shows again diagrammatically the same contact by means of peritoneal lavage. The basic principles which I consider are involved in the treatment of uræmia: (1) To remove the cause where possible. (2) To reduce the load on the kidney. (3) To assist or take over the function of the failing or failed kidney in the hope that it may recover. (4) To relieve symptoms without thereby prejudicing recovery.

(1) *Removal of the cause.*—In so many cases the cause is unknown, but a careful survey of the patient in general and of his urinary tract in particular should be made, keeping in mind infections and obstructions.

(2) *The load of the kidney may be eased* by reducing protein breakdown, thus diminishing the metabolic products to be excreted. Protein intake may be limited and at the same time sufficient carbohydrates should be given to prevent the body having to break down proteins

FIG. 3.—Diagram of artificial kidney in action.

FIG. 4.—Diagram of peritoneal dialysis.

to provide energy for ordinary needs. In starvation protein is rapidly broken down after the carbohydrate supply is exhausted. Therefore, starvation especially of carbohydrates is detrimental to uræmia and a low-protein and high-carbohydrate diet should be advised. Neither should the circulation be overloaded with fluids or diuretics. Water and urea, the best diuretics, usually exist in plenty unless the patient has suffered loss from diarrhoea, vomiting and sweating.

It must not be forgotten that the relief of symptoms is one of the supreme duties of the doctor, but I would utter a warning against, first, the use of more than the minimal quantities of sedatives, and secondly, against the forced ingestion of fluids particularly by the intravenous route, especially in the presence of cardiac failure.

(3) To turn now to the assistance of the failing or failed kidney, it must first of all be assured that the organ receives sufficient quantities of oxygen, and for this reason any serious degree of anæmia should be corrected by blood transfusion. Cardiac failure must also be corrected, if possible, because the kidney cannot do its work without sufficient blood-pressure. Many patients suffering from uræmia, especially the aged, are deficient in hæmoglobin.

There are two methods of making intimate contact with the body fluids across semi-permeable membranes, for the purpose of removing diffusible toxins and restoring the physical and chemical constitution of the extracellular fluid. First, by peritoneal lavage, and secondly, by conduction of the blood through a semi-permeable tube immersed in a suitable solution. I will briefly go over the history of these methods.

In 1914, Abel, Rowntree and Turner performed artificial kidney experiments on dogs using a tube of semi-permeable membrane immersed in physiological saline solution. Gantner in 1923 used peritoneal lavage for the treatment of uræmia in dogs after bilateral ligation of ureters, following the demonstration by Putnam that urea, creatine and other crystalloids diffused into peritoneal fluid from the blood. So far as I know the story of the artificial kidney and of peritoneal dialysis starts with the workers I have mentioned.

The most impressive contribution came from Bliss, Kasteler and Nadler in 1932, who found that dogs after bilateral nephrectomy survived on an average three days unless peritoneal lavage was used. Peritoneal lavage extended life to between thirteen and sixteen days, and in one instance over 9 grammes of urea were removed from the blood stream in twenty-four hours. These workers used saline and found, and I think this point is of very great importance, that the animals died of generalized œdema, especially severe in the lungs.

In 1938 Wear, Sisk and Trinkle, used peritoneal perfusion for the treatment of two cases of uræmia following carcinoma of the bladder. They reduced the blood urea but vast quantities of perfusing fluid were used to recover rather small amounts of urea.

In recent years the work originated by Abel, Rowntree and Turner has been revised, extended and developed by Kolff of Kampen.

skin and lungs 1½ litres. It appears that by sweating, respiration and dialysis the body was deprived of about 3 litres of fluid and this no doubt accounted for the disappearance of œdema. The amount of urea recovered in all was 38.5 grammes.

In this case a considerable quantity of urea was removed from the blood stream by dialysis; more interesting still is the examination of the reaction of the blood chlorides to the dialysis with glucose in water. Much chloride was removed.

Fig. 9 shows the changes. It is estimated that 52 grammes of chloride were extracted from the body, again we had failed to take proper care of the electrolyte and water balance in the extracellular fluid.

Another point of great interest arises from the examination of the samples of fluid taken every quarter of an hour. It appears that equilibrium is reached in about two hours.

It was resolved that should another case turn up further care must be taken with the composition of the dialysing fluid, so that on the one hand water and salt were not lost to the body, nor were water and salt excessively added.

CASE VI.—In February 1947, a male patient, aged 51, was admitted to hospital with anuria of thirty-six hours' duration. A week before admission his doctor thought he was developing pneumonia and gave him a supply of sulphadiazine. He took 24 grammes in six days and had been instructed to drink plenty of fluid, but had not done so. On examination he appeared fairly fit for his age, he had a slightly furred tongue and was tender on palpation in both loins. His chest was clear. A catheter was passed but no urine obtained.

Large quantities of alkaline fluids were given by mouth and the next day no urine had been secreted and a cystoscopy was performed. There was considerable œdema of both ureteric orifices, some fine brownish crystals were seen in the bladder and on the left side crystals and clot were protruding from the orifice. These crystals were subsequently identified as those of sulphadiazine.

During the day the blood urea rose from 99 to 117 mg. % and his clinical condition deteriorated throughout the day and he began to show signs of marked œdema of the lungs. At 6 p.m. a cystoscopy was performed but catheters would not pass up the ureters and so it was decided to do a nephrostomy on one side. The kidney was exposed and a clear rush of urine followed the incision of the pelvis and a Cabot's nephrostomy was performed. After the operation a plastic tube with side holes was introduced into the recto-vesical pouch and the bronchial tree sucked out by bronchoscopy. On return to the ward 2,000 c.c. of 5% glucose in normal saline was run rapidly into the peritoneal cavity. Here we were using saline to avoid chloride depletion and glucose to maintain osmotic pressure.

Half-hourly samples of fluid were taken for analysis and the remaining fluid sucked out three hours later. Fig. 10 shows the urea changes. 1,650 c.c. were recovered. The dialysis was repeated with the same solution, but as the patient complained of pain the tube had to be withdrawn and a fine

FIG. 8.—Case V.

FIG. 9.—Case V.

FIG. 10.—Case VI.

trocac passed into the peritoneal cavity in the right iliac fossa, and 1,600 c.c. of fluid drained by this route. Suction of the bronchial tree had to be performed again while the patient was in bed as his chest was very bubbly.

By the next morning the blood urea was 117 mg. % and his general condition much improved. 277 c.c. had drained from the nephrostomy and in the evening he passed 700 c.c. of clear urine. Thereafter the patient improved rapidly and was discharged from hospital well.

A biopsy of the kidney taken at operation showed sulphadiazine crystals in the tubules.

In this patient the bronchopneumonia or œdema of the lungs from which he was suffering was the most dangerous condition, and I think the repeated suction of the bronchial tree was the main factor in his recovery. The dialysis, while it was beneficial, cannot be regarded as having been a success. While it was functioning the blood-urea level was reduced but it rose again after the dialysis was discontinued. Only 4 grammes of urea were recovered from the efflux.

This is just a brief account of my experience with peritoneal dialysis, and the results are not impressive. My accounts are not complete and I have given but a few of the hundreds of estimations which were done in the laboratory while the cases were treated. I should like to pay tribute to the work done by Mr. Roland Jones and Dr. J. Penfold who helped me. Those undertaking peritoneal dialysis must be prepared to stay up all night.

What have we gained from our experience?

next day it was found his blood urea was 460 mg.% and he had only passed a few c.c. of urine. The next day the patient's condition began to deteriorate again and although the cause of his uræmia was not known it was decided that pending further investigation to reach an accurate diagnosis, peritoneal dialysis was justified to assist the failing kidney.

A rubber tube was passed down through the abdominal wall into the lower part of the peritoneal cavity and 2 litres of double strength saline were run in as quickly as possible and left in the pelvic cavity for six hours. The running in of the fluid at this rate did not cause discomfort. The fluid was gently sucked out and the dialysis repeated twice more. 10,000 c.c. of fluid in all were run into the peritoneal cavity and 6,500 recovered and found to contain 18.8 grammes of urea. Fig. 7 shows the blood urea levels and the levels in the washing fluid.

Meantime the patient's condition deteriorated and he became œdematous, especially in the lungs and died two days after admission.

The post-mortem showed gross pulmonary œdema, but a normal liver and apparently normal kidneys. There was no peritonitis. Section of the liver and kidney showed no gross abnormality.

The treatment in this case was unsatisfactory in that no cause was found for the uræmia. It may

FIG. 5.—Case II.

FIG. 6.—Case III.

FIG. 7.—Case IV.

have been prerenal in type. We recognized, rather too late, that the man was absorbing huge quantities of saline from the peritoneal cavity, and that like some of the animals used in experimental fields, the cause of death was pulmonary œdema.

It was resolved that should another opportunity for peritoneal dialysis arise, an attempt should be made to avoid overloading the patient with water and chlorides, and we realized also that we had been aiming at the removal of urea and forgetting the necessity of making a real attempt to take care of the physical and chemical composition of the extracellular fluid.

CASE V.—In January 1947 a man, aged 23, was admitted to hospital complaining of diarrhoea, vomiting and malaise. He had a medical history of some length. In May 1943 he was said to have suffered from some form of renal infection and in August 1943 he had been in hospital with œdema of the ankles, feet and face. He was then known to have albumin in the urine and red cells but no casts. Apparently he was diagnosed as a case of nephritis and sent home.

On admission in January 1947 he was pale, ill-looking and drowsy, with a furred tongue and moderate œdema and ascites. His blood-pressure was 180/120 and his urine loaded with albumin. His blood urea was 30 mg.% and hæmoglobin 36%. He continued to vomit and became more drowsy and was given a slow intravenous drip of 5% glucose in saline for three days, and some blood. After this the blood urea fell to 123 mg.%, moist sounds appeared in both lung bases and the infusion was discontinued. The urine output continued to fall and by the evening of the 20th, ten days after admission, his blood urea was 300 mg.%. His condition was rapidly deteriorating and it was decided that the danger period might be tided over by peritoneal dialysis. A plastic tube was inserted into the recto-vesical pouch through a small incision in the right iliac fossa, and on opening the peritoneum urea content of 300 mg.%, identical with that of the blood. Dialysis was started at about 9.30 a.m. with 2,000 c.c. of 5% glucose in water and 1 gramme of novocain run into the peritoneal cavity. It was decided to use glucose and water, a solution with an osmotic pressure sufficient to prevent the loss of large quantities of water into the blood stream, and novocain was added lest the glucose solution caused pain. Samples of this fluid were withdrawn every quarter of an hour for two hours, in order to determine the rate of urea dialysis and the optimum time at which to discontinue and withdraw the fluid. After three hours the dialysis was discontinued and the fluid in the peritoneal cavity sucked out. After a short interval another 2 litres of 5% glucose in water was run rapidly into the peritoneum and retained for a further three hours, samples being drawn off every quarter of an hour.

Fig. 8 shows the blood urea levels and the level in the fluid withdrawn at intervals. The patient's general condition did not improve and he died.

Post-mortem examination showed marked hypertrophy of the left ventricle and slight œdema of both lungs, but not of the subcutaneous tissues. The liver was pale with cloudy swelling, the kidneys very pale with capsules adherent and section showed obvious chronic nephritis.

During the last twenty-four hours of his life the patient passed no urine whatever. 12 litres of 5% glucose in sterile water were run into the peritoneal cavity and in all 13½ litres were recovered. The patient sweated considerably during the day and had hypernæa, so that he probably lost by

also produces agitation. This ensures that a fresh sample of blood is being constantly brought to the dialysing surface. In fact, the success of agitation has enabled me to cut down the size of the drum and the dialysing surface. We have also found that by synchronizing our drums to our pumps so that 10 millilitres of blood enters the machine for each complete rotation, a better and more even film is produced which leads to better dialysis. This machine, however, is bulky and has a large number of points which have to be attended to. The bath water is not only exposed to the air, adding to the chance of becoming infected but also the dialysed products tend to build up in the water and thus slow down dialysis. This has led us to search for a machine of simpler design and we have found that by leading a cellophane tube through a machine in which there is a series of plates 1/16th inch apart a large dialysing surface can be achieved. The flow of dialysing fluid is arranged by means of a number of small tubes in the plates which allow the dialysing fluid to flow from the centre outwards in either direction. Unfortunately this machine does not at the moment produce as satisfactory dialysis as the rotating machine.

The most important of all the factors which control successful dialysis is the composition of the fluid in the dialyser. Hitherto these fluids have been of the simple electrolyte pattern, they have contained salts which are isotonic with normal blood but have added glucose

FIG. 1.

FIG. 1.—General view of machine in use. A.—Blood is obtained from radial artery. B.—Blood is restored to a suitable vein.

FIG. 2.—It is essential to control the in and out flow of blood by means of synchronized pumps. The pumps are designed to inject 10 c.c. for every complete rotation of the drum, thus ensuring even distribution of blood over the dialysing surface.

FIG. 2.

to raise the osmotic pressure and although these materials have been used with success in the past, they have one grave disadvantage, that the osmotic action is not maintained, for there is a rapid diffusion of glucose into the patient which is followed by water shift. For example, we have found that whereas we started with 20 litres of fluid in our bath water, this was reduced at the end of two hours' dialysis to 17 litres of which only 1 litre and a third could be accounted for by evaporation. We feel that this flow of water from the bath into the circulation leads to circulatory discrepancies and possibly cardiac failure. We therefore feel it necessary to use a material which is non-dialysable in our bath water to counteract this effect and we hope to produce a fluid which is not only isotonic but also iso-osmotic. Unfortunately this is not all, for as Dr. Campbell has recently confirmed, the plasma osmotic pressure of patients with uremia is raised and, in a case recently treated, this was in the region of nine atmospheres and was reduced to nearly seven by treatment. It may be necessary to produce a fluid which is maintained at the same osmotic pressure throughout treatment.

SUMMARY

It seems that it is now mechanically possible to withdraw and return the blood without detriment to the patient. Although a rotating type of dialyser produces the maximum dialysis it is bulky and it is felt that before long a more portable type of dialyser can be achieved. Although successful cases are being recorded, further work is required to find an ideal dialysing fluid.

My thanks are due to the Medical Research Council for an expenses grant, Mrs. Adair of the Physiological Department, Cambridge University; Dr. Campbell of Messrs. May and Baker; and last, but not least, to Mr. Harris, Managing Director, and Mr. Harrison of Goddard's Garage for the painstaking care with which they have constructed the many apparatuses used in this research.

I think we have confirmed that by peritoneal dialysis urea, and presumably other toxic products, can be removed from the blood stream.

There is no doubt that clinical improvement occurs which cannot be translated into statistical terms.

We have shown that care of the fluid electrolyte balance is of the greatest importance.

When intermittent injection is used we have shown that rapid diffusion of urea occurs, reaching the level of that in the blood within two hours, and we have also shown that the concentration of urea in the wash may exceed that in the blood stream.

Before peritoneal dialysis as the treatment of uræmia can be put upon a safe basis it is necessary to settle certain questions: (a) The method of carrying out peritoneal lavage, whether by continuous perfusion or intermittent injection and withdrawal. (b) The constitution of the proper fluid for perfusion.

(a) It is my belief at present, that intermittent injection and withdrawal is better and safer than continuous perfusion. Continuous perfusion requires vast quantities of sterile fluid and the exchange goes on so rapidly that dangerous changes may occur before the laboratory estimations can indicate their presence. Disaster may be on the patient while one is waiting for laboratory results. I prefer therefore intermittent injection and withdrawal because one can call a halt for the assessment of the position between each perfusion. In continuous perfusion it is possible that the fluid may follow one track which will soon be enclosed in adherent coils of bowel and omentum, so that the contact area between the perfusing fluid and the peritoneum is very much reduced.

(b) The fluid should have the following qualities: (i) It must be a fluid permitting rapid diffusion of waste products into it. (ii) It must be a fluid which will not grossly alter the electrolyte and water balance of the extracellular fluid. (iii) It must have an osmotic pressure near that of plasma. (iv) It must be adjusted to combat acidosis and alkalosis.

We have used various solutions, the most satisfactory in our cases probably being 5% glucose in saline. William Abbott has shown by animal experimentation that a modified Hartman's solution containing glucose satisfies the criteria of removing waste products and not upsetting too grossly the extracellular fluid. Fine, Frank and Seligman use a modified Tyrode solution. The composition of these fluids has been published.

In the modern treatment of uræmia peritoneal dialysis undoubtedly has a part to play. It should only be used in cases of temporary renal suppression when there is definite hope that the kidneys will recover sufficiently to maintain life, and it must be used with the greatest care for it is a dangerous procedure. It must above all not make the patient worse. Attention must not be focused entirely upon the removal of waste products to the exclusion of maintaining the physical and chemical stability of the extracellular fluid. Neither the cardiovascular system nor the kidney should be overloaded with water.

Peritoneal dialysis is a method in its infancy. It may one day be the most potent weapon in our hands for the treatment of uræmia and it may even be extended to the relief of other toxæmias.

Dialysis of Blood for the Treatment of Uræmia. [Précis]

By E. M. DARMADY, M.R.C.P.

In the past, blood dialysis for the treatment for uræmia has largely failed. Kolff, however, overcame these difficulties, first by using a cellophane tube as a dialysing membrane and secondly by using a rotating drum to spread a small quantity of blood over a large dialysing surface. It is, of course, necessary to heparinize the patient fully and for this purpose 200 to 300 mg. of heparin are given before the treatment starts. This is backed up by running heparin into the machine whilst the dialysis is occurring. Many authorities have suggested that the treatment is unsuitable owing to the liability to bleed but it has been found that blood transfusion and protamine sulphate will antagonize the heparin adequately in the case of sudden hæmorrhage. In considering an ideal design for such a machine it is important that a free continuous flow of blood is obtained from the patient through the dialysing system and finally to the patient again. The blood is best extracted from the radial artery since veins of large calibre are insufficient to give necessary quantities of blood (fig. 1). It is important that the amount of blood which enters and leaves the machine should be controlled, since if too much blood is allowed to enter, the dialysing surface is swamped, and the blood inadequately dialysed. In my machine the pump controls the flow of blood between the patient and the dialysing tubes and thus ensures that the surface is adequately covered. I have further found that provided the inflow and outflow pumps are exactly synchronized there is no danger of shock to the patient (fig. 2). At first it was thought that it was of importance to limit the amount of blood withdrawn from the body at one time but by filling the machine with blood first this does not prove to be an obstacle. By winding the dialysing tubing round a rotating drum, it not only spreads a small quantity of blood over the dialysing surface but

also produces agitation. This ensures that a fresh sample of blood is being constantly brought to the dialysing surface. In fact, the success of agitation has enabled me to cut down the size of the drum and the dialysing surface. We have also found that by synchronizing our drums to our pumps so that 10 millilitres of blood enters the machine for each complete rotation, a better and more even film is produced which leads to better dialysis. This machine, however, is bulky and has a large number of points which have to be attended to. The bath water is not only exposed to the air, adding to the chance of becoming infected but also the dialysed products tend to build up in the water and thus slow down dialysis. This has led us to search for a machine of simpler design and we have found that by leading a cellophane tube through a machine in which there is a series of plates 1/16th inch apart a large dialysing surface can be achieved. The flow of dialysing fluid is arranged by means of a number of small tubes in the plates which allow the dialysing fluid to flow from the centre outwards in either direction. Unfortunately this machine does not at the moment produce as satisfactory dialysis as the rotating machine.

The most important of all the factors which control successful dialysis is the composition of the fluid in the dialyser. Hitherto these fluids have been of the simple electrolyte pattern, they have contained salts which are isotonic with normal blood but have added glucose

FIG. 1.

FIG. 1.—General view of machine in use. A.—Blood is obtained from radial artery. B.—Blood is restored to a suitable vein.

FIG. 2.—It is essential to control the in and out flow of blood by means of synchronized pumps. The pumps are designed to inject 10 c.c. for every complete rotation of the drum, thus ensuring even distribution of blood over the dialysing surface.

FIG. 2.

to raise the osmotic pressure and although these materials have been used with success in the past, they have one grave disadvantage, that the osmotic action is not maintained, for there is a rapid diffusion of glucose into the patient which is followed by water shift. For example, we have found that whereas we started with 20 litres of fluid in our bath water, this was reduced at the end of two hours' dialysis to 17 litres of which only 1 litre and a third could be accounted for by evaporation. We feel that this flow of water from the bath into the circulation leads to circulatory discrepancies and possibly cardiac failure. We therefore feel it necessary to use a material which is non-dialysable in our bath water to counteract this effect and we hope to produce a fluid which is not only isotonic but also iso-osmotic. Unfortunately this is not all, for as Dr. Campbell has recently confirmed, the plasma osmotic pressure of patients with uræmia is raised and, in a case recently treated, this was in the region of nine atmospheres and was reduced to nearly seven by treatment. It may be necessary to produce a fluid which is maintained at the same osmotic pressure throughout treatment.

SUMMARY

It seems that it is now mechanically possible to withdraw and return the blood without detriment to the patient. Although a rotating type of dialyser produces the maximum dialysis it is bulky and it is felt that before long a more portable type of dialyser can be achieved. Although successful cases are being recorded, further work is required to find an ideal dialysing fluid.

My thanks are due to the Medical Research Council for an expenses grant, Mrs. Adair of the Physiological Department, Cambridge University; Dr. Campbell of Messrs. May and Baker; and last, but not least, to Mr. Harris, Managing Director, and Mr. Harrison of Goddard's Garage for the painstaking care with which they have constructed the many apparatuses used in this research.

The Artificial Kidney: Its Clinical Application in the Treatment of Traumatic Anuria

By E. G. L. BYWATERS, M.R.C.P., and A. M. JOEKES, B.M.

DURING the late war, workers at the British Post-Graduate Medical School became interested in pigment nephrosis, following burial beneath debris, which they showed to be due to muscle necrosis. Since then we have observed similar histological changes in the kidney of almost all traumatic anuria cases resulting from civilian industrial and traffic accidents, without any prolonged compression: As Barlow, Bywaters and Stead were able to show in 1944, a number of these cases excreted myohæmoglobin in the urine, derived from the necrotic muscle near the fracture sites, and we believe, therefore, that the majority of cases of traumatic anuria are due to pigment nephrosis resulting either from myolysis, e.g. vessel rupture or obstruction (Bywaters, Belsey *et al.*, 1942), muscle rupture (Barlow, Bywaters and Stead, 1944), electric shock (Fischer *et al.*, 1947), flogging (de Langen, 1946) or weight of the unconscious body (Gunther, 1940), or from hæmolysis, e.g. overheating, mismatching, myanesis (Hewer and Woolmer, 1947), Welch infection (Hill, 1946), intravenous water as in transurethral prostatectomy (Burnett *et al.*, 1947), intravenous soap solution in abortion (Weilerstein, 1944), sulphonamide hæmolysis, &c. In addition, other adjuvant factors, we believed, were probably also of importance, such as low rate of urine flow and of renal blood flow, low urinary pH and high salt concentration. It seems to us possible that proteins other than pigmented ones might also be involved in other conditions.

Now the immediate interest of all these differently produced lesions is that they affect primarily the distal convoluted tubule and they have thus been described by Lucké (1946) under the heading of "Lower Nephron Disease". If the patient can be tided over the first week, the affected epithelium is desquamated and excreted in the urine as a cellular coat to the pigment cast: regeneration with obvious mitosis from the basement membrane occurs and a diuresis sets in. If this is early enough or large enough the patient will recover and may ultimately, e.g. in five months, reach up to 100% of normal renal function. But as may be seen in fig. 1, the patient may die in uræmia despite a diuresis of even up to 2 litres daily, chiefly because this maximum output is not sufficient to offset the low concentrating power of the kidney in its early phase of recovery. The only means we had of dealing with this situation were of no great value: (a) We could depress serum potassium level (from whose cardiotoxic effects these patients seemed on occasion to die), by the injection of insulin, thus down which are responsible for uræmia by giving saline and producing generalized oedema, but this, if carried too far, is extremely dangerous since it leads to pulmonary oedema; (c) purging and sweating can only eliminate very small quantities of metabolites.

We were thus anxiously looking for some reliable method of tiding the patient over this danger period when we heard that a Dutchman had perfected an artificial kidney (Kolff and Berk, 1944). In response to our invitation, Dr. Kolff was kind enough to come over to set up and used first in October 1946. Since that time, the Kidney Unit has dialysed 12 patients, a small number compared with the number of suitable cases occurring in the Metropolitan Area. The essential details of these are listed in Table I.

TABLE I

Case No.	Diagnosis	Hours of dialysis	Blood flow ml./min.	Fall in blood urea mg./100 ml.	Grammes urea removed	Survival days
I	Bilateral hydronephrosis	1.0	10	470-?	—	3.0
II	Cortical necrosis (post-partum)	3.3	75	316-223	27.0	0.3
III	Post-traumatic anuria	4.1	86	390-211	32.1	—
IV	Hæmoglobin nephrosis	7.5	58	460-209	92.0	0.5
V	Acute glomerulonephritis	3.0	80	504-428	29.0	0.4
VI	Chronic nephritis	1.0	72	750-?	—	0
VII	Bilateral hydronephrosis	4.4	51	440-292	44.1	1.6
VIII	Post-operative anuria	4.1	76	424-264	33.1	—
IX	Aspirin suicide	3.0	58	105-59	7.5	5.0
X	Acute glomerulonephritis	2.3	50	428-307	21.0	0.2
XI	Chronic nephritis	3.7	70	400-238	65.0	0.4
XII	Bilateral hydronephrosis	3.3	80	360-178	28.7	14.0

INDICATIONS

The type of case best fitted for the artificial kidney is one in whom recovery of renal function will eventually occur, that is, one with either functional disorder or disease affecting the tubules rather than the glomeruli. Once the glomeruli are damaged, as in subacute or

chronic glomerulonephritis, polycystic disease, advanced long-standing hydronephrosis, or cortical necrosis, no restitution will occur. In uræmia of functional origin, e.g. extrarenal azotæmia or alkalosis, adequate attention to the electrolyte composition of the body should restore health, unless a calcium nephrosis has supervened, as sometimes seems to happen in alkalosis. Thus in the uncomplicated case there is seldom need to use the artificial kidney. In lower nephron disease, however, many will fail to recover spontaneously and it is these that will probably turn out to be the best indication for the use of this machine. As will be seen from the second column of Table I, only a few cases were of this type; the majority, some of them obscure in nature on first admission, turned out ultimately to be cases of glomerulonephritis. These were dialysed, sometimes even without full knowledge of the

FIG. 1.—Case of ischemic muscle necrosis due to crush injury, developing anuria despite intake of 150 ml. per hour over three days. Decapsulation produced no increase in urine output. A spontaneous diuresis developed on the seventh day, reaching 2½ litres per day with continued rise of blood-urea level, and death from uræmia on the ninth day. Note that urea concentration runs parallel to blood level, and thus shows no sign of return in concentrating ability.

diagnosis, because the prognosis was believed to be otherwise fatal. The same holds for the cases of hydronephrosis due to inoperable carcinoma; they were cases whose condition before dialysis was too bad even for pyelostomy to be carried out. It will be seen that two cases were dialysed for less than an hour; one of these was our first case in whom incannulation was unsatisfactory, producing such a very low rate of arterial inflow (10 ml. per minute) that dialysis was discontinued; the other was moribund at the beginning of dialysis, with a blood urea of 750 mg.%, and died in one hour.

FIG. 2 (Case III).—Development of oliguria following an explosion, with blood urea reaching 390 mg.%. A five-hour dialysis (4.1 effective hours at 86 ml. per minute), reduced blood urea to 211 mg.%, and removed 32 grammes urea. Following dialysis, note secondary rise in blood urea which is overtaken by diuresis.

SURVIVAL

Of the remaining 10, 2 have survived, and, we believe, probably because of the dialysis rather than in spite of it, although this is difficult to substantiate except by statistical means on a larger series of cases.

CASE III.—A male, aged 31, had been knocked down by the explosion of a car battery and possibly rendered unconscious for a short period. He walked home having no obvious injury. The next two days he vomited repeatedly; it was not until the fourth day that he became oliguric and on the seventh day he attended the Outpatient Department at University College Hospital complaining of "urine in the breath" and oliguria. The next day he was admitted with a blood urea of 102 mg.%. As the oliguria persisted despite 5 litres of intravenous sulphate, and the blood urea rose to 246 mg.%, a right splanchnic block was done and a cystoscopy performed at which a clear efflux was seen from the right and none from the left kidney. He was therefore transferred to the British Post-Graduate Medical School on the twelfth day (blood urea 390 mg.%, CO_2 (C.P.) 44 vols.%, chloride as NaCl 419 mg.%, hæmoglobin 88%, Haden 13.6 grammes%). Urine, pH 8.6, albumin 40 mg.%, urea 526 mg.%, ammonia 54 mg.%, chloride 260 mg.%. After dialysis for five hours with the removal of 32 grammes of urea, his condition improved, but oliguria was still present (*see fig. 2*) with low urea content, 565 mg.% and a still lower chloride level, 120 mg.%, despite a rise in plasma-chloride level to 476 mg.%. It was not until the third day after dialysis that urine output reached a satisfactory level with an increase in urea concentration to 1040 mg.% and following this, with chloride by mouth, the plasma chloride rose. Thereafter except for a right perinephric abscess, and root paralysis L 2, 3 and 4, recovery was uninterrupted. Follow-up showed a normal intravenous pyelogram and maximum sp. gr. 1.024.

CASE VIII.—A female, aged 52, was admitted to St. John's Hospital, Lewisham, for removal of gall-stone.

Examination.—B.P. 135/85. Urine: no albumin, sp. gr. 1.020.

Operation.—Following myanesin injection, cholecystectomy was performed with the removal of a stone impacted at the junction of cystic and common duct. Appendix was removed and right kidney was found to be normal. The blood urea rose and remained at a very high level despite a urine output of about a litre per day (*see fig. 3*), and some vomiting. Urine studies after operation showed albuminuria,

FIG. 3 (Case VIII).—Chart showing uræmia, following cholecystectomy: dialysis removed 33 grammes urea and blood urea fell from 424 to 264 mg.%, with gradual recovery on a high fluid intake, and a later improvement of concentrating ability.

many granular casts, a specific gravity 1.010–1.014, chloride content (as NaCl) 200 mg. (third and fifteenth post-operative day), urea 600 mg.% (fifteenth day) and 100 mg.% (twenty-third day). Blood studies showed hæmoglobin 10.2 grammes%, plasma protein 5 grammes% (sixth day), chloride as NaCl 370 mg.%, CO_2 (C.P.) 47.6 vols.% (seventeenth day), sodium 238 mg.%, phosphate 10.2 mg.%, creatinine 10.7 mg.% (twenty-third day).

¹Due probably to sulphate retention.

On admission to Hammersmith Hospital (twenty-sixth post-operative day) she was mentally confused, no oedema, no raised venous pressure, B.P. 155/90, CO₂ (C.P.) 38.5 vols.%, chloride as NaCl 468 mg.%, blood urea 424 mg.%, sodium 334 mg.%, potassium 20.5 mg.%. She was dialysed for 4.1 hours and given four bottles of blood, with the removal of 33 grammes of urea and a reduction of blood urea to 264 mg.%, rise of chloride to 548 mg.% and of CO₂ (C.P.) to 45 ml.%.

In the eight days following admission and dialysis almost anything given by mouth was vomited; and despite a large parenteral intake blood urea rose and urine output remained stationary at about 1.2 to 1.5 litres/day. On the thirty-fifth post-operative day intravenous therapy started a gradual increase in output (which thereafter rose to 4 litres/day) and, as may be seen from the chart, a gradual rise in urine urea concentration occurred to 400 mg.% despite this large diuresis and the continuously falling blood level, thus attesting a renal recovery.

Follow-up studies have shown no abnormality by pyelography, and function has gradually returned towards normal (Table II).

TABLE II.—RENAL FUNCTIONAL RECOVERY (CASE VIII)
Days post-op. Clearance figures

37	Glomerular filtration (mannitol)	4.2 ml./min.
	Renal plasma flow (PAH)	10.4 ml./min.
68	Glomerular filtration (mannitol)	20.0 ml./min.
	Renal plasma flow (PAH)	130.0 ml./min.
77	Urea clearance	26% of normal
134	Creatinine clearance	20.0 ml./min.
	Urea clearance	39% of normal
168	I.V.P. showed fairly good concentration both kidneys, with normal outline	
291	Creatinine clearance	168.0 ml./min.
	Renal plasma flow	452.0 ml./min.

Comment.—This was probably a case of pigment nephrosis due to myanesin hæmolytic. The available data was insufficient to support this or any other ætiological hypothesis.

Of the remaining 8, all died at varying intervals, up to fourteen days. In some cases this was due to the inevitably fatal character of the disease, as in several with severe and advanced glomerulonephritis; in some, it was due to the dangerously labile cardiovascular state, and this was particularly noticeable in the cases with acute glomerulonephritis where it seemed very easy to overload. In one case where it seemed possible that we might be successful, in that the patient had a pigment nephrosis, conditions antecedent to his admission tipped the scales against his recovery:

CASE IV.—A male, aged 36, after some bleeding following herniorrhaphy was transfused, at another hospital, with 500 ml. of incorrectly matched blood. Within forty-five minutes, backache, rigors and nausea developed (B.P. 170/110). 120 ml. of urine containing free hæmoglobin was withdrawn two hours later, and over the next day he became oliguric (120 ml./day), jaundiced, blood urea 106 mg.% despite lactate (2 litres), 5% glucose saline (2 litres), alkali sodium sulphate and caffeine. A high spinal anæsthetic was given with no result.

On the third day 30 ml. urine only was passed, with no casts but containing methæmoglobin. B.P. 170/100, hæmoglobin 10.2 grammes%, urea 110 mg.%. Glucose saline (4 litres) and sulphate (1 litre) were given, bilateral renal decapsulation was performed and peritoneal washouts were started through a catheter (1.1 litre in twenty-four hours, urea content 100 mg.%).

Thereafter blood urea rose steadily (see fig. 4). Dyspnœa, venous congestion and oedema developed due to overload and the urine output over the fourth and fifth days averaged 120 ml./day, hæmoglobin 7.6 grammes%, CO₂ (C.P.) 50 ml.%, Na 321 mg.%, chloride as NaCl 351 mg.% (fourth day). Another attempt at peritoneal dialysis was made on the sixteenth day without improvement, despite morphia, atropine, paraldehyde, caffeine, sodium bicarbonate, potassium citrate, magnesium sulphate, ephedrine, benzedrine, ascorbic acid, ferrous sulphate, anahæmin, phenobarbitone, sodium sulphate, sodium lactate, sucrose, glucose, saline, Hartman's solution, blood, plasma, and penicillin.

He was admitted to the British Post-Graduate Medical School on the eighteenth day comatose, grossly oedematous, and very heavily infected at all three incisions with pyocyaneus. B.P. 200 mm.Hg. The patient was dialysed for 7.5 hours and given four bottles of blood with the removal of 92 grammes urea and fall of blood level from 560 mg.% on entry to 209 mg.%.

He came out of coma and became rational, asking for a cup of tea and conversing with his neighbour in the ward. Signs of pulmonary oedema evident on entry had receded. Six hours later, however, his condition suddenly worsened with dyspnœa, loss of consciousness and signs of pulmonary oedema, death occurring twelve hours after the end of dialysis. Post mortem (peritoneal fluid urea 350 mg.%) confirmed the pulmonary congestion, widespread pyocyaneus infection and pigment nephrosis.

Comment.—Gross overloading with fluid and pyocyaneus infection seemed to contribute to this end, after a very successful dialysis both from the view of the blood-urea level and the systemic fluid overload. It seemed also possible that glucose deposition as glycogen might sufficiently alter electrolyte balance to upset the established equilibrium.

SURVIVAL

Of the remaining 10, 2 have survived, and, we believe, probably because of the dialysis rather than in spite of it, although this is difficult to substantiate except by statistical means on a larger series of cases.

CASE III.—A male, aged 31, had been knocked down by the explosion of a car battery and possibly rendered unconscious for a short period. He walked home having no obvious injury. The next two days he vomited repeatedly; it was not until the fourth day that he became oliguric and on the seventh day he attended the Outpatient Department at University College Hospital complaining of "urine in the breath" and oliguria. The next day he was admitted with a blood urea of 102 mg.%. As the oliguria persisted despite 5 litres of intravenous sulphate, and the blood urea rose to 246 mg.%, a right splanchnic block was done and a cystoscopy performed at which a clear efflux was seen from the right and none from the left kidney. He was therefore transferred to the British Post-Graduate Medical School on the twelfth day (blood urea 390 mg.%, CO_2 (C.P.) 44 vols.%, chloride as NaCl 419 mg.%, hæmoglobin 88%, Haden 13.6 grammes%). Urine, pH 8.6, albumin 40 mg.%, urea 526 mg.%, ammonia 54 mg.%, chloride 260 mg.%. After dialysis for five hours with the removal of 32 grammes of uræa, his condition improved, but oliguria was still present (*see fig. 2*) with low uræa content, 565 mg.%, and a still lower chloride level, 120 mg.%, despite a rise in plasma-chloride level to 476 mg.%.

It was not until the third day after dialysis that urine output reached a satisfactory level with an increase in uræa concentration to 1040 mg.%, and following this, with chloride by mouth, the plasma chloride rose. Thereafter except for a right perinephric abscess, and root paralysis L 2, 3 and 4, sp. gr. 1.024.

CASE VIII.—A female, aged 52, was admitted to St. John's Hospital, Lewisham, for removal of gall-stone.

Examination.—B.P. 135/85. Urine: no albumin, sp. gr. 1.020.

Operation.—Following myanesin injection, cholecystectomy was performed with the removal of a stone impacted at the junction of cystic and common duct. Appendix was removed and right kidney felt to be normal. The blood urea rose and remained at a very high level despite a urine output of about a litre per day (*see fig. 3*), and some vomiting. Urine studies after operation showed albuminuria,

FIG. 3 (Case VIII).—Chart showing uræmia, following cholecystectomy: dialysis removed 33 grammes uræa and blood urea fell from 424 to 264 mg.%, with gradual recovery on a high fluid intake, and a later improvement of concentrating ability.

many granular casts, a specific gravity 1.010–1.014, chloride content (as NaCl) 200 mg. (third and fifteenth post-operative day), uræa 600 mg.%, (fifteenth day) and 100 mg.%, (twenty-third day). Blood studies showed hæmoglobin 10.2 grammes%, plasma protein 5 grammes% (sixth day), chloride as NaCl 370 mg.%, CO_2 (C.P.) 47.6 vols.% (*see* twentieth day), sodium 288 mg.%, phosphate 10.2 mg.%, creatinine 10.7 mg.%, (twenty-third day).

¹Due probably to sulphate retention.

HEMORRHAGE

However, one death at least was probably related to therapy, a patient with uræmia due to acute glomerulonephritis (Case X). After a successful dialysis removing 21 grammes urea and bringing blood level from 428 to 307 mg.%, he suddenly developed an acute headache three hours after his return to the ward and died with subdural hæmorrhage; although purpura does occur spontaneously in nephritis it seems probable that heparinization played a considerable role here. This complication of heparinization does not seem to have occurred in any of Kolff's cases (Kolff, 1947) and we have had no serious trouble with bleeding in other cases. The incannulation wounds do not bleed if large vessels are secured and adequate time for clotting is allowed before heparinization. Further, we have had no bleeding from a quite recently separated placental site (Case II) or from recent operation wounds (Case IV). It has now been found possible to reduce the total heparin needed for a normal-sized adult from 1 gramme to 500 mg. without clotting in the machine. Protamine sulphate will bring coagulation time back to normal in a few minutes, but it is necessary to give enough to neutralize all the heparin (Table III).

TABLE III

1 gramme protamine sulphate	=	1.5 grammes heparin
Heparin (Boots) 50 mg. in 5 ml.	=	5,000 Toronto units
Heparin (Swedish) 50 mg. in 1 ml.	=	5,000 internat. units
Protamine Sulphate (Swedish) 5 ml. of 1% solution	=	50 mg. protamine
Hence 5 ml. protamine sulphate solution	=	75 mg. heparin

OTHER TECHNICAL DETAILS

While we have made no major alteration in the set-up described by Kolff (1947), we have introduced several modifications which we think to be improvements. Fig. 5 shows a modification of the circuit which avoids the excessive pressures under which blood was formerly pumped from the machine into the patient's vein, often measuring as high as 300 mm.Hg, and partly responsible, we thought, for venous spasma. The pump drives blood from the venous end of the machine into a simple gravity-feed burette; this also allows for a further modification recently introduced by Joekes and Bull where, instead of continuous flow, a strictly measure-for-measure bleeding and replacement is performed; this is of especial value in those patients with labile circulations, such as in acute glomerulonephritis or severe chronic anæmia where overloading or overbleeding is particularly dangerous. Even with measure-for-measure venous replacement of arterial outflow, however, the osmotic forces in the bath may produce an increase or a decrease in body fluid and circulating volume. Of great value in difficult cases is the introduction of a catheter into the right auricle and the return of blood through this. With this in situ, regular readings can be made of right auricular pressure and of cardiac output, so that early warning of tendencies to overload or exsanguinate is available. An internal catheter diameter of 2 mm. is necessary to maintain an approximate rate of flow of 100 ml./min. at a pressure of 100 cm. H.O.

We have not found it essential to change the bath water during the course of even an eight-hour dialysis since the arterial level of urea, &c., is dependent on an equilibrium between the urea output of intracellular- (45% of body-weight) and interstitial-fluid compartments and the bath-water urea uptake; its rate of fall seems to be little affected by rise of bath-water concentration as high even as 50% of the blood level (*see* fig. 6). The composition of the dialysing fluid we have used is as shown in Table IV. In severely œdematous patients we

TABLE IV.—COMPOSITION OF BATH WATER

Constituents		Concentration per 100 ml.	
600 grammes NaCl	..	Calcium	.. 3 mg.
1,500 grammes Glucose	..	Glucose	.. 1,500 mg.
200 grammes NaHCO ₃	..	Chloride (as NaCl)	630 mg.
40 grammes KCl	..	Sodium	.. 290 mg.
100 litres tap water	..	CO ₂ (C.P.)*	.. 54 ml.
		Potassium..	.. 20 mg.

* Combining Power

have used 2 grammes% glucose, but as in the body this is stored as glycogen, the resultant electrolyte shifts might possibly result in a potassium deficiency, as we have seen in insulin-treated diabetics. The level of glucose in the patient's blood reaches only as high as 600 to 700 mg.% although the post-kidney blood may be as high as 1,500 mg.%. We have, therefore, used a potassium concentration at the upper end of normality (Note that 20 mg.% in serum is 21.5 mg.% in serum-water). It would probably be better to use some macromolecular substance not diffusible through cellophane, such as dextran, gum acacia, or even plasma protein, but we have not yet been able to do this.

Other types of death were also associated with conditions antecedent to dialysis; thus Case V was cyanosed before and became almost asphyxiated during the dialysis due to a widespread bilateral bronchopneumonia: the blood in the coils of cellophane was dark blue in colour.

FIG. 4 (Case IV).—Chart showing development of uræmia, following mismatched transfusion. Following failure of spinal anæsthesia (Sp.) peritoneal dialysis (P.D.) and decapsulation, dialysis on the artificial kidney for seven and a half hours removed 92 grammes urea, but death occurred twelve hours after, from a return of pulmonary oedema and widespread sepsis.

FIG. 5.—Modification of Kolff's artificial kidney showing return of blood to gravity-feed burette following dialysis.

FIG. 6 (Case IV).—Showing continued fall of arterial urea levels with decrease of arteriovenous concentration gradients due to rise in level of bath-water concentration. Note that concentration of urea in the venous end of the kidney runs parallel to and just slightly above the bath-water concentration.

DISCUSSION ON STAPHYLOCOCCAL INFECTIONS

Professor Wilson Smith: *Factors concerned in the virulence and host specificity of staphylococci* [Summary].—In spite of widespread distribution and the frequency with which it causes infections of man and lower animals the staphylococcus still presents many unsolved problems. The factors concerned in virulence and specificity are extremely complex and, notwithstanding the extensive investigations which have been carried out in recent years, offer a fruitful field for further study. For example, little is known of the factors which determine tissue invasion by a staphylococcus which has long sojourned as a harmless parasite in the host. How far does the production of ferments like hyaluronidase and fibrinolysin affect the type of pathological lesion and the spread of infection through the tissues? Do different strains of staphylococci possess different host specificities? Is mutation a major factor in infectivity? On this last question I would say only that in my own opinion the key to the solution of some of our problems lies in the readiness with which staphylococci mutate. Hale (1947) in my laboratory produced stable "G", or small colony, mutants which retained the phage type, coagulase activity and penicillin sensitivity of the parent strain but had lost α toxigenicity. Such mutations occurring in Nature might well affect epidemiological and infectivity patterns of behaviour and their study from this angle might be well repaid.

The virulence of an organism is based chiefly upon its invasiveness and its toxigenicity and the staphylococcus provides an excellent example of the utilization of both these mechanisms and of their interaction. A number of metabolites concerned in virulence are known and have been extensively investigated. Of these the available evidence suggests that α toxin and the leucocidin of Pantón and Valentine (1932) are major toxic factors, that coagulase is a major factor in the initial stages of tissue invasion and that fibrinolysin and hyaluronidase may possibly help to determine the clinical type of infection. The β toxin seems to be of little importance in human infection but may play a role in infections of lower animals. The enterotoxin produced by some strains is, of course, a cause of food poisoning but is not concerned with infection in the true sense of the term. Evidence in support of these statements has been provided by four different methods of investigation.

(1) *Correlation studies.*—Several investigators have attempted to analyse the virulence factors of the staphylococcus by isolating numbers of strains and by studying the correlations between their production of various metabolites and the clinical evidence of their pathogenicity or non-pathogenicity. All workers agree that the closest correlation occurs with staphylocoagulase. For example, the investigation by Schwabacher *et al.* (1945) of over 800 strains isolated from human sources indicates that in order to be pathogenic a staphylococcus must be able to produce coagulase. The converse, that power to form coagulase makes an organism pathogenic, does not, however, necessarily follow. Additional factors may be essential. Thus these same workers found that over 98% of coagulase-positive strains isolated from definite staphylococcal infections produced also α toxin and hyaluronidase. The same combination of metabolic activities was shown by about 90% of coagulase-positive staphylococci obtained from persons with no sign of infection. On the other hand, coagulase-negative strains, whether isolated from wounds or from healthy persons, were never found to produce either α toxin or hyaluronidase. Our own unpublished results with human strains are in agreement as far as coagulase and α toxin are concerned, suggesting that both these factors may be essential in the infective process in human beings. In lower animals the position may be different. H. W. Smith (1947) found a high degree of correlation between the coagulase, β toxin and fibrinolysin production of staphylococci from animal infections and when his figures are compared with those we obtained with human strains it appears that for some animal species β toxin may replace α toxin as the important toxigenic virulence factor. The possible significance of leucocidin emerges from the work of Valentine and Butler (1939) who suggest that it may largely determine the type and severity of human infections consequent upon tissue invasion by a pathogenic staphylococcus.

Correlation studies, however, have very definite limitations and other research methods are necessary to elucidate the modes of action of the various factors and their interaction.

(2) *Human immunization trials.*—Studies along this line have been confined to trials of either whole bacterial vaccines or toxoid prepared from α toxin and have resulted in but little advance in our knowledge of staphylococcal virulence factors. The disadvantages of using human beings as experimental animals are especially operative in the case of

ADJUVANT THERAPY

The patient is, if time permits, premedicated with amidopyrine (0.6 grammes six-hourly for twenty-four hours) to guard against rigors. These are probably due to bacterial pyrogen produced on moist rubber tubing allowed (after vigorous cleaning in soda, hydrochloric acid and tap water) to lie around for an hour before autoclaving; this is a point not usually appreciated, but one very difficult always to eliminate. Sedation is accomplished with pentothal 0.2 gramme, nembutal or sodium gardenal 3 grammes repeated as necessary. Penicillin is given as a routine, and calcium gluconate injections are necessary since the bath water contains only such small amount of calcium as is contributed by the tap water (and varies thus from place to place). We have also added to the circulating blood such substances as thiamine and ascorbic acid, since such substances may be lost into the bath water. The body store of various other "threshold" substances, normally reabsorbed by the kidney, such as amino-acids, may also become depleted, but we have not yet been able to recognize any such effects clinically.

In the after-period we endeavour to maintain an intake of 2,000 calories, since various people, including, recently, Professor Borst of Amsterdam, have emphasized the nitrogen-sparing powers of a high calorie intake. He gives a mixture of 200 grammes butter and 200 grammes sugar daily, a teaspoonful of which, given iced, is quite palatable; 400 grammes, however, is distinctly tedious, our patients tell us, however disguised, and it needs a patient and persuasive nurse and a co-operative and non-vomiting patient to take it. With such an intake, body protein, normally broken down on low calorie intakes to provide calories, is spared; instead of producing 10 grammes N_2 /day (that is, 20 grammes urea and equivalent to a daily blood urea rise of 40 mg. % in a 65 kg. man or a urine output of 2 litres at the usual maximal pathological urea concentration of 1 gramme %) the body produces a mere 2 grammes N_2 (equivalent to 4 grammes urea). This means that a patient with no kidneys should last five times as long, since the substances producing uræmic death such as potassium, &c., come almost all from endogenous protein breakdown. We had also thought to increase tubular regeneration with testosterone, and have given it, but have had no chance to evaluate results. Theoretically it should be of value in association with a protein-sparing diet.

OTHER APPLICATIONS

Dialysis is a method obviously applicable to other intoxications or states of severe electrolyte imbalance. We have dialysed a suicidal patient aged 72 with aspirin poisoning and congestive heart failure. There was improvement following removal of 5 grammes of salicylic acid in the bath water, bringing the blood level from 31 to 21 mg. % and the CO_2 (C.P.) from 35 to 43 ml. %. It is hoped to treat more such cases.

While the clinical value of this new weapon will always be its life-saving capacity, its experimental use in animals will be intensely interesting because of one's ability with it to alter the whole internal environment of the body cells at will. There is obviously room for a great deal of improvement; Alwall's dialyser (1947) seems a step in the right direction. We have a great deal more to learn about its effective operation and about its usefulness relative to peritoneal dialysis and dietary measures.

Teamwork is essential for successful operations of this kind and we acknowledge with gratitude the help of Dr. Lennox Eales in the early stages, and of Dr. Graham Bull in the recent cases, of Mr. John Manders, Miss Patricia Burrows and others who from time to time have been co-opted.

We acknowledge here also the kindness of clinicians who have referred cases to us: Mr. F. J. F. Barrington, Dr. Kenneth Harris and Mr. David Wallace, Dr. Hill, Dr. Hooson, Mr. Hesketh Roberts, Dr. Mallinson, Mr. Dashmukh and our colleagues at the Post-Graduate Medical School of London.

DISCUSSION ON STAPHYLOCOCCAL INFECTIONS

Professor Wilson Smith: *Factors concerned in the virulence and host specificity of staphylococci* [Summary].—In spite of widespread distribution and the frequency with which it causes infections of man and lower animals the staphylococcus still presents many unsolved problems. The factors concerned in virulence and specificity are extremely complex and, notwithstanding the extensive investigations which have been carried out in recent years, offer a fruitful field for further study. For example, little is known of the factors which determine tissue invasion by a staphylococcus which has long sojourned as a harmless parasite in the host. How far does the production of ferments like hyaluronidase and fibrinolysin affect the type of pathological lesion and the spread of infection through the tissues? Do different strains of staphylococci possess different host specificities? Is mutation a major factor in infectivity? On this last question I would say only that in my own opinion the key to the solution of some of our problems lies in the readiness with which staphylococci mutate. Hale (1947) in my laboratory produced stable "G", or small colony, mutants which retained the phage type, coagulase activity and penicillin sensitivity of the parent strain but had lost α toxigenicity. Such mutations occurring in Nature might well affect epidemiological and infectivity patterns of behaviour and their study from this angle might be well repaid.

The virulence of an organism is based chiefly upon its invasiveness and its toxigenicity and the staphylococcus provides an excellent example of the utilization of both these mechanisms and of their interaction. A number of metabolites concerned in virulence are known and have been extensively investigated. Of these the available evidence suggests that α toxin and the leucocidin of Pantón and Valentine (1932) are major toxic factors, that coagulase is a major factor in the initial stages of tissue invasion and that fibrinolysin and hyaluronidase may possibly help to determine the clinical type of infection. The β toxin seems to be of little importance in human infection but may play a role in infections of lower animals. The enterotoxin produced by some strains is, of course, a cause of food poisoning but is not concerned with infection in the true sense of the term. Evidence in support of these statements has been provided by four different methods of investigation.

(1) *Correlation studies.*—Several investigators have attempted to analyse the virulence factors of the staphylococcus by isolating numbers of strains and by studying the correlations between their production of various metabolites and the clinical evidence of their pathogenicity or non-pathogenicity. All workers agree that the closest correlation occurs with staphylocoagulase. For example, the investigation by Schwabacher *et al.* (1945) of over 800 strains isolated from human sources indicates that in order to be pathogenic a staphylococcus must be able to produce coagulase. The converse, that power to form coagulase makes an organism pathogenic, does not, however, necessarily follow. Additional factors may be essential. Thus these same workers found that over 98% of coagulase-positive strains isolated from definite staphylococcal infections produced also α toxin and hyaluronidase. The same combination of metabolic activities was shown by about 90% of coagulase-positive staphylococci obtained from persons with no sign of infection. On the other hand, coagulase-negative strains, whether isolated from wounds or from healthy persons, were never found to produce either α toxin or hyaluronidase. Our own unpublished results with human strains are in agreement as far as coagulase and α toxin are concerned, suggesting that both these factors may be essential in the infective process in human beings. In lower animals the position may be different. H. W. Smith (1947) found a high degree of correlation between the coagulase, β toxin and fibrinolysin production of staphylococci from animal infections and when his figures are compared with those we obtained with human strains it appears that for some animal species β toxin may replace α toxin as the important toxigenic virulence factor. The possible significance of leucocidin emerges from the work of Valentine and Butler (1939) who suggest that it may largely determine the type and severity of human infections consequent upon tissue invasion by a pathogenic staphylococcus.

Correlation studies, however, have very definite limitations and other research methods are necessary to elucidate the modes of action of the various factors and their interaction.

(2) *Human immunization trials.*—Studies along this line have been confined to trials of either whole bacterial vaccines or toxoid prepared from α toxin and have resulted in but little advance in our knowledge of staphylococcal virulence factors. The disadvantages of using human beings as experimental animals are especially operative in the case of

ADJUVANT THERAPY

The patient is, if time permits, premedicated with amidopyrine (0.6 grammes six-hourly for twenty-four hours) to guard against rigors. Dr. V. D. Allison gave a résumé of recent work on the serological typing of *Staph. pyogenes* and described the development of bacteriophage typing (Fisk, 1942, and Wilson and Atkinson, 1945). The properties of the phages used, and the technique of typing were shortly described.

The application of serological and bacteriophage typing to the investigation of outbreaks of staphylococcal infection has shown that there is a definite correlation between the two methods. Outbreaks investigated included pemphigus neonatorum in maternity units and nursing-homes, mastitis among mothers in maternity units, food-poisoning due to staphylococcal enterotoxin; and strains from a series of cases of sycosis barbæ were also investigated serologically by Hobbs, Carruthers and Gough (1947).

Much new information on the epidemiology of staphylococcal infections has been gained by the investigation of pemphigus neonatorum (Allison and Hobbs, 1947).

Twenty-three outbreaks of staphylococcal food-poisoning were investigated over a period of two years, and it appeared as though certain serological and phage types were particularly liable to produce enterotoxin and cause epidemics under suitable conditions. The importance of the nose as the ultimate reservoir of *Staph. pyogenes* was stressed, but the skin and especially septic abrasions and cuts, and even healthy-looking cuts, were frequently implicated as breeding grounds for infective strains of the organisms.

Investigation of strains from cases of sycosis barbæ showed the importance of treating the noses of carriers of staphylococci concurrently with the infection in order to prevent relapse after apparent cure.

The lessons to be learnt from the investigation were shortly discussed and suggestions were made for the improvement of techniques in infant nurseries, hospital wards and the hygienic handling, or avoidance of handling, of food. The ubiquity of the staphylococcus renders the prevention and control of infections caused by it a formidable problem.

Dr. A. McDiarmid: *Enzootic staphylococcal infection in young lambs associated with tick-bite*.—Staphylococcal infections occur in practically all the domestic animals and birds, but most of these cases are sporadic, rarely fatal, and of little importance economically. There are, however, exceptions, such as mastitis in cattle and sheep, and I shall briefly discuss yet another disease caused by *Staphylococcus aureus* which is responsible for much death and debility in young lambs on hill farms throughout Britain. This infection differs in some interesting ways from the usual sporadic type of staphylococcal infection and is now recognized as a specific disease, enzootic in distribution with a definite age-incidence, and invariably associated with the presence of the common sheep tick *Ixodes ricinus* L. Thus it has several features of considerable interest to those engaged in the study of the epidemiology of staphylococcal infections.

As long ago as 1894, McFadyean, described a condition in sheep in Northumberland caused by a slightly chromogenic micrococcus; he named this condition pyæmic spinal meningitis and attempted to transmit the disease, by inoculating cultures subcutaneously into experimental sheep. These attempts were unsuccessful, because, although local abscesses appeared at the inoculation sites, no pyæmia developed. Stewart and Ponsford (1937) confirmed these observations and suggested that the disease was responsible for the deaths of many young lambs and subsequently a survey by Taylor, Holman and Gordon (1941) showed that the incidence of the infection in dead lambs brought for examination from tick-infested farms in Perthshire, was 29%.

Practically any breed of sheep can be affected provided the environment conditions are suitable, and infection must be contracted soon after birth as pyæmic cases are generally observed in lambs about a fortnight to one month of age. On hill farms, lambs, even a day old may harbour large numbers of ticks and thus the opportunity for early infection can readily be appreciated. The sites of tick-bite are usually inflamed and small abscesses may be present from which *Staphylococcus aureus* can be isolated. The causal agent may also be recovered from the heart blood of very young tick-infested lambs in which no visible abscesses are present and these constitute true septicæmic cases (McDiarmid, 1946a). Pyæmia, however, is the form of the infection most generally recognized and abscesses may be present in almost any situation in the body. The pressure of an abscess in the vicinity of the central nervous system may produce impairment of gait or even complete paralysis, depending on the situation of the lesion and thus, clinically, these cases may frequently be confused with true louping-ill, the cause of which is a filtrable virus.

One of the difficulties of assessing the true economic importance of the disease is its

staphylococcal investigations because of the ubiquity of the microbe and the protean nature of the lesions it may evoke. Nevertheless such reports as are available indicate that a antitoxic immunity is of importance in conferring some degree of increased resistance to infection (Parish *et al.*, 1934). Unfortunately some of the virulence factors like coagulase are non-antigenic but immunization trials with leucocidin might yield information of value.

(3) *In vitro* studies.—Certain activities of the virulence factors, though interesting, can have no significance in infection. For example, a toxin lyses rabbit erythrocytes but not human erythrocytes. This should make us cautious about attributing pathogenic significance to factors such as fibrinolysin and hyaluronidase because of their *in vitro* activity. Indeed the work of Evans with *Cl. welchii* goes to show that any influence these substances may have in experimental gas gangrene infection is so overshadowed by the toxic factor as to be negligible. Phagocytosis, however, is so well established as the first line of defence of the host after invasion of tissues has occurred that any anti-phagocytic activity of a staphylococcal metabolite is probably significant. Such activity is readily demonstrable *in vitro* in the cases of leucocidin and coagulase. Hale and I were able to show that the coagulase activity in this respect is specific against staphylococci so that other species of bacteria incorporated in the test mixtures are taken up by phagocytes just as readily as if no coagulase were present (Hale and Smith, 1945). This indicates that, unlike leucocidin, the action of the coagulase is upon the microbes and not upon the phagocytic cell. In other words, coagulase protects staphylococci against ingestion by phagocytes. *In vitro* experiments with plasmas of different animal species have given an inkling that coagulase may also be concerned in the host specificities of different strains of staphylococci. It now seems fairly certain that there are several different coagulases with different ranges of activity against the plasmas of various animals and a wide field for investigation by *in vitro* techniques is thus opened up.

(4) *Animal infection experiments*.—The importance of a toxin has been clearly demonstrated by two types of experiment: (1) Direct demonstration of its toxic effects, e.g. production of skin necrosis by intracutaneous inoculation of guinea-pigs and the lethal effect of intravenous inoculation of rabbits. (2) Immunization of animals with toxoid and toxin followed by the inoculation of living staphylococci. The second type of experiment has shown that a high level of antitoxic immunity may suffice to protect against experimental infection, but often the protection is incomplete so that in spite of modification of the course of infection the animals eventually succumb. This is in keeping with the view that in the case of staphylococci no single virulence factor is of predominant importance.

This line of investigation is obviously worth extending to other factors like leucocidin, hyaluronidase and fibrinolysin. Coagulase, however, is neither directly toxic nor antigenic so that a more indirect approach has been necessary. A comparison of strains capable of coagulating guinea-pig plasma with those not able to do so showed that the former were much more virulent for the guinea-pig when inoculated by either the intracardiac or intratesticular route. Again pre-treatment of staphylococci with a coagulable plasma rendered them more infective for mice, a species which is relatively insusceptible to staphylococcal infections, probably because mouse plasma is non-coagulable by the staphylocoagulase of nearly all strains. The analysis of the role of coagulase in infection has been attempted by many modifications of such kinds of animal experiments and all go to confirm its importance (Smith, Hale and Smith, 1947).

To summarize: I suggest as a basis for discussion that in the case of staphylococci there is no one all-important infectivity factor such as the toxin of type A, *Cl. welchii*. Coagulase and a toxin are certainly major factors in human infections but other toxins, like the β toxin, may be found to take the place of a toxin in the infection of other animal species. The indications are that coagulase helps the organism to initiate infection whilst toxins come into play subsequently. Leucocidin is also important but whether it is essential in the genesis of an infection we do not know; possibly its chief importance is in determining the severity and type of the disease once an infection has been established. Fibrinolysin and hyaluronidase may also play a part in the development of the infective process but the demonstration of their *in vitro* activities does not suffice to establish their *in vivo* significance.

JOINT DISCUSSION No. 2

Sections of Medicine, Radiology and Surgery

[February 24, 1948]

Chairman—Sir ALUN ROWLANDS, K.B.E., F.R.C.P.
(Vice-President of the Section of Medicine)

DISCUSSION ON CHRONIC DISEASES OF THE PERICARDIUM

Dr. B. T. Parsons-Smith: The diagnosis and rational treatment of chronic pericarditis not only includes physiological and clinical considerations but also a clear conception of the various ætiological factors known to be responsible for the disease and for the morbid anatomy secondary thereto. The reason for this is not far to seek. Chronic pericarditis is not a single or a constant condition. It comprises a number of different processes and a variety of stages which are of different significance and which call for totally different kinds of management. The disease occurs as an intercurrent complication in cases of chronic carditis; its tuberculous origin has been amply confirmed, as has also its intimate relationship to polyserositis; additional causes deserving of passing mention include chronic renal disease and diabetes in their final stages, coronary disease and malignant disease, the latter by direct spread from viscera in the neighbourhood of the heart or by blood-borne metastases. Two well-recognized varieties of chronic pericarditis, the adhesive and the constrictive, although combined in a certain proportion of cases, are deserving of separate consideration. In the majority of cases, rheumatism or tuberculosis constitutes the pathological background of the adhesive group. If rheumatic the condition may be singularly elusive from the diagnostic point of view owing to the fact that the clinical indications of the pericardial affection are frequently masked by signs of co-existing valvular and myocardial disease. Although, however, it is common knowledge that, with extensive internal adhesions, and complete obliteration of the sac, localizing signs are, as a rule, entirely lacking, it is generally agreed that external adhesions are capable of clinical recognition. These latter are instrumental in the formation of attachments from the pericardium to certain of the adjacent structures including the ribs, the sternum, the lungs, the diaphragm and the spine, also for the development of indurative changes in the mediastinum. The diagnosis of adherent pericardium involves an extensive clinical examination of which the outstanding features in all cases should be the routine radiological investigation. The physical signs of agreed diagnostic value are as follows:

(1) Pericardial friction sounds and triple heart rhythm, the third sound of the latter being that recently described by Professor C. Lian as “the late systolic pleuro-pericardial snap”.

(2) A persistently raised venous pressure with evidence of stasis in the systemic and the portal circuits.

(3) Varying degrees of peripheral œdema, the distribution of which may include

co-existence with other infections. Frequently a young lamb may be affected with two or more diseases at the same time; louping-ill often exists along with pyæmia and tick-borne fever may even be present in the same lamb. Lamb dysentery and pulpy kidney disease may also co-exist with staphylococcal infection, and on a hill farm, unless one carries out a very detailed bacteriological examination, it is impossible to decide which factor may be responsible for the death of the lamb.

The precise way in which the tick acts in the causation of the disease is not yet fully understood. Tick-bite appears to be essential for the development of the disease because the infection is only seen in tick-infested lambs and the staphylococci isolated from the small abscesses at the site of tick-bite are apparently the same as those recovered from the internal lesions. Moreover staphylococcal abscesses rarely appear at wounds caused by surgical interference such as docking or castration or even at the umbilicus, which is a favourite entrance for other pathogenic organisms. It is possible that the tick may act merely in a passive way, creating a small punctured wound and thereby carrying in staphylococci which the tick has picked up during its wanderings on the surface of the body. Owing to the anticoagulating nature of the tick's secretions the organisms have every opportunity of gaining immediate access to the blood-stream instead of being arrested at the original site of entry. *Staphylococcus aureus*, incidentally, can be recovered from the skin of normal ewes and lambs and these strains are potential pathogens, resembling in every way the strains recovered from actual pyæmic cases. The organism has also been recovered from engorged ticks attached to pyæmic lambs, but not from ticks obtained from normal lambs (McDiarmid, 1944). Foggie (1947) has carried on this work and apparently does not believe the tick can carry the infection through the moult and then transmit the infection to another lamb. The evidence, so far, all points to the tick as a mechanical aid to the development of infection rather than as a true vector.

As regards the bacteriology of this condition, many strains of staphylococci have been examined. Most of the strains are coagulase-positive and produce septicæmia or pyæmia, according to the dosage, when injected intravenously in mice, guinea-pigs and young lambs (McDiarmid, 1946*b*, *c*, and 1948). They give rise to bright orange pigmentation when grown on milk agar and produce α and β toxins. Their biochemical reactions are, with rare exceptions, identical, and cross agglutination tests show a considerable degree of serological relationship. Recently Smith (1947) by phage typing, has confirmed the close relationship between strains recovered from pyæmic cases.

In order to reduce the rate of infection on tick-infested farms, various preventive methods have been tried. The best method of attack is to reduce the tick population and render the lambs immune to tick infestation over as long a period as possible. Progress towards this end is being made and D.D.T. dips should prove to be of considerable value. In the second place, can the lamb be given a passive immunity from the ewe at birth? Active immunity is impracticable because of the early age-incidence of the disease. In Scotland we have attempted to hyperimmunize ewes with toxoid, prior to parturition. The antitoxin content of the ewe's colostrum was high at parturition and consequently the blood of the lamb after sucking showed a high level of antibody comparable to that of the mother's blood, but this high antitoxin content in no way protected the lamb against a small test dose of the staphylococcus.

Penicillin therapy could, perhaps, be used either alone or in conjunction with antitoxin, as these strains are fully sensitive to this antibiotic, but again the practical difficulties in dealing with conditions prevailing on a hill sheep farm could hardly be overcome. Diagnosis would be invariably too late and mechanical impairment of function would have ensued before treatment could be applied.

nausea and an irritating cough; the heart was found to be considerably enlarged, the apex impulse could not be seen or felt, the sounds were faint, the pulse small and rapid (110), the respiratory rate 22, the temperature intermittent and rising (100° – 101°) and the blood-pressure 110/80; there was a loud friction rub over the whole præcordium of maximum intensity at the base; the cardiogram showed low voltage curves with inverted T waves in leads I, II, IVR and IVF and the X-ray showed the typical shadow of a large pericardial effusion; the patient's progress appeared to fall into three phases:

- (1) The phase of increasing effusion with hypotension and congestive failure.
- (2) The phase of decreasing effusion with a steady rise of blood-pressure and temporary recovery.
- (3) The phase of deterioration characterized by a rising pulse-rate, a falling blood-pressure, a diminished pulse-pressure, pulsus paradoxus, congestive failure with gross œdema and an increasing irregularity of the cardiac shadow by X-ray, suggestive of progressive thickening of the pericardium. The authors suggested that the apparent improvement during the second phase of the man's illness was illusory, the relief following the absorption of the pericardial exudate being not yet offset by the hampering effect of the gradual thickening of the visceral pericardium on the action of the heart.

It remains to mention constrictive pericarditis, a condition characterized pathologically by widespread indurative disease of the pericardium, the effect of which is to restrict the range of cardiac motility, limiting more particularly the filling capacity of the ventricles and so diminishing the volume of their output per beat. Elevation of the venous pressure is a further development of considerable significance in constrictive pericarditis, being probably the outstanding cause of the œdema and the serous effusions which frequently characterize the disease. Lyons and Burwell (1946) investigated the effect of raised venous pressure upon cardiac filling and cardiac output in patients with constrictive pericarditis and they compared their results with the reactions of a normal heart in which the natural response to a rise in venous inflow is an increase in its filling and output capacities. They tested the effects in patients with constrictive pericarditis both of increasing and of decreasing the venous pressure by intravenous infusions of glucose and saline and by phlebotomy respectively, and their circulatory measurements in these circumstances excluded any variation in the volume of the cardiac output. They concluded that, by reason of the limited capacity of the ventricles to dilate during diastole, the raised venous pressure in constrictive pericarditis was without effect as a compensatory mechanism. The authors emphasized the similarity of constrictive pericarditis and congestive heart failure, characteristic features in each of these conditions being salt retention and elevation of the blood volume, and they correlated these developments with the raised venous pressure and the prolonged circulation time, each a significant manifestation in the clinical picture of the two diseases. The subjective symptomatology of constrictive pericarditis being singularly vague, it is generally agreed that its diagnosis must depend entirely on physical examination. The presenting signs may be summarized for practical purposes as those of circulatory failure without evidence of structural heart disease. Distension of the venous system is an outstanding feature in all cases. There is usually some degree of cyanosis, the neck veins are firm and engorged, the liver is enlarged, there is generally ascites, possibly also peripheral œdema, the latter located at times in the face and the upper extremities. Examination of the heart is, as a rule, singularly negative; the area of dullness and the apex impulse are usually ill-defined or entirely obscured by co-existing pleural effusion, but the size and the shape of the heart can be estimated by radioscopy and it is noteworthy that, in the majority of cases, there is little or no evidence of cardiac enlargement.

the face, the chest wall and the upper extremities, also ascites and painless non-pulsatile hepatic enlargement, all in the absence of orthopnoea.

(4) A small, low tension pulse of the paradoxical type.

Certain additional physical signs have been put forward, viz. immobility of the apex impulse, a fixed area of cardiac dullness, also systolic retraction of the apex region and the left lower intercostal spaces posteriorly; the practical value of these signs in the diagnosis of adhesive pericarditis has, however, been materially discounted by reason of the fact that they may feature other cardiac affections, notably those with considerable cardiac enlargement.

Radiological and kymographic studies furnish conclusive proof of pericardial adhesions and they should be regarded as essential items in the examination of all cases. Significant abnormalities include a decreased amplitude of cardiac pulsation and partial or complete fixation of the heart and the diaphragm during respiration; varying degrees of cardiac enlargement are usually present and, in evaluating this sign, due consideration must be given to co-existing disabilities, both valvular and myocardial; further valuable signs are the presence of visible adhesions from the pericardium to neighbouring structures, irregularities in the contour of the cardiovascular shadow, possibly also deformity and general narrowing of the retrocardiac mediastinum.

Recognition of tuberculosis as an ætiological indication in chronic pericarditis is nowadays firmly established and, assuming that the condition is diagnosed in its uncomplicated stage, there is a reasonably favourable chance that it will respond to suitable treatment. The incidence of the disease has been widely investigated both in this country and abroad. Suzman (1943) analysed a consecutive series of 1,893 autopsy records and found that in 6% of the 102 tuberculous cases there was evidence of pericardial involvement. Kornblum and his colleagues (1933) reported a 4% incidence of pericardial affection in fatal cases of pulmonary tuberculosis. Heimann and Binder (1940) studied 31 cases in the non-European hospital, Johannesburg; in some of their cases the pericarditis was a complication of a generalized tuberculæmia, 9 had signs of pulmonary tuberculosis and tuberculous root glands were present in every case; their conclusion was that tuberculous pericarditis in South African natives was not rare as a primary entity. In a recent communication, Ellman (1945) gives it as his considered opinion that tuberculosis reaches the pericardium (*a*) by the blood stream in miliary tuberculosis, or (*b*) by direct extension from a mediastinal focus, and he states emphatically that a primary tuberculous pericarditis may, for all practical purposes, be regarded as non-existent. The clinical picture of chronic tuberculous pericarditis is complex and variable. The presenting symptoms may be principally those of a pericardial effusion, or of adhesions in and around the sac, or of constrictive pericarditis in its full form and in all cases there is likely to be some degree of circulatory failure, possibly also varying phases of pyrexia; whenever possible, the pericardial exudate should be examined; a straw-coloured lymphocytic fluid is regarded as suspicious and the diagnosis of tuberculosis may, in some cases, be confirmed by culture or by guinea-pig inoculation. It is common knowledge, however, that the tests usually employed are not always infallible and that negative results do not necessarily exclude a tuberculous ætiology. Suzman (1943) recorded a case of tuberculous pericarditis, confirmed by autopsy in which, during life, the fluid was repeatedly sterile on culture, the Mantoux test negative and a guinea-pig test negative on two occasions.

Barrett and Cole (1944) reported a fatal case of tuberculous pericarditis, the early clinical diagnosis of which was confirmed by inoculation of a guinea-pig, the latter dying of generalized tuberculosis five months (an unusually long period) after inoculation. The patient, a man aged 22, was admitted to hospital complaining of general debility, a dull pain in the chest (præcordial region), breathlessness on exertion,

From the whole it is abundantly clear that, by pericardiectomy, the defective circulatory mechanics of constrictive pericarditis can be remedied to a considerable extent, the patient's subjective symptoms being thereby proportionately relieved.

Mr. T. Holmes Sellors [Abstract]: The interest of the surgeon in chronic pericardial diseases centres on the phenomenon of cardiac compression, and it is not only on the treatment, but on the development of this state that attention should be given. The established picture with its ætiological factors is commonly recognized, but there is considerable uncertainty as to the progress and development from the earliest onset. We have been able to observe a dozen cases from their onset into the full syndrome of constriction, and, whereas polyserositis was evident in some of the cases, others simply showed a pericardial effusion.

An average picture can briefly be given as follows :

A child of 10 years had a febrile illness which was associated with a pericardial effusion; this was thought to be of rheumatic origin and the patient was kept at rest. The effusion reached considerable size, giving evidence of tamponade which was relieved by aspiration performed on two occasions. Four months later a right-sided pleural effusion developed, and at this time it was observed that the venous pressure was raised to a small degree, though the pericardial effusion itself had largely diminished. The right-sided effusion disappeared spontaneously in the course of six weeks, but a small collection then appeared in the left pleural cavity. This also absorbed, but by this time there was liver enlargement and ascites which, taken in conjunction with the rising venous pressure, suggested that constricting pericarditis was developing. This process over all took fifteen months and a further four months' rest was enforced before operation was undertaken.

In cases in which polyserositis was observed the effusion in the pleural cavities persisted in spite of aspiration, and the finding of tubercle bacilli in the ascitic fluid suggested that the peritoneum was involved by the diffuse tuberculous process. Two of these cases showed signs of pericardial constriction, but were obviously the subjects of diffuse and active tuberculous disease from which they died in eighteen months and two years respectively from the onset.

Almost every case showed evidence of its tuberculous origin, even though this was only finally established by pathological examination of the excised pericardium. The importance of recognizing tuberculosis as a cause of the condition lies in the fact that tuberculous scar tissue exerts a more powerful cicatricial effect than normal fibrous tissue, and that selection of the right time for operation in this type of case is a matter of great importance.

Many of the cases seen in adult life give little or no history of onset, and it is remarkable, judging from the extent of calcification, how the heart has been able to compensate for the restriction, probably over a period of years, before producing symptoms. There would appear to be a sudden bankruptcy which can be relieved as dramatically as it occurs on occasion by a very limited excision of pericardium. On the other hand, patients in middle or old age who develop the signs of constriction do not always do well. This may be due to the fact that heart failure has developed within the constricted pericardium which, if removed, is followed by the ordinary picture of congestive heart failure. It has also been suggested that the prolonged effect of the raised venous pressure on the liver produces permanent damage to this organ. However, in general, it is remarkable how ably the body is capable of withstanding prolonged pericardial constriction without clinical signs.

The heart sounds are best described as distant, they may be accompanied by soft systolic murmurs and pericardial friction sounds but their description otherwise does not call for special comment. The pulse is usually fast and of small volume, the blood-pressure is subnormal, its records being characterized frequently by paradoxical fluctuations. The above-mentioned signs should in all cases be confirmed by radiological and kymographic investigation, the value of which, in the accurate diagnosis of constrictive pericarditis, is both fundamental and impressive. The heart shadow may be normal in size or slightly enlarged owing to varying degrees of thickening of the pericardium; the heart's pulsation may be feeble or absent entirely and the outlines of its chambers are in varying degree obscured; the heart and the mediastinum may be fixed and displaced, the retrosternal and the retrocardiac spaces obliterated; the margins of the pericardium may be irregular and the presence of calcified plaques is frequently noted; there may be visible adhesions from the pericardium to the neighbouring viscera and, if these are attached to the diaphragm, its puckered surface and its limited range of excursion are clearly defined. The cardiogram may provide valuable supporting evidence in the diagnosis of constrictive pericarditis; characteristic discrepancies of the curves include low-voltage complexes and flattening or inversion of the T waves in the præcordial as well as in the limb leads; Graybiel and White (1946) have suggested that these appearances, which closely simulate coronary heart disease, are due to sub-epicardial myocardial inflammation and scarring; not infrequently there are changes in the R-T segments and in the T waves similar to those recorded in acute myocardial infarction but, as Ellman (1945) has noted, the Q waves are not exaggerated in constrictive pericarditis and the direction of the R-T segments and the T waves are similar in all the leads.

In common with the increasing number of cardiovascular diseases which are being subjected to operation, the treatment of constrictive pericarditis exemplifies in ample form the existence of an intimate liaison between physicians and their surgical colleagues. Pericardiectomy is nowadays firmly established as the approved remedy for patients suffering from constrictive pericarditis who are otherwise in a sufficiently favourable condition to undergo a major operation. Circulatory measurements are essential in the selection of cases and their comparative estimates before and after operation are of considerable prognostic importance. The measurements include readings of the venous blood-pressure, the total blood volume, the cardiac output per minute, the cardiac output per beat, the vital capacity, the circulation time and the arterial blood-pressure (*see* Table I). Lyons and Burwell (1946) reported 2 cases of constrictive pericarditis including with each a series of circulatory measurements made under standard conditions both before and after operation and the following is a typical extract of their findings on one case:

TABLE I

	Normal values	Case I before operation	Case I after operation
Venous blood-pressure mm. water	Below 150	217	108
Total blood volume in c.c.	5,400	6,570	5,300
Heart rate per minute	64	74	70
Oxygen consumption per minute	231	213	196
A-V difference vol. O ₂ per litre blood ..	59.0	65.0	51.5
Cardiac output in litres per minute ..	3.87	3.28	3.83
Systolic output in c.c. per stroke	60.4	44.0	53.2
Blood flow in litres per sq. m. surface area ..	2.21	1.89	2.06
Vital capacity in c.c.	4,350	2,500	2,500
Circulation time in seconds	15-20	41	34
Arterial blood-pressure mm.Hg	120/80	114/74	110/70

The more significant features of Table I are the post-operative lowering of the venous blood-pressure with an increased cardiac output and blood flow, a diminished blood volume and an increased circulation rate.

lateral approach avoids the difficulty of a low-placed or big breast in women and is satisfactory for secondary operations, when only slight or moderate improvement has been obtained after an anterior excision.

The exposed heart, once the lung has retracted, is covered with loose fibro-fatty tissue which is vascular. When this is removed the yellow-white casing of the pericardium is seen and an incision is made into this on a site which avoids the anterior branch of the left coronary artery. It is often difficult to establish the right layer for a start and judicious dissection must follow until the brown (and bloody) muscle fibres are exposed. Once flaps have been raised the dissection is continued, either as far as the limits of the ventricular exposure will allow, or as far as the general condition of the patient permits. Extrasystoles are common during manipulation and the heart should be given regular periods of rest to prevent gross arrhythmia. Superficial bleeding from muscle usually stops spontaneously, but, if persistent, fibrin foam or muscle patches may be required. Tearing of heart muscle is an obvious danger and is most likely to occur near the auriculo-ventricular groove, or over the thin-walled right ventricle. The pericardial flaps should not be cut away until the dissection is complete since in emergency they could be sutured over a tear in the muscle. No ligatures must be applied to the coronary vessels.

The results in 21 operation cases are fairly satisfactory. Three deaths occurred, one some hours after operation probably from ventricular fibrillation, the other two died before operation was started following a very small dose of pentothal. In both cases the chest was opened with the minimum of delay and though in one case the heart was started again the patient died without recovering consciousness. In the other instance no response at all could be elicited from the heart muscle in spite of various stimuli applied to it. The remaining patients recovered from the operation with one exception who died of congestive heart failure some time later. Out of the 17 survivors 14 are performing some form of work or have normal activity, though critically some of these would not pass as completely fit. It has been noted that reduction in the venous pressure, after an initial good post-operative fall, is slow and four to six months should be allowed to elapse before deciding on the final figure. The same applies to enlargement of the liver, but ascites subsides rapidly and we have not had to remove abdominal fluid in any case after operation.

Diagnostic errors can occur and on two occasions we have explored the pericardium for suspected constriction to find, in one instance, a gross tricuspid lesion and in the other thrombosis of the right auricle and venæ cavæ. These cases may be quoted as illustrating some difficulties in diagnosis, since the clinical picture was identical with many of the constrictive lesions on which we operated.

In the hands of an experienced thoracic team the risks of exploration of the pericardium are small and it is felt that if all other means have failed to establish diagnosis operation should be considered. In our own experience this course was justified in a number of cases where definite constriction was recognized without the classical signs and symptoms being present.

Dr. Peter Kerley: Radiological examination of pericardial diseases, other than large effusions, has been greatly stimulated by the successful surgical treatment of adhesions which interfere with normal cardiac function. Scarcely a month passes without some new report of such cases in one of the many radiological journals and as a result we are overburdened with descriptive signs many of which are unreliable or applicable only to a particular case. Assessment of the value of these signs and of the various techniques required to demonstrate them is no easy task. Every radiologist viewing large numbers of chest cases often sees cases of gross chronic pulmonary disease with obvious pleuro-pericardial adhesions and even kinking or torsion of the great veins without any clinical evidence of cardiac embarrassment. Conversely we

The selection of time for the operation is largely influenced by the probability of the tuberculous origin, and, as has been said, in children the maximum period of bed rest must be allowed to enhance quiescence of disease process. In adults or elderly people quiescence may be assumed and only a short period of preparation and assessment be required.

In a series of 45 cases which we have observed tuberculosis has been established in the majority. Untreated suppurative pericarditis was a probable cause in one instance, and there were 4 cases of undetermined origin. Rheumatic pericarditis did not produce constriction, though, on occasions, it produced transitory cardiac tamponade.

The classical description of the heart in this condition is not always accurate, for though this organ may appear small and quiet, it is always possible to have a large heart outline which sometimes shows quite obvious pulsations. The enlargement of the heart may be due to the actual thickening of the pericardium and movement may be more obvious in some parts of the heart than in others.

Treatment.—A pericardial effusion may require aspiration for diagnostic purposes as well as for relief of pressure. This procedure may have to be repeated and gas replacement is sometimes of value in demonstrating the thickness of the parietal pericardium, as well as the size of the heart itself. The site for aspiration should be made from below between the costal margin and xiphisternum, puncturing through the diaphragm the lower part of the pericardial sac. The risks of pleural damage and hæmorrhage when the anterior intercostal routes are used should lead to their exclusion. On two occasions I have performed a deliberate excision of the left parietal pericardium to allow a persistently accumulating effusion to drain into the larger surface of the pleural cavity, and then at a later date proceeded with excision of the organized visceral layer.

The treatment of established constriction is excision of both layers of the pericardium. A preliminary period of rest accompanied by efforts to reduce ascites or other effusions is indicated. Mercurial diuretics with a restricted fluid intake help to improve the general condition.

The planning of pericardial excision is based on the fact that the essential mechanical problem lies in the prevention of the full diastolic phase of the ventricles. This was originally fully described by Richard Lower and is certainly more acceptable than the assumption that a constriction occurs round the caval orifices and auricles. Constriction can certainly occur over these areas, but it is not of great importance and can hardly be remedied with safety by surgery. Both ventricles should be freed as far as circumstances permit, with the proviso that the right heart must not be freed too extensively before the left to prevent possible pulmonary congestion. The general condition of the patient may not allow full excision and then every endeavour should be made to free the apex and left border of the heart. Both layers of the pericardium, as has been said, must be excised so that the actual heart muscle itself is exposed. Anæsthesia is most satisfactory with controlled endotracheal ether and oxygen. Cyclopropane allows an agreeably high concentration of oxygen, but leads to cardiac irregularities. Barbiturates are best avoided, as also chloroform.

The original standard exposure of the pericardium was designed as an extrapleural operation, but the difficulty of access to the left border of the heart without tearing the pleura was considerable. The present view is that the approach to the heart should be through a deliberate transpleural incision, which can be (1) through the third left interspace with division of one or more costal cartilages, or (2) posteriorly following excision of the seventh or eighth rib. Anteriorly the heart is closer to the surface and the mediastinum is stable, but there is less room, while the posterior approach finds the heart at a deeper level and may be a difficult exposure if there has been pre-existing pleurisy. I prefer the anterior incision especially with bad risks where only a small preliminary pericardiectomy may be permissible. The postero-

Since there are not many kymographs about, I will deal with the major radiological signs on the basis of investigation by any reasonable standard equipment. First and foremost is alteration in the shape of the heart. It is very unlikely that any adhesions of consequence can be present without altering the shape in one plane or another. Since the site most affected is the right border and the anterior surface we should concentrate on these—moreover these are two aspects where we are less likely to be misled by co-existing mitral or aortic disease. A continuous convex right border from

FIG. 1.—Obliteration of the normal cardiac contours on the right side. This heart was adherent to the sternum.

FIG. 2.—Obliteration of the normal contours on both borders of the heart. The small pear-shaped heart is typical of extensive intrinsic adhesions.

FIG. 3.—Dense extrinsic and intrinsic pericardial adhesions with pleural obliteration at both bases. The heart has a triangular shape.

FIG. 4.—Extrinsic and intrinsic adhesions. The right border is straight and the left border round. On both sides the normal contours are obliterated.

diaphragm to aorta is the most consistent alteration in shape in constrictive pericarditis, and a dilated vena cava above this is strong corroborative evidence. A similar continuous convex curve is seen on the left border in the presence of extensive intrinsic adhesions. The heart then is globular or pear-shaped like a pendant (fig. 2). Less frequently the borders are quite straight and the heart has a triangular or polygonal shape (fig. 3). Combinations occur with one border straight and one convex (fig. 4).

occasionally stumble on cases with obvious deforming pericardial adhesions or even pericardial calcification where symptoms have been dismissed as functional or wrongly attributed to associated valvular or myocardial disease.

The radiological findings in a gross case are irregularity of the cardiac borders, diminished or absent pulsation, limited diaphragmatic movements and associated pleural thickening. In advanced cases it is comparatively easy to deduce from the shaggy radiological mass that pericardial adhesions are present but in cases of minor degree in which the adhesions may be no less disabling, there are many variations of these signs. Accurate analysis of them with the most exacting technique is necessary if we are to get anywhere near a precise anatomical diagnosis.

A simple screen examination and a few straight pictures may be sufficient to demonstrate fixation of the heart but it is certain that many of what I will call the sub-clinical cases will be overlooked if we rely on these standard procedures. The patient must be examined in both supine and erect positions and, above all, it is necessary to take the lateral pictures in the recumbent position. In at least one frontal and one lateral view a grid should be used and that much underrated instrument, the X-ray kymograph, can, despite its defects, sometimes prove diagnostic.

Usually we are dealing with combinations of extrinsic and intrinsic adhesions, the former offering resistance to systole and the latter preventing the normal systolic-diastolic change in form and position. Surprising combinations of both occur and of course the whole radiological picture may be complicated by associated valvular disease.

The radiologist's job is first to prove the presence of adhesions and secondly to locate them accurately. If he can do this his evidence may determine the necessity or otherwise for surgical interference and even indicate the most suitable surgical approach.

We know from both living records and autopsy experiments of fluid in the pericardium that the most dependent part of the pericardial sac is that area around the apex and on the posterior border of the left ventricle. This is also the area of greatest movement. As an effusion is absorbing the residual fluid gravitates into this corner and the vigorous left-sided thrust of the heart tends to squeeze residual fluid out over the relatively quiet right border and sternal aspect of the right ventricle. The majority of adhesions are right-sided and anterior, and although they may be very disabling they can cause little apparent distortion of the shape, size, position and pulsation of the heart. The following case is a classical example of this type of adhesions:

The subject is a doctor who in 1929 had pneumonia and pericarditis was also suspected. On recovery from the acute stage he had dyspnoea which was attributed to myocardial damage on the basis of abnormal electrocardiographic findings. He had an inverted T wave in leads 1, 2 and 3. Subsequently 1 and 2 reverted to normal. Some years later when in America he again had dyspnoea and after a very full investigation by an eminent cardiologist was told he had a coronary thrombosis. He came to England and before joining the Army consulted another cardiologist because of excessive pulsation in the veins of his neck. He was assured that this was anatomical and that he had a cardiac neurosis. He served overseas, and again complaining of dyspnoea after several attacks of malaria, was correctly diagnosed as adhesive pericarditis by Dr. Evan Bedford. It was left to his wife, however, to detect his calcification on what I think was an indifferent X-ray picture. The straight picture (fig. 1) shows a normal-sized heart but two obvious abnormalities—a convex right border from diaphragm to aorta without an intervening notch at the level of the lung root, and a distended superior vena cava. On an over-penetrated picture a ragged area of calcification was visible but easily mistaken for disease in the lung. In the first oblique view there was apparent enlargement of the heart to the left but no calcification was visible. The second oblique view showed a small heart again without visible calcification until a grid and a kymograph were used. The kymographic pictures taken at the same distance clearly show the whole pathology. His heart is firmly adherent to the sternum, partly adherent to the base and probably completely stuck on the right border up to the exit of the superior vena cava (figs. 5, 6 and 7). The P.A. kymograph shows another useful sign—increased pulsation on the left border with a relative decrease of pulsation on the aorta (fig. 5). The reason for this is discussed later.

emphasis is laid on the small quiet heart for it tends to make us forget that disabling adhesions also occur with normal and large hearts. The possibility of adhesions forming in an already enlarged heart should always be kept in mind. In such a case the adhesions may be responsible for hepatic enlargement and ascites, and the differential diagnosis from right-sided congestive failure can be made by the radiological demonstration of a small right ventricle and auricle. Schwedel gives a beautiful demonstration of this. A chronic encysted effusion may also cause enlargement of the heart shadow but of an eccentric type and Roesler describes enlargement due to a pericardium over an inch thick.

It is uncommon to see the heart markedly displaced to one or other side. Adhesions at the base keep it in a central position even when there are gross pleuro-pulmonary adhesions and fibrosis which one would expect to cause a lateral drag. Basal adhesions prevent the heart from moving upwards during inspiration but this sign is also present in a big heart without any adhesions. If the diaphragm is free except under the base of the heart, the medial and tendinous portions will be stationary during inspiration while the lateral parts will move steeply downwards. This causes apparent elevation of the heart during inspiration—an optical illusion similar to the sensation of movement in a stationary train when another on the neighbouring track moves forward slowly.

If the anterior surface of the heart is adherent to the sternum the retrosternal space is opaque and does not widen or illuminate during deep inspiration. Occasionally one can directly visualize bands between the heart and the sternum. Similar phenomena can be demonstrated in the posterior mediastinum with posterior adhesions. Unless, however, one can actually see bands of adhesions reduction in size and illumination of these spaces is an unreliable sign for there are too many normal variations. If the heart is enlarged these signs are valueless.

Much valuable information can be gained by studying the movement in the lateral recumbent position and this should be done on both sides. In this position the normal heart sags to the dependent side during expiration and moves away from it on inspiration. Absence of this inspiratory shift is proof of extensive external adhesions. This sign only becomes invalid if there is a big heart with congestive failure and fluid in the pericardial or pleural cavities.

Abnormalities of pulsation are frequent and although best observed on a kymograph the major ones can be detected by screening. Pulsation is increased or decreased according to the underlying pathology. With severe constriction pulsation is absent or negligible. If one area is free it shows increased pulsation. If this free area happens to be the left border, the increased pulsations are in marked contrast to diminished pulsations on the aorta (fig. 5). The increased amplitude on the ventricular border does not represent an increased stroke volume but is merely an increased marginal excursion to compensate for loss of movement.

If we find absent or very feeble pulsation without evidence of circulatory embarrassment we can infer that the adhesions are linear and that the pericardial sac is not obliterated. Roesler believes that absent pulsation with a normal circulation is proof of the persistence of movements of the atrio-ventricular septum.

In most cases the pulmonary vessels are normal or show only slight congestion, a striking anomaly if there is congestive failure in the greater circulation. The absence of pulmonary stasis is explained by the fact that the disease usually affects the right heart more than the left. It is a curious fact that even big pericardial effusions seldom compress the left auricle and nearly all writers on calcification of the pericardium comment on the rarity of calcification in the region of the left auricle.

Calcification of the pericardium is of course the radiological hall-mark. We do not know in what percentage of cases it occurs but it is certainly not seen very often. The calcified deposits may be granular, linear or coralliform and combinations of all

An absolutely straight border indicates involvement of the mediastinal pleura and external fixation. In the pear-shaped heart the cardiophrenic angles are free while in the triangular-shaped heart these angles are usually obliterated but care should be

FIG. 5.—Kymograph of an unsuspected case of adhesive pericarditis. This heart is adherent anteriorly and on the right. The left border is free. Note the abnormal increased amplitude on the left ventricular border as compared with the normal amplitude on the aorta. Same case as fig. 1.

FIG. 6.—Same case in the first oblique view. There is apparent enlargement of the heart to the left.

FIG. 7.—Same case in the second oblique view. The heart is apparently small and a ring of calcification to the sternum and base is clearly visible.

taken not to confuse normal fat deposits with such obliteration. The superior vena cava is often wider and denser than normal and the aortic knuckle is small. If the mediastinal pleura on the left side is extensively involved the aortic knuckle may be invisible or its convex outer border may appear straight. Localization of adhesions to certain areas may cause free areas to bulge like a hernia. If the apex escapes it may bulge like a cardiac aneurysm while if the posterior border escapes it may bulge like an enlarged left auricle. Extensive adhesions, either extrinsic or intrinsic, usually obliterate all radiological signs of associated mitral or aortic disease.

As a rule the heart is central in position and small. In some ways too much

DISCUSSION ON MALIGNANT DISEASE OF THE PHARYNX, EXCLUDING THE NASOPHARYNX

J. F. Simpson: *Cancer in the laryngopharynx.*—The gravity of this problem is shown in the report for 1945 of the Clinical Research Committee of the British Empire Cancer Campaign which states that out of 384 cases of laryngopharyngeal cancer only 19 survived the five-year period. Similarly in 1946 the Holt Radium Institute, Manchester, reported that out of 220 cases 9 cases survived the five-year period. It is because the symptoms are insidious that presentation is often late and to many palliation is all that can be offered. The early symptoms may be no more than a mild pricking sensation in the throat and slight muffling of the voice or a "catch in the swallow". An enlarged gland may be the first manifestation in pyriform fossa growths in as many as 25% of the cases. This symptomatology is in marked contrast to that of cancer of the vocal cords and is reflected in the expectation of cure.

When choosing between surgery and irradiation as the method of treatment it is sometimes difficult to suppress a personal bias, but it is essential that each case should be considered individually and not as a member of a group. The histology of the neoplasm and its operability are decisive factors in the choice of treatment. When the tumour is found to be of a type known to be especially amenable to radiotherapy the choice must be irradiation. Such tumours will include lymphosarcoma, reticulosarcoma, lympho-epithelioma and basal-cell carcinoma. These are more common in the nasopharynx and oropharynx but when occurring in the laryngopharynx generally originate in the vallecular region. These tumours spread early to the glands and the entire lymphatic field must always be treated at the same time as the primary focus.

Secondary growths are occasionally encountered in the laryngopharynx and require irradiation. The following three examples were recently encountered: an oat-celled bronchial carcinoma in the pyriform fossa which presented as the first evidence of malignant disease; a papillary carcinoma of the thyroid invading the posterior wall in a man of 21 in whom the primary growth had apparently been successfully removed a year previously; and thirdly, an example of a multicentric growth showing as scattered nodules. This was seen six months after the removal of a minute carcinoma from the floor of the mouth.

The vast majority of tumours in the laryngopharynx are squamous-cell carcinomata and laboratory aids have not as yet superseded the clinical assessment in the decision as to choice of treatment. The grading of squamous-cell carcinoma as described by Broders may indicate the liability to metastasize but it appears to carry little weight to-day in the prediction of the response of the individual tumour to irradiation. Even serial biopsy under irradiation is not without its errors. Constant clinical observation during and after treatment seems to be the only means of judging its effect. This is a matter of the utmost importance and should be carried out by the radiotherapist and the surgeon consulting together.

Inoperability is an indication for irradiation of carcinoma but this is a relative term as "inoperable cases in some hands become operable". Apart from the general physical condition and temperament of the patient the glandular metastases usually determine operability.

Current opinion seems fairly agreed upon the lines of treatment in regard to the glandular metastases. A search for glands should always be made during the excision of the primary growth, even though none was detected on clinical examination. Where none is found and the excision is considered satisfactory, it is better to place reliance on post-operative observation than to embark upon immediate routine post-operative irradiation.

If the primary focus has been successfully treated by external irradiation through the gland fields but with failure to control the glands themselves these should be removed surgically if possible. The temptation to give a second course of therapy whilst they are still operable must be resisted. Thus whenever possible glandular metastases must be excised where the primary focus has been successfully treated, whether by surgery or irradiation.

Operations on the laryngopharynx are now largely standardized and during the last few years operative mortality has decreased with the introduction of chemotherapy and the antibiotics together with improved methods of anaesthesia. Other aids, such as con-

three may be found together. The sites of preference for calcification are the coronary sulcus, the diaphragmatic surface and the sternal aspect of the right ventricular area. The left ventricular area with the exception of the apex comes next. Rarely do we find the whole sac armour-plated. Pericardial calcification must be differentiated from a calcified infarct and intracardiac calcifications. An infarct in the common site on the left border is easy to diagnose by the shelf-like projection in the first oblique view but an apical infarct might be very troublesome. Calcified valves and calcified thrombi show considerable and characteristic movements. A calcified left auricle may look very like pericardial calcification but it usually forms a complete ring, can be localized to the left auricle and on the kymograph shows auricular pulsations. There is no X-ray evidence which throws any light on the ætiology of the uncalcified types unless there is associated pulmonary tuberculosis. Some years before the war we had a case in Westminster Hospital in which the causative agent was actinomycosis but the visible lung changes of pulmonary suppuration might have been produced by any of the common organisms. Occasionally we see pericardial effusions secondary to carcinoma of the lung but I have not known one live long enough to be deemed chronic. (I have a strong suspicion that deep X-ray therapy may cause adhesive pericarditis and that not all the superior vena caval obstructions are due to malignancy. Deep therapy can certainly produce pleural obliteration.)

Looking through the literature on calcification of the pericardium, one finds opinion about equally divided on rheumatism and tuberculosis as the cause. If we postulate a similar basis for pleural and pericardial calcification, blood would be a most important factor. The large-scale mass radiography surveys have shown 10 cases of pleural calcification following trauma for every one due to tuberculosis. There are a few reports of pericardial calcification following trauma. Glenn describes its development two years after a crush injury, Schwarz has one case following a heavy direct blow over the heart and Zdansky one as a sequel to a stab wound.

We have not yet exhausted all the possibilities of radiological investigation of the pericardium. It is certain that we will have first-class X-ray cinematography in the next year or two. I made a brief mention of tomography earlier on. Looking over some tomograms I was struck by a number in which a double shadow of systole and diastole was quite sharp and clear. It is only a question of selecting the right penetration and accurately timing the tomographic movement with the heart rate to reproduce this in any given case and there are no insuperable mechanical difficulties. There are certainly possibilities in the method; it would be much cheaper than either kymography or cinematography and capable of adaptation to any standard equipment.

DISCUSSION ON MALIGNANT DISEASE OF THE PHARYNX, EXCLUDING THE NASOPHARYNX

J. F. Simpson: *Cancer in the laryngopharynx.*—The gravity of this problem is shown in the report for 1945 of the Clinical Research Committee of the British Empire Cancer Campaign which states that out of 384 cases of laryngopharyngeal cancer only 19 survived the five-year period. Similarly in 1946 the Holt Radium Institute, Manchester, reported that out of 220 cases 9 cases survived the five-year period. It is because the symptoms are insidious that presentation is often late and to many palliation is all that can be offered. The early symptoms may be no more than a mild pricking sensation in the throat and slight muffling of the voice or a "catch in the swallow". An enlarged gland may be the first manifestation in pyriform fossa growths in as many as 25% of the cases. This symptomatology is in marked contrast to that of cancer of the vocal cords and is reflected in the expectation of cure.

When choosing between surgery and irradiation as the method of treatment it is sometimes difficult to suppress a personal bias, but it is essential that each case should be considered individually and not as a member of a group. The histology of the neoplasm and its operability are decisive factors in the choice of treatment. When the tumour is found to be of a type known to be especially amenable to radiotherapy the choice must be irradiation. Such tumours will include lymphosarcoma, reticulosarcoma, lympho-epithelioma and basal-cell carcinoma. These are more common in the nasopharynx and oropharynx but when occurring in the laryngopharynx generally originate in the vallecular region. These tumours spread early to the glands and the entire lymphatic field must always be treated at the same time as the primary focus.

Secondary growths are occasionally encountered in the laryngopharynx and require irradiation. The following three examples were recently encountered: an oat-celled bronchial carcinoma in the pyriform fossa which presented as the first evidence of malignant disease; a papillary carcinoma of the thyroid invading the posterior wall in a man of 21 in whom the primary growth had apparently been successfully removed a year previously; and thirdly, an example of a multicentric growth showing as scattered nodules. This was seen six months after the removal of a minute carcinoma from the floor of the mouth.

The vast majority of tumours in the laryngopharynx are squamous-cell carcinomata and laboratory aids have not as yet superseded the clinical assessment in the decision as to choice of treatment. The grading of squamous-cell carcinoma as described by Broders may indicate the liability to metastasize but it appears to carry little weight to-day in the prediction of the response of the individual tumour to irradiation. Even serial biopsy under irradiation is not without its errors. Constant clinical observation during and after treatment seems to be the only means of judging its effect. This is a matter of the utmost importance and should be carried out by the radiotherapist and the surgeon consulting together.

Inoperability is an indication for irradiation of carcinoma but this is a relative term as "inoperable cases in some hands become operable". Apart from the general physical condition and temperament of the patient the glandular metastases usually determine operability.

Current opinion seems fairly agreed upon the lines of treatment in regard to the glandular metastases. A search for glands should always be made during the excision of the primary growth, even though none was detected on clinical examination. Where none is found and the excision is considered satisfactory, it is better to place reliance on post-operative observation than to embark upon immediate routine post-operative irradiation.

If the primary focus has been successfully treated by external irradiation through the gland fields but with failure to control the glands themselves these should be removed surgically if possible. The temptation to give a second course of therapy whilst they are still operable must be resisted. Thus whenever possible glandular metastases must be excised where the primary focus has been successfully treated, whether by surgery or irradiation.

Operations on the laryngopharynx are now largely standardized and during the last few years operative mortality has decreased with the introduction of chemotherapy and the antibiotics together with improved methods of anaesthesia. Other aids, such as con-

tinuous suction drainage and the use of semidigested protein foods to give a high concentration with tube feeding, may play a part.

The surgery may be divided into two types: (1) Simple excision without serious loss of structure or function, i.e. lateral transthyroid pharyngotomy; (2) large mutilating operations in which structures are sacrificed, i.e. pharyngolaryngectomy.

There is an intermediate group in which plastic procedures are necessary to make good the excised portion of the pharynx and to restore function:

When the neoplasm has invaded the framework of the larynx so that its removal is required, as much of the pharyngeal mucosa as possible is left so as to join the oropharynx with the œsophagus, but the entire segment of pharynx may have to be removed with the larynx. Recent American publications have stressed the necessity of removing the hyoid bone and tongue tissue above it in some cases to reduce the chance of recurrence in the pre-epiglottic space—a point too often disregarded here.

Because of the advanced state of the disease and poor condition of the patient when first seen irradiation and not radical surgery is the treatment more frequently applied. Furthermore, irradiation can be applied to almost every case, but this must not be taken to mean that irradiation is the only form of treatment for cancer of the laryngopharynx, a belief too prevalent to-day. Radiotherapists recognize that the response to irradiation varies at the different sites in the laryngopharynx and comparatively good response is expected in the vallecula, epiglottis and aryepiglottic fold but the black spots of the laryngopharynx are the pharyngeal wall, pyriform fossa and the post-cricoid region.

This clinical fact must always be taken into consideration when planning treatment and will naturally give bias towards irradiation in the favourable sites. It is in these same places with the exception of the vallecula that the more limited form of surgery may be applicable when the growth is small. The choice between such surgery and irradiation as a first line of treatment in these cases is a difficult one. Every aspect of each case must be weighed, the selection being highly individual and set rules cannot be applied. It is in these positions that a carefully watched therapeutic trial of irradiation may yield good results, especially when the growth is superficial and non-infiltrating. If a full course fails to produce complete disappearance of the cancer a second course will not produce a cure. It follows, therefore, that as soon as irradiation is thought not to be controlling the disease urgent consideration must be given to the possibility of radical surgery. This revision of treatment may supply the last and only chance of prolonging life, apart from a possible cure.

The formidable nature of the operation of median translaryngeal pharyngotomy together with the fair expectation from irradiation rules out surgery for vallecular growths. It is rare for pyriform fossa and post-cricoid carcinomata to be suitable for local excision but when such surgery is possible it should be given every consideration on account of the unfavourable response to irradiation at these sites.

Once any carcinoma of the laryngopharynx is thought to have invaded the cartilage of the larynx, with the exception of the free portions of the epiglottis, it is best to give first place to surgery even though this means pharyngolaryngectomy. All these decisions are of course made in the light of the state of the lymphatic glands, &c. They should not be made by the surgeon or radiotherapist working alone but as a team in which consultation results in planned attack. Furthermore, observation after operation or radiotherapy forms one of the most important responsibilities which this team must undertake.

Statistics have been avoided as almost every individual case must in the end require a separate category and this makes comparison dangerous, but some figures must be quoted to appreciate the degree of success which may be obtained by surgery. Lionel Colledge was able to state in his Lettsomian Lecture, Medical Society of London, 1943, that 13 out of 39 patients (33%) were well ten years after lateral pharyngotomy and 6 out of 16 cases (37%) for a similar period after pharyngolaryngectomy. These figures undoubtedly represent the peak to which this branch of surgery has been brought. Last year Orton of Newark presented to the American Laryngological Association a series of 51 cases of pharyngeal carcinoma in which surgery was the method of treatment and resulted in 27% of five-year cures.

In the British Empire Cancer Campaign already referred to there were 49 cases in which there were no glandular metastases or invasion of the adjacent tissues. Of these only 2 were subjected to radical surgery (pharyngotomy). The two cases which received surgery survived the five-year period and 6 out of the 47 which received irradiation (13%).

The treatment of cancer of the laryngopharynx must be carried out by a team. The possibility of good surgical results in suitable cases must be remembered in view of the Cancer Act. If this Act means that patients are to be sent direct to the radiotherapist without the benefit of surgical opinion it will be a sad thing, but if it means consultation and following up by a team then we may reasonably expect improvement in results in the integrated use of the only two weapons at our disposal.

R. S. Pilcher: In 100 consecutive cases of cancer of the pharynx admitted to University College Hospital there were 70 men and 30 women. Men had a maximum incidence at 60-64, women at 50-54. In 29 women the growth was post-cricoid, in 1 woman and 70 men the growth was epilyngeal. In the epilyngeal group two sites are important, the pyriform fossa because of its frequency (42 cases), the lateral wall because it is the most favourable for conservative surgery (9 cases). Observations on the symptoms show further distinctions between the epilyngeal and post-cricoid groups. Dysphagia was the first symptom in 11 women, but only 10 men. It was, however, the dominant symptom on admission in 25 women and 32 men, the average duration of symptoms before admission being eight months. Enlargement of cervical glands was the first symptom in 22 men, but only 1 woman. While it is true that the post-cricoid growth is less likely to be symptomless than one in the pyriform fossa and, therefore, more likely to be noticed before it has metastasized to glands, it also appears that the former metastasizes less rapidly than the latter. Even a large post-cricoid cancer with over a year's duration may remain localized to the primary site. The distinction is important for in the epilyngeal group it is often the glandular metastases that determine inoperability, while in the post-cricoid it is usually the local spread of the primary. Gland dissection should always form part of the surgical treatment of the epilyngeal growth, but may sometimes be omitted in the post-cricoid. Common to the symptoms of both groups is the onset with some abnormal but trivial sensation in the throat. These sensations, which are variously described by the patients, were the first symptoms of the disease in 30 men and 13 women. Suggestive of cancer, when a patient complains of an abnormal sensation in the throat, is its definite localization and its persistence. Indirect laryngoscopy for any persistent localized discomfort in the throat is the most promising contribution to early diagnosis of cancer of the pharynx.

Of the 100 cases, 49 were judged to be operable—35 men and 14 women. Estimates of operability vary widely, but that this series is not a particularly favourable one is suggested by the need for emergency tracheotomy or gastrostomy, or both in 25 cases, apart from the use of these measures as part of radical treatment. Radical operations were completed in 25 men and 14 women with 9 operative deaths in the former and 7 in the latter. 4 men and 3 women survived five years or more without recurrence, the shortest observed period being five years, the longest 14 years. All operations were of the conservative type and the series includes no example of pharyngolaryngectomy. The chief cause of mortality was sepsis and none of the operations in the series was performed later than 1935 when the benefits of chemotherapy were not available. In addition to the cases treated surgically there were two survivals of five years or more after irradiation—both being operable cases. One of these had repeated local recurrences before five years and died of the disease. The total of five-year survivors out of the 100 cases was, therefore, 9 and of these 8 survived five years or more without recurrence.

The aim of the conservative operation devised by Wilfred Trotter is to remove the growth and to preserve the functions of the larynx and pharynx. It is sometimes possible, particularly if the growth is on the lateral wall, to reconstitute the pharynx by simple suture of the defect, but usually a 2-stage operation with replacement by skin is necessary and incisions are planned with this in view.

For post-cricoid tumours excision of the whole circumference of the pharynx is usually necessary and to replace this the incision outlines a rectangular flap, with its free end in front, which will, at the second stage, be rolled into a tube. From the base of the flap the incision is continued up to the mastoid and down to the clavicle.

For the epilyngeal tumours smaller areas of skin replacement are needed and flaps hinged on the mucocutaneous junction made at the first stage are adequate. The skin that is turned in at the second stage to form new pharyngeal wall should be taken from below the lower edge of the beard. The main skin incision for epilyngeal growth should be a curved one across the neck just below the beard line. From the centre of this another incision can be made down to the clavicle. When the pharynx is closed no skin for turning in should be taken from above the transverse incision. After the skin incisions have been made according to the expected plan of reconstruction and flaps raised the next step is the gland dissection. The sternomastoid is usually retained and is sutured to the prevertebral fascia in front of the carotid sheath to afford the latter some protection from infection. To expose the pharynx, one-half of the thyroid cartilage is removed and sometimes half the hyoid bone. If the growth involves the thyroid the ala is not completely removed, but is left attached after division of the cartilage in the mid-line. The pharynx is opened at any convenient point at least a centimetre from the edge of the tumour as determined by palpation, and from this opening excision is completed with the pharyngeal aspect of the growth in view. If a post-cricoid growth encircles the pharynx separate openings must be made above and below. After excision of the growth mucosa is sutured to skin all round the defect, making a single stoma for an epilyngeal growth and usually a double one for a post-

tinuous suction drainage and the use of semidigested protein foods to give a high concentration with tube feeding, may play a part.

The surgery may be divided into two types: (1) Simple excision without serious loss of structure or function, i.e. lateral transthyroid pharyngotomy; (2) large mutilating operations in which structures are sacrificed, i.e. pharyngolaryngectomy.

There is an intermediate group in which plastic procedures are necessary to make good the excised portion of the pharynx and to restore function:

When the neoplasm has invaded the framework of the larynx so that its removal is required, as much of the pharyngeal mucosa as possible is left so as to join the oropharynx with the œsophagus, but the entire segment of pharynx may have to be removed with the larynx. Recent American publications have stressed the necessity of removing the hyoid bone and tongue tissue above it in some cases to reduce the chance of recurrence in the pre-epiglottic space—a point too often disregarded here.

Because of the advanced state of the disease and poor condition of the patient when first seen irradiation and not radical surgery is the treatment more frequently applied. Furthermore, irradiation can be applied to almost every case, but this must not be taken to mean that irradiation is the only form of treatment for cancer of the laryngopharynx, a belief too prevalent to-day. Radiotherapists recognize that the response to irradiation varies at the different sites in the laryngopharynx and comparatively good response is expected in the vallecula, epiglottis and aryepiglottic fold but the black spots of the laryngopharynx are the pharyngeal wall, pyriform fossa and the post-cricoid region.

This clinical fact must always be taken into consideration when planning treatment and will naturally give bias towards irradiation in the favourable sites. It is in these same places with the exception of the vallecula that the more limited form of surgery may be applicable when the growth is small. The choice between such surgery and irradiation as a first line of treatment in these cases is a difficult one. Every aspect of each case must be weighed, the selection being highly individual and set rules cannot be applied. It is in these positions that a carefully watched therapeutic trial of irradiation may yield good results, especially when the growth is superficial and non-infiltrating. If a full course fails to produce complete disappearance of the cancer a second course will not produce a cure. It follows, therefore, that as soon as irradiation is thought not to be controlling the disease urgent consideration must be given to the possibility of radical surgery. This revision of treatment may supply the last and only chance of prolonging life, apart from a possible cure.

The formidable nature of the operation of median translingual pharyngotomy together with the fair expectation from irradiation rules out surgery for vallecular growths. It is rare for pyriform fossa and post-cricoid carcinomata to be suitable for local excision but when such surgery is possible it should be given every consideration on account of the unfavourable response to irradiation at these sites.

Once any carcinoma of the laryngopharynx is thought to have invaded the cartilage of the larynx, with the exception of the free portions of the epiglottis, it is best to give first place to surgery even though this means pharyngolaryngectomy. All these decisions are of course made in the light of the state of the lymphatic glands, &c. They should not be made by the surgeon or radiotherapist working alone but as a team in which consultation results in planned attack. Furthermore, observation after operation or radiotherapy forms one of the most important responsibilities which this team must undertake.

Statistics have been avoided as almost every individual case must in the end require a separate category and this makes comparison dangerous, but some figures must be quoted to appreciate the degree of success which may be obtained by surgery. Lionel Collidge was able to state in his Lettsomian Lecture, Medical Society of London, 1943, that 13 out of 39 patients (33%) were well ten years after lateral pharyngotomy and 6 out of 16 cases (37%) for a similar period after pharyngolaryngectomy. These figures undoubtedly represent the peak to which this branch of surgery has been brought. Of these only 2 were subjected to radical surgery (pharyngotomy). The two cases which received surgery survived the five-year period and 6 out of the 47 which received irradiation (13%).

The treatment of cancer of the laryngopharynx must be carried out by a team. The possibility of good surgical results in suitable cases must be remembered in view of the Cancer Act. If this Act means that patients are to be sent direct to the radiotherapist without the benefit of surgical opinion it will be a sad thing, but if it means consultation and following up by a team then we may reasonably expect improvement in results in the integrated use of the only two weapons at our disposal.

carcinoma of the tonsil which have extended a few millimetres into the base of the tongue. The response of the growth in the tonsillar fossa has been most successful, but the response, with identical dosage, of that portion of the growth invading the tongue has been poor, and active growth has persisted there. This difference in response can only have been due to the difference in the tumour bed.

With reference to tumours of lymphatic origin. Although there are not a large number of them it is important that they should be recognized as their treatment and prognosis are different from that of the squamous carcinomata.

Any of the members of the group of lymphomata, such as lymphosarcomata, reticulum-cell sarcomata, may give rise to tumours in the oropharynx. They may cause diffuse enlargement of the tonsil similar to ordinary tonsillar hypertrophy. The tumour projects from the tonsillar fossa as a rounded or irregular-shaped mass which may attain a considerable size.

At first the tumour does not appear to infiltrate the surrounding tissues. As the tumour progresses, it infiltrates the pillar and encroaches diffusely upon the soft palate. It may also extend into the base of the tongue. There may be superficial ulceration. The consistency of the tumour is harder than normal tonsil, but usually it is softer than carcinoma. The metastases in the cervical glands are comparatively soft and isolated in the beginning. They become fixed to surrounding tissues at a fairly early stage, but they are rarely adherent to the skin.

A lymphoma in the pharynx is only one manifestation of a generalized disease. The disease may remain localized in the throat for some months, or even many years, but sooner or later enlarged glands will appear elsewhere in the body, such as enlarged axillary or inguinal glands, or enlarged mediastinal or abdominal glands; or deposits may arise in the liver, spleen or bones. It is important to realize the widespread tendency of this growth from the very first. A complete examination of the patient should therefore be made. So often one is asked to treat a patient with a tumour in the pharynx and on examination one finds enlarged glands elsewhere in the body. Naturally it is useless to treat the tumour in the throat only.

(A table of the age-incidence in the 89 cases was shown.)

Most of the patients were between 50 and 80 years of age. There were relatively few under 50. There were more males than females. 10 of the 20 women had post-cricoid carcinoma.

In deciding between operation or radiotherapy, all patients were seen by both the surgeon and the radiotherapist, and the various methods of treatment discussed.

Cases of cancer of the pharynx with an operable tumour can be treated and cured by the operation of lateral pharyngotomy or pharyngolaryngectomy. The majority of cases, however, referred to the radiotherapist are already inoperable; or if they have an operable tumour, their general condition is too poor to stand a big operation. During the last three years, any operable cancer of the hypopharynx, including the post-cricoid cancers, was operated on if the patient was in a fit condition to stand an operation. The number of cases treated by surgery alone show how few were considered suitable for operation.

Inoperable cancers of the hypopharynx were treated by radiotherapy. Squamous carcinomata of the oropharynx were treated in one of two ways. In a few cases part or the whole of the tumour was removed by diathermy and then X-ray treatment was given, and in the other cases irradiation alone was used. All tumours belonging to the malignant lymphomata group were treated by radiotherapy alone. We do not consider that they are suitable for surgery, since they are only one manifestation of a generalized disease, and we consider there is a risk of general dissemination of the growth if the tissues are cut into. These tumours are all radiosensitive.

Great care was taken in planning the technique of irradiation treatment, especially in estimating the extent of the growth. It is of utmost importance to know the limits of the growth, otherwise the area of irradiated tissue may be inadequate and parts of the growth may be untreated.

Œsophagoscopy and direct laryngoscopy are usually necessary to determine the full extent of the growth, and even then it may be impossible to pass the œsophagoscope beyond the growth and find the lower end. A lateral straight X-ray of the soft tissues of the neck either with or without barium in the pharynx or cervical œsophagus, and also tomographs may be of immense help, particularly in post-cricoid cancers.

One of the chief hindrances to the successful treatment of cancer of the pharynx is sepsis. Sepsis not only renders the growth more radioresistant, but makes the patient more likely to succumb to some infection of the lungs, such as bronchopneumonia. It is frequent for a frail elderly patient to develop a low-grade bronchopneumonia during the course of X-ray treatment.

Every means should therefore be taken to eliminate all septic foci in the mouth—teeth

cricoid. It is not always possible to determine operability until the pharynx is opened. If after opening the pharynx it does not appear possible to perform a conservative excision a pharyngolaryngectomy may be done with the first stage of reconstruction of the pharynx and the formation of a permanent tracheotomy.

Some details of the successful cases deserve comment. In the first place all 5 epilaryngeal cases had involvement of cervical glands. In 4 the gland dissection was done at the same time as the pharyngotomy and in 1 four weeks before. The experience of this small series certainly lends no support to the opinion that if glands are involved radical operation is not worth attempting. In 3 cases the pharynx was closed by primary suture and in 2 a fistula was made and closed at a second stage. In spite of these successes with primary closure, Trotter's final opinion was that a fistula should always be made at the first operation as a safeguard against sepsis.

In 1932 Trotter published 6 other cases of survival without recurrence for five years or more—the longest being twenty years so that from one hospital we have knowledge of 13 successful radical operations. When one considers the perseverance of surgeons in other fields such as cancer of the œsophagus and lung it is surprising that so little is being attempted for cancer of the pharynx. The greatest obstacle to success in the past was infection, and in penicillin and sulphonamides we have the means of controlling this risk. In addition to chemotherapy there have been advances in the knowledge of anaesthesia and nutrition which should further increase the margin of safety. The time is ripe for surgeons to apply these new resources to the surgery of cancer of the pharynx and to make fresh efforts to treat this distressing disease.

Gwen Hilton: *Carcinoma of the pharynx.*—In the Radiotherapy Department of University College Hospital during the years 1942 to 1946 inclusive, 89 cases of pharyngeal growths were seen.

Of these 89 cases, 7 were considered too ill for any form of treatment, and 6 were treated by surgery alone.

One great difficulty in comparing the results of treatment of cancer of the pharynx is that of the exact diagnosis of the site of the growth. In most of the cases seen, the growth was so advanced that the whole of one side of the oro- or hypopharynx was involved. A growth which is confined to the pyriform fossa or aryepiglottic fold, or a tonsillar growth which has not invaded the neighbouring tissues, is rarely sent for radiotherapy. Sometimes, however, as the growth shrinks under treatment, it is possible to be fairly certain of its actual site of origin. The cases have been divided up into those having growths arising in the oropharynx, the hypopharynx and the post-cricoid region. There were 16 cases with growths in the oropharynx, 63 cases with growths in the hypopharynx and 10 cases with growths in the post-cricoid region. To give an idea of the extent of the primary growth they have been divided into two stages: Stage I included cases in which the growths were confined to the tissue of origin. Stage II included cases in which the growths had become diffuse and spread from their point of origin to involve other pharyngeal structures.

Only 13 cases of the whole 76 were included in Stage I. The remaining growths were Stage II. It was surprising to find that no glands were palpable in 17 Stage II cases although the primary had involved the whole or part of one side of the oro- or hypopharynx. In 25 of the Stage II growths, however, there were large masses of matted glands in the neck.

It is seen from this that most of the growths were advanced. They are a discouraging group of cases, only a small number of them offering even a chance of cure.

The usual duration of symptoms before the patient was first seen was three to four months, but a few patients gave quite long histories of twelve to eighteen months, and this raised the average duration of symptoms to six months. The duration of symptoms in cases with widespread growth was usually short, suggesting that in advanced cases the progress of the disease was more rapid from the beginning. A biopsy was done in 73 of the 89 cases. All the 16 cases where no biopsy was taken were advanced, and there was no doubt as to the clinical diagnosis. All the hypopharyngeal growths from which a biopsy was taken were squamous carcinomas, except one, in which parts of the section suggested a lympho-epithelioma.

The growth in the hypopharynx of one case which was demonstrated at the meeting was a fibrosarcoma. It was not included in this series, as the treatment was only carried out in 1947. The immediate response of this tumour to irradiation was good. The biopsies of tumours arising in the oropharynx showed not only the more usual squamous carcinomata, but also some tumours of lymphatic origin, under which term are included the reticulocell sarcomata, the lymphosarcomata, &c.

The histological picture before treatment did not always help in the prediction of the response to irradiation. Histologically identical growths may respond differently to irradiation according to the tumour bed from which they arise. For instance, one sees cases of

MEETING HELD AT GUY'S HOSPITAL, LONDON

Coarctation of the Aorta in the Neonatal Period.—C. W. KESSON, M.R.C.P.

In spite of the fact that coarctation of the aorta is not uncommon and that the defect is present at birth, few cases have been reported in infancy and none appears to have been published where the diagnosis has been made in life in the neonatal period.

The following case is of interest in that manifestations were present enabling a clinical diagnosis to be made on the fourth day of life, and the diagnosis was confirmed at post-mortem, when the child was 4 months old.

G. W., male aged 4 months.

The second child of a mother who has mitral stenosis, due to recurrent rheumatic infection in childhood. Her first child, a boy now aged 6½, is reported to be perfectly well.

During this pregnancy extra periods of rest were prescribed and she was throughout under close observation, but no indication for the termination of pregnancy developed.

On 28.9.47 the child, who weighed 5 lb. 9 oz. was delivered naturally, at full term. There was no dyspnoea or cyanosis. Breast feeding was instituted and sucking was satisfactory. On 2.10.47, when 4 days old, cyanosis developed after feeding and on crying.

The baby was not dyspnoeic but general cyanosis developed on crying. Forcible pulsation was observed in the neck and also in both axillary and brachial arteries. The whole course of the axillary and brachial arteries was clearly demarcated on the two sides.

The blood-pressure was equal in the two arms: systolic 125 and diastolic approximately 90, but sounds audible to zero.

The blood-pressure in the legs could not be determined. No pulsation could be detected in either femoral artery.

There was cardiac enlargement, rate 160, regular rhythm, no murmur was audible. No finger clubbing, no evidence of collateral circulation.

Chest X-ray: Heart shadow occupied three-quarters of the thorax. No rib notching.

On the evidence of (1) Abnormally forcible pulsation in the arteries of the arm and neck; (2) raised arm blood-pressure; (3) absence of pulsation of the femoral arteries; (4) cardiac enlargement, a diagnosis of coarctation of the aorta was made.

Progress.—The baby had difficulty in obtaining an adequate food intake from the breast and complementary feeds of half-cream national dried milk were given from the 10th day. At 12 days the cyanosis was persistent, associated with an increased respiratory rate (70) and heart-rate of 170. There was no pyrexia and no change in the physical signs. Breast feeding was abandoned. Oxygen was administered with relief of the cyanosis.

Gradual improvement occurred, the cyanosis again becoming intermittent, the heart-rate falling to 130 and the respiratory rate to 40. There was a slow erratic gain in weight to 6 lb. 15 oz. and the baby was discharged on 13.12.47, the cyanosis having completely subsided. Slow progress was continued at home until 1.2.48 when he developed an upper respiratory tract infection. On 3.2.48 he became worse, refusing his feeds; there was dyspnoea and the cyanosis had recurred. On 4.2.48 he was readmitted to hospital gravely ill with bronchopneumonia, which proved fatal within twenty-four hours. At this time (age 4 months) he weighed 9½ lb.

should be removed and infected gums treated. Penicillin either in the form of lozenges, sprays or injections should be employed to deal with the infection on the growth itself. We often spend a week or more dealing with the infection before beginning irradiation, and find the time well spent.

In addition the general condition should be improved as much as possible. The cancer patients having radiotherapy require the same careful general treatment as do those having, for example, a partial gastrectomy. The medical and nursing care of the patient before and during the treatment is most important. Since the growth frequently causes great difficulty in swallowing, the patient is often thin, wasted and anæmic from lack of adequate nourishment. If solids cannot be swallowed, a high calorie fluid diet must be given, and the vitamin content must be considered. If the patient cannot take adequate nourishment by mouth, a gastrostomy must be considered. This should be carried out before the treatment is begun, since it is unwise to interrupt a course of irradiation in the middle. Similarly, if a tracheotomy is indicated, it should be performed before beginning treatment. Any anæmia should be treated by full doses of iron, and in some cases by transfusion. The progress of patients often depends on building up their blood.

During the course of the treatment there is bound to be a severe reaction of the mucous membrane of the throat if adequate irradiation is given—and the patient will then need most careful nursing. Much can be done to alleviate the pain and soreness in the throat by giving tablets, such as benzocaine tablets, to suck before meals, or benzocaine emulsion to sip during the meals and aspirin sprays and gargles in between.

What benefit has the radiotherapy been to the patient? 15 out of the 71 cases which had a complete course of X-ray treatment are alive now. The average duration of life of the 71 patients was 18.4 months. The average duration of the 15 patients who are alive now is 36.6 months. The longest survival in this group so far is five years eight months. The growth in this case was confined to the epiglottis. It is interesting to note that the 3 cases in which the growth was confined to the epiglottis and aryepiglottic fold are alive. The longest survival period is five years eight months, the second four and a half years and the third two and three-quarter years.

The prognosis of the tumour of lymphatic origin, such as the lymphosarcomata and reticulum-cell sarcomata, which have infiltrated the surrounding tissues, appears to be better than the carcinomata when these have spread beyond the tissue of origin. One of the patients in whom the tumour had spread from the tonsillar fossa on to both pillars of fauces, the soft palate and down the pharyngeal wall has so far lived four years three months, despite the infiltration of the surrounding tissues. The section showed a stem-cell sarcoma.

The average duration of life of 18.4 months may not show a great prolongation of life, but I do not think one should only consider the duration of life of the patient when one is trying to assess the benefit which may be derived from any form of treatment; but one should also consider whether palliation is achieved and whether the patient is free from pain and able to work. We have only considered the disease to have been palliated by treatment when both the primary growth and the enlarged glands in the neck have undergone at least 50% diminution in size, when the patient's symptoms have improved sufficiently for him to say that he really feels better and able to work, and has gained weight. In quite a large proportion of the cases we did achieve palliation, but in a number it was short-lived, especially in many of the 25 cases which had a huge projecting mass of matted glands in the neck. The treatment in these cases was a failure because the improvement was so short-lived. The average duration of life in these 25 cases was only 7.7 months. The mass of glands in the neck was greatly reduced in size, but a hard residuum usually remained which sooner or later caused severe pain, almost impossible to relieve. Only very occasionally did the matted masses of glands resolve completely. In such cases with extensive secondary masses in the neck, therefore, it does require considerable judgment to decide whether or not radiotherapy is worth while.

There is a second category in which this decision may also be difficult. That is when clinical cachexia is prominent and when the sepsis in the throat does not clear up with preparatory treatment. In the first place irradiation is never successful in the presence of uncontrolled sepsis and, in the second place, it is difficult to prevent lung infections which are apt to be fatal. Real palliation was, however, achieved in many of the remaining cases. Unfortunately one can rarely say beforehand from the clinical examination, plus the plain histology, that is without special cytological counts, whether or not the treatment will be successful.

Lieut.-Colonel W. L. Harnett, [Medical Secretary to the Clinical Cancer Research Committee of the British Empire Cancer Campaign, contributed statistics showing the results of treatment in 511 cases of primary pharyngeal cancer, in which the survival rate in each stage of the disease was compared with the five-year expectation of life. It is hoped that this contribution will appear in full in the *Journal of Laryngology and Otology*, together with a complete report of the meeting.

had a normal arm blood-pressure in the neonatal period. Finally there is evidence that a raised pressure may become further elevated, at any rate during the period of growth (Steele, 1941; Campbell and Suzman, 1947).

The present evidence leads one to the conclusion that although a raised arm blood-pressure may occur in the neonatal period, this is not invariable and it may prove to be unusual but the exact frequency must await the collection of further data from cases investigated at this period of life.

Campbell and Suzman (1947) show that forcible pulsation of the arteries of the neck is a common manifestation; in the cases reviewed by Rhodes and Durbin (1942) it was more frequently commented upon in those over 10 years old but it was this feature which first aroused suspicion in the present case.

Eisenberg (1938) expressed the opinion that absent or feeble femoral pulsation was the simplest and most direct method of making the diagnosis. This is supported by the fact that of the 34 cases where this examination was recorded, femoral pulsation was absent in 24 and in 10 only feeble pulsation was detectable (Rhodes and Durbin, 1942). The absence of femoral pulsation was an essential part of the diagnostic evidence in the present patient.

Although the demonstration of a collateral circulation by clinical or radiological methods is of great diagnostic help in the older age-groups, they have rarely been present in children under 6. Rooke (1938) records a child of 3 in whom a collateral circulation was demonstrable clinically but there was no erosion of the ribs. Neuhauser (1946) reports the presence of rib notching at the age of 19 months.

The present evidence suggests that these manifestations are unlikely to be of help in the youngest age-groups.

Præcordial murmurs can do no more than raise suspicion of the diagnosis. The murmur heard in the interscapular space is more important. No murmur was ever audible in the present case. Cyanosis will occur in those cases where the descending aorta is entirely dependent on a patent ductus arteriosus for its blood supply, as the result of complete occlusion of the aorta proximal to the site of the insertion of the ductus arteriosus. In the present case the cyanosis was almost certainly pulmonary in origin and probably due to atelectasis secondary to the enormous cardiac enlargement. The reasons for this statement are that the cyanosis was immediately relieved by the administration of oxygen, and it was completely absent from the age of 2 months until the terminal bronchopneumonia at 4 months.

Conclusions.—Evidence is already available to suggest that not all cases of coarctation of the aorta will present features enabling a diagnosis to be made in the neonatal period. It is, however, considered that more cases would be recognized if palpation of the femoral pulse became part of the routine medical examination and if coarctation of the aorta was considered in all cases with cardiac murmurs or where there was a forcible pulsation in the neck arteries.

I wish to acknowledge my indebtedness to Dr. P. R. Evans, and also to the Department of Medical Illustration at Guy's Hospital for the drawing of the specimen.

Post-mortem (Dr. Keith Simpson) 5.2.48.—Deep cyanosis was present in the lips and at the nail beds; the ankles and feet were also (more generally) cyanosed. No clubbing of the fingers. There was considerable enlargement of the heart (weight 54 grammes). The pericardium was normal. The left ventricular wall measured 1.4 to 1.6 cm. The endocardium and muscular wall of the left auricle was also markedly thickened though neither cavity was appreciably dilated. Both septa were normal and the foramen ovale was functionally closed and largely adherent from thickening of the auricular endocardium. The ductus arteriosus was closed, the dimple of the site alone remaining on both pulmonary and systemic aspects. Constriction of the aorta occurred at the termination of the aortic arch immediately distal to the origin of the left subclavian; at the point of maximum narrowing the intima was slightly wrinkled and thickened and the lumen reduced to 0.6 mm. No obvious collateral circulation was established and there were no other vascular anomalies (see fig. 1).

The common iliac arteries appeared hypoplastic, but in fact compared equally in diameter with those of 3 other children of between 3 and 5 months who were seen during the succeeding five days.

FIG. 1.

Respiratory system.—The upper respiratory tract was filled with œdema fluid tinged with blood, and this was further complicated by the addition of thin pus in the lower bronchial tract, the mucous membrane of which was inflamed by recent suppurative bronchitis. Patches of coarse collapse were present throughout both lungs, no part being affected more than another, and there was some general congestion, but neither to a marked degree.

There was no evidence macroscopically of pneumonia.

Routine examination, including the brain, revealed no further abnormalities.

Comment.—Campbell and Suzman (1947) have enumerated the cardinal clinical features in coarctation of the aorta as follows: (1) A raised blood-pressure in the upper half of the body. (2) Forcible pulsation of the arteries of the neck. (3) Feeble or absent pulsation in the femoral arteries and the abdominal aorta, and a low blood-pressure in the legs with a high or relatively high pressure in the arms. (4) The collateral circulation shown round the scapulæ, on the side of the chest wall, and over the anterior abdominal wall. (5) The collateral circulation shown by notching of the ribs on X-ray examination. (6) A systolic murmur (rarely with a thrill) at the base of the heart and often in the back, sometimes with a diastolic murmur.

It is generally agreed that, with rare exceptions, the blood-pressure in the upper half of the body is raised. Lewis (1933) stated: "It may seem natural to assume that if high pressure is found in the adult case, it has been present continuously from the first year of life; actually experience shows that assumptions of the kind are not without danger."

Although we still lack adequate records covering the younger age-groups, a raised pressure has usually been recorded at the initial examination (King, 1937; Steele, 1941; Rhodes and Durbin, 1942). The present case shows that this raised pressure may occur even in the neonatal period.

Cases of coarctation of the aorta have been described where the arm blood-pressure was normal (Blackford, 1928; King, 1937; Bramwell, 1947). Other cases have had a normal pressure which has become elevated during the course of time (Farris, 1935; Schwartz and Tice, 1939). It is reasonable to assume that these cases would have

FIG. 3.—Lateral X-ray of patient's skull shows obstructed nose and nasopharynx (A) and depression of soft palate (B).

FIG. 4.—X-ray of right humerus showing metastasis.

Malignant Nasopharyngeal Tumour with Exophthalmos.—D. G. VULLIAMY, M.B.
C. B., aged 4 years.

The child was quite well until whooping cough July 1947.

August 1947: Slight trauma to left knee after which tenderness of lower third of femur developed with pyrexia. Blood culture: *Staph. aureus*. Acute osteomyelitis diagnosed at Dartford County Hospital. X-ray of femur then normal and pyrexia responded to penicillin. "Glazed look" of eyes noted by parents at this time (? onset of blindness).

September 1947: Onset of drowsiness, anorexia, headache and gradually increasing exophthalmos. Deterioration of vision in right eye.

October 1947: Increasing blindness, spreading to left eye. Optic atrophy in the right, papilloedema of the left. Thought to have retro-orbital neoplasm but radiotherapy not carried out owing to poor ultimate prognosis.

November 1947: Exophthalmos subsided and general condition improved. Blindness remained. Nasal discharge—right side.

December 1947: Admitted to Guy's Hospital. Afebrile, good appetite, able to play happily with toys. Some exophthalmos of right eye (fig. 1) and oedema of conjunctivæ. Slight exophthalmos of left eye. Perception of light only in both eyes. *Discs*. Bilateral optic atrophy. Exaggeration of deep reflexes in legs, ankle clonus, bilateral extensor plantar responses and absent abdominal reflexes. Tenderness over long bones especially tibiæ. Blood-stained nasal discharge from right nostril. Palpable swelling in nasopharynx with some depression of palate.

X-rays.—*Skull* showed progressive rarefaction of bone in nasal region and obstruction of nasopharyngeal airway (fig. 2 normal, fig. 3 patient). *Long bones*: Small areas of rarefaction (e.g. 2 mm. by 3 mm.) particularly at ends of bones, increasing in size later (fig. 4).

Blood picture: Hypochromic anæmia only. No abnormal white cells. *C.S.F.* normal. *Serum cholesterol* 100 mg. %. *Biopsy of tumour* in nasopharynx—an undifferentiated round-cell tumour, ? sarcoma, ? neuroblastoma. *Tibial puncture*: Needle entered secondary deposit and smear showed mass of similar small round cells. *Sternal puncture*: Normal marrow.

Course.—January-February 1948 (fig. 5). Exophthalmos again increased. Hard rounded swelling appeared in skull (right frontal region) extremely radiosensitive. No further radiotherapy given, however, on account of metastases. General condition deteriorated with remissions and death occurred on 26.2.48.

Autopsy.—Tumour 7.5 cm. by 10 cm. by 7.5 cm., apparently arising in the nasopharynx and growing up through the floor of the middle cranial fossa involving body and wings of sphenoid, and destroying optic nerves. Pressure atrophy of base of brain in this region. Small deposit 3 cm. diameter in frontal bone (R.). Infiltration of cervical lymph glands both sides. Wedge-shaped hæmorrhagic deposits in cortex both kidneys.

Microscopy showed that tumour consisted of uniform mass of small round cells resembling lymphocytes. Deposits in lymph glands and kidneys consisted of similar cells. Tonsils showed malignant hyperplasia. Suprarenals normal.

Comment.—This case presented an interesting diagnostic problem. The illness began with slight trauma to the leg followed by local pain and pyrexia, which was diagnosed as osteomyelitis; such an onset is described as occurring in "Ewing's tumour" of bone, and many of the subsequent features fitted well with Ewing's clinical description, including the nature of the spread.

According to Willis (1948), however, the majority of Ewing's tumours are not primary tumours of bone but secondary deposits usually from suprarenal neuroblastomata.

occurred while penicillin was being given) produced viscid mucopus. One stertorous breath taken through mouth for each 8 to 12 inspiratory efforts per minute. Sucking-in of lower ribs and suprasternal and submandibular regions. Orthopnoëic. Fed on expressed breast milk by pipette three-hourly.

November 21, 1947: Probe passed into nostrils met bony obstruction at 1 inch on either side. Breast feeding exhausted child after five sucks. Alternate tube and bottle feeds. Baby collapsed in asphyxial attack in which respiratory efforts reached 80-100 per minute. Revived in oxygen tent when tongue pulled forward.

December 4: Lipiodol X-ray of nose showed obstruction. Nasal discharge less after this. At times three or four consecutive breaths through mouth. Changed from breast milk to half-cream Cow and Gate.

January 21, 1948: (Esophageal feeds abandoned. Breathing through mouth much more easily.

February 27: Very well. Satisfactory weight gain (fig. 1). Breathing through mouth but with some effort.

Bilateral Choanal Atresia.—L. F. W. SALMON, M.B. (for R. J. CANN, M.S.).

CASE II.—Female aged 18 months. Seen at St. Helier Hospital, by Mr. R. J. Cann, within a day or two of birth, the complaint being intermittent asphyxia and difficulty with sucking.

Diagnosis.—Bilateral choanal atresia.

It was decided to treat her conservatively, and she was seen again at Guy's at 6 months old, when she was gaining weight and managing well. At her next visit, three months later, she was having difficulty with taking solid food, and it was decided to admit her.

Admitted on her first birthday, but no surgical treatment undertaken for three months.

Operation, on 9.10.47, under general anæsthesia. Both diaphragms were broken down and found to be membranous. The child was breathing through her nose within forty-eight hours of operation, and has remained well since.

Bilateral Choanal Atresia.—L. F. W. SALMON, M.B. (for R. J. CANN, M.S.).

CASE III.—Female aged 15 years. Admitted when 2 days old under Mr. W. M. Mollison with the complaint that she could not suck, and that she became cyanosed when the mouth was closed.

Diagnosis.—Bilateral congenital choanal atresia.

Operation nine days after admission.

Without anæsthetic a labyrinthine gouge was passed through each side of the nose in turn and an opening made through the obstructing diaphragm on each side. The diaphragm was bony.

The patient's condition was at once improved and she was discharged a week after operation. She was readmitted once or twice in the next six months and once more recently for the apertures to be enlarged.

Dr. Philip Evans: This rare congenital anomaly (fig. 2) interests the pædiatrician primarily as a cause of neonatal asphyxia; it is well to remember that in the newborn child "the nostrils are the proper channel through which respiration takes place, that breathing through the mouth is an unnatural accomplishment learned afterwards" (Ronaldson, 1881, *Edin. med. J.*, 26, 1035). The difficulty may have been exacerbated in Case I by micrognathia. The key to the diagnosis is that there is inspiratory recession in the submandibular region as well as of suprasternal tissue and the lower part of the thorax, i.e. the obstruction is above the level of the glottis. The intermittent manner in which the obstruction (due to the apposition of tongue and palate) is overcome is also characteristic. The consistency and position of the post-nasal plates may be gauged by probing, while lipiodol dropped into the nostrils provides an elegant radiological demonstration of the lesion.

In the present case the striking remission of symptoms and subsidence of the exophthalmos would also have been consistent, as these tumours are known to retrogress occasionally.

The section from biopsy material and the puncture of the secondary deposit in the tibial marrow would both have supported the diagnosis, as the typical rosette formation of neuroblastomata is frequently absent in young subjects.

No primary suprarenal tumour was, however, found and only the final histological examination of autopsy specimens demonstrated the diagnosis of primary lymphosarcoma of the nasopharyngeal lymphoid tissue.

Bilateral Choanal Atresia.—L. F. W. SALMON, M.B. (for R. J. CANN, M.S.).

CASE III.—Female aged 15 years. Admitted when 2 days old under Mr. W. M. Mollison with the complaint that she could not suck, and that she became cyanosed when the mouth was closed.

Diagnosis.—Bilateral congenital choanal atresia.

Operation nine days after admission.

Without anæsthetic a labyrinthine gouge was passed through each side of the nose in turn and an opening made through the obstructing diaphragm on each side. The diaphragm was bony.

The patient's condition was at once improved and she was discharged a week after operation. She was readmitted once or twice in the next six months and once more recently for the apertures to be enlarged.

Dr. Philip Evans: This rare congenital anomaly (fig. 2) interests the pædiatrician primarily as a cause of neonatal asphyxia; it is well to remember that in the newborn child "the nostrils are the proper channel through which respiration takes place, that breathing through the mouth is an unnatural accomplishment learned afterwards" (Ronaldson, 1881, *Edin. med. J.*, 26, 1035). The difficulty may have been exacerbated in Case I by micrognathia. The key to the diagnosis is that there is inspiratory recession in the submandibular region as well as of suprasternal tissue and the lower part of the thorax, i.e. the obstruction is above the level of the glottis. The intermittent manner in which the obstruction (due to the apposition of tongue and palate) is overcome is also characteristic. The consistency and position of the post-nasal plates may be gauged by probing, while lipiodol dropped into the nostrils provides an elegant radiological demonstration of the lesion.

In Case I breast and bottle feeding were exhausting. Nutrition was maintained, but no more, by pipette feeding. When alternate feeds were given by œsophageal tube the infant gained weight; the tube was used until the baby was 9 weeks old.

Dr. P. Evans showed a colour film made by Dr. Brian Stanford of the normal relationship of sucking and breathing in a healthy baby, and followed it with one of Case I, made by Mr. Eric Gwynne-Evans.

Mr. E. Gwynne-Evans: The movements of an infant are not so haphazard or aimless as might be supposed. By studying the movements of foetal sheep that had been isolated in a warm saline bath (Barcroft) and the movements of non-viable as well as viable foetuses in man (Gesell) it has been shown that they are the forerunners of movements necessary to preserve existence after birth. In fact, the viability of a prematurely born infant is dependent upon these movements being sufficiently well developed to support life independently of the maternal circulation.

The movements of muscles in breathing and feeding appear early and are deeply ingrained in the make-up of the newborn infant. They are more or less stereotyped in form; Gesell describes them as "survival patterns" and they are universal to all. This film demonstrates three main features of the newly born infant's equipment: the firmly established and insistent rhythm of the respiratory musculature; the automatic "patterning" of the oro-facial muscles in sucking and the dependence of the infant on a free nasal airway.

In both the acts of sucking and nasal breathing, soft tissue profile radiographs have shown that the posterior part of the tongue and the soft palate are closely applied to one another. This "patterning" of the palato-lingual musculature shuts off the oral cavity from the nasopharyngeal airway, and is so deeply ingrained within an infant's make-up that in this infant with congenitally obstructed posterior nares, prodigious efforts are made by the respiratory musculature to overcome the obstruction.

Consequently, when the infant is at rest, the ratio between efforts to breathe through the nasal passages and the mouth, is about eight to one, and the cyclical attacks of partial asphyxia which occur are relieved mostly by crying. During the act of sucking, the inspiratory efforts result in gross indrawing of the epigastrium, intercostal spaces, supraclavicular triangles and the submandibular tissues, until eventually a stage of asphyxia is reached and is relieved by oral breathing.

In this particular case, the indrawing of the intercostal spaces suggested an obstruction of the airway, but as Dr. Evans pointed out, it was the indrawing of the submandibular tissues that indicated the site of the obstruction to be above the larynx.

With regard to the future, when sucking is no longer the predominant method of feeding, it will be easier for the tongue to fall away from the palate; the lips will tend to remain apart, and mouth-breathing proper will supervene. It has been noticed, however, that in these special circumstances the ability to mouth-breathe has been acquired at an earlier date, i.e. before the time when sucking is replaced by spoon feeding.

Mr. L. F. W. Salmon: The treatment of cases of bilateral congenital choanal atresia presents many difficulties. The rather less rare cases of unilateral atresia, although calling for attention later in life, are not the same grave problem and, of course, are usually not seen by the pædiatrician.

Dr. Evans has drawn a graphic picture of the precarious nature of the first months of life in the bilateral cases. That these manage to survive, however, even in the absence of the correct diagnosis, is borne out by recently published figures (Durward, Lord and Pelsen, 1945). Of 46 established cases, 11 were first referred for a surgical opinion between the ages of 21 and 45, and 17 between 11 and 20.

Dr. Evans has discussed the nursing and management of these cases. The arguments against postponing operation revolve round the risks the infant must then face, e.g. asphyxia, inanition, sinus infection and its complications, pulmonary infections or atelectasis.

The arguments against early operation are: (1) The danger of surgical procedures in the first days of life. (2) The danger of an operation on the airway of a sick baby, and (3) The technical difficulties.

I believe that as long as the child continues to thrive and put on weight, the operation should be postponed, if possible, until at least the end of the second year.

Brains from Streptomycin-treated Cases of Tuberculous Meningitis.—G. PAYLING WRIGHT, D.M., and R. J. W. REES, M.B.

The brains and spinal cords from the first three fatal cases of tuberculous meningitis treated with streptomycin at this Centre (Guy's Hospital) were exhibited as

gross anatomical specimens. The patients were all young children between 2 years 6 months and 2 years 10 months, who had been admitted for treatment. All had received streptomycin for at least eight weeks before death.

CASE I.—B. M., male, aged 2½ years.

Admitted May 31, 1947, with three-week history of increasing drowsiness, weakness and fits. Diagnosis confirmed; intramuscular and intrathecal streptomycin commenced June 7 for nine weeks, condition deteriorated and he died in coma 18.8.47.

Autopsy showed primary tuberculous complex of left lung; no miliary tuberculosis. Thrombosis of longitudinal sinus; small tubercles along Sylvian fissures; a thick gelatinous basal exudate. Considerable degree of symmetrical hydrocephalus; a large caseous tuberculoma in choroid plexus of left lateral ventricle.

CASE II.—M. H., male, aged 2 years 10 months.

Admitted November 15, 1947, in a semiconscious state. Diagnosis confirmed, and intramuscular and intrathecal streptomycin given for eight weeks. Died in coma January 22, 1948.

Autopsy showed primary tuberculous complex of right lung; a few inactive miliary lesions in spleen and liver. Marked yellow basal exudate particularly in interpeduncular fossa; severe symmetrical hydrocephalus with a few small tubercles in choroid plexus.

CASE III.—G. T., male, aged 2½ years.

Admitted June 8, 1947, with short history of facial weakness, spasticity of legs and marked nystagmus; diagnosis confirmed. Intramuscular and intrathecal streptomycin given for eight weeks. Stopped because of very poor condition. Remained in coma and died January 18, 1948.

Autopsy showed primary tuberculous complex of right lung; no miliary lesions in body. Thick basal exudate and very severe hydrocephalus.

These cases were demonstrated to show what we considered at that time to be important changes that develop after prolonged but unsuccessful treatment. The findings have been fully supported in the recent report on tuberculous meningitis treated with streptomycin (Report of Tuberculosis Trials Committee of the Medical Research Council, *Lancet*, 1948, i, 582).

The base of each brain was covered by a thick, yellowish and gelatinous exudate, most marked in the interpeduncular fossa. Ziehl-Neelsen films prepared from these basal exudates contained very large numbers of acid-fast bacilli morphologically resembling typical tubercle bacilli. Cultures from the material confirmed them to be tubercle bacilli of human type and all sensitive to streptomycin (0.25 to 0.5 mg. streptomycin per ml.), identical in sensitivity to the cultures obtained before treatment with streptomycin. Despite the very large number of tubercle bacilli present in the basal exudate at autopsy, the C.S.F. during life had shown a progressive falling off in numbers of organisms seen in direct film and subsequent culture, 2 cases having a sterile C.S.F. during the last two and four months of life respectively.

The brains had been cut coronally to display the lateral ventricles. All 3 showed a symmetrical hydrocephalus of considerable degree, in Case III the cortex measured only 0.5 to 0.75 cm. in thickness, with flattening of the convolutions and narrowing of the sulci. One of the cases was fully investigated during life (Case II) and found to have a hydrocephalus of the communicating type. The choroid plexuses of the lateral ventricles contained several small tubercles and in Case III a tuberculoma measuring 1 cm. in diameter.

Case I showed three foci of gross nodular thickening of the dura opposite the lumbar intervertebral spaces, which on section proved to be non-tuberculous, probably traumatic, granuloma associated with the very large number of lumbar punctures made.

Miliary Tuberculide of Skin.—RONALD MAC KEITH, D.M.

B. V., male, born 4.10.42.

On 20.8.47 sudden onset of breathlessness and fever; sent to hospital as acute anterior poliomyelitis, but found to have miliary tuberculosis and transferred to Guy's Hospital.

27.8.47: Acutely ill, dyspnoëic, respirations 60 to 90. X-ray chest showed miliary shadows. No choroidal tubercles at this date and on 7.9.47 streptomycin treatment (0.2 grammes I.M. six-hourly) started and continued to present date. His general condition has steadily improved.

16.9.47: Many tubercles present in choroid. Since then these have been gradually resolving. Before admission the cerebrospinal fluid contained 7 lymphocytes per c.mm. From October there was a gradual rise till on 10.12.47 there were 192

FIG. 1.—Skin of palms (photograph taken 3.5.48).

FIG. 2.—Section of a lesion ($\times 65$).

lymphocytes and 20 polymorphs, but since then these have fallen to 16 lymphocytes and 1 polymorph. By November 1947 the lung fields had become clear. About this time dusky red papular lesions up to 8 mm. diameter, some with necrotic centres, gradually developed. These (fig. 1) are very gradually diminishing. Biopsy examination of a lesion showed a histological picture consistent with a diagnosis of miliary tuberculide of the skin (fig. 2).

POSTSCRIPT.—In June 1948 these skin lesions were still present, having only slightly diminished.

[April 23, 1948]

Acute Infantile Hemiplegia**PRESIDENT'S ADDRESS**

By W. G. WYLLIE, M.D., F.R.C.P.

ACUTE INFANTILE HEMIPLEGIA needs to be defined. The term has been in use since the middle of the nineteenth century to denote certain cases of hemiplegia of sudden tempestuous onset in children, of a few weeks to 6 or more years of age. The outcome may be quickly, or gradually, lethal; there may be permanent hemiplegia with mental impairment, or slow, though often only partial, recovery; or, most interesting of all, rapid and complete restoration to normal health with no repetition of the convulsive assault.

My material consists of 7 cases of acute infantile hemiplegia, 6 encountered within the last twelve months—which shows it as a not uncommon condition—and 1 older case with rapidly fatal issue, added because of its complete histological investigation. 5 boys and 2 girls, with ages between 11 months and 4 years; 5 with spontaneous onset, 1 complicating mumps and whooping cough, and the seventh due to a tuberculoma. Of the 7, 2 were rapidly fatal, 1 gradually fatal, 2 made a rapid, and 2 a gradual, recovery.

The aetiology is still speculative, though some hard facts have emerged. At least we know that the same clinical picture may be produced by many different causes and cover a variety of anatomical lesions.

Between 1840 and the 1920s, the output of writing on the subject grew prodigiously, chiefly in collecting cases and theorizing on their causation. Interest then abated and since the 1920s only a few thorough studies of the pathology of individual cases have been added. Recently, speculation has been busy on the aetiology of the paralyses, sometimes bilateral, sometimes unilateral, complicating the infectious fevers, especially of the demyelinating type. A new lead has been given by experimental pathology to the study of the demyelinating encephalopathies. The subject of infantile hemiplegia at least deserves discussion, even if much further clarification is needed.

The clinical picture.—The onset of acute infantile hemiplegia is always spectacular. The description given by Dr. James Taylor serves as well to-day as when he wrote it in 1905. He said, “a child, hitherto healthy, suddenly becomes ill without any apparent cause, between the ages of 1 month and 6 years. The early symptoms are severe, and consist of convulsions, fever, often vomiting, and always coma”. The convulsive element may be lacking, especially in the post-exanthematous cases, and, without it, irritability and stupor pass into coma. Two-thirds of all infantile hemiplegias, Taylor stated, were ushered in by convulsions. These symptoms persist for twenty-four hours to a week, and, during this period, or as consciousness returns, it is apparent that a hemiplegia is present, affecting the face, the arm, and lastly the leg. “The limbs remain flaccid for some days, after which the flaccidity begins to lessen, and the limbs become spastic. In some cases the paralysis completely disappears.”

To my mind, the hemiplegia fully developed has some resemblance to that produced by the apoplectic stroke in the arteriosclerotic adult, where a massive and sudden vascular catastrophe occurs in the territory of the middle cerebral artery. The uselessness of the arm exceeds that of the leg; the facial weakness tends to disappear first. There the similarity ends. As Taylor said, the commencement of infantile hemiplegia has no parallel in the adult hemiplegia. Further, the anatomical lesions are dissimilar.

In addition to the cases of apparently spontaneous eruption, one must add, as Taylor remarked, that in about a third of the infantile hemiplegias the disease appears as a complication of one of the infectious fevers. Even in 1905 he added, and I think this equally important to-day, there was no obvious connexion between the specific

Biopsy examination of a lesion showed a histological picture consistent with a diagnosis of miliary tuberculide of the skin (fig. 2).

POSTSCRIPT.—In June 1948 these skin lesions were still present, having only slightly diminished.

hemiplegias of antenatal and natal origin, however, are in existence from birth and only a small percentage of such cases are epileptic. I have nothing more to say about them except that abnormal labour is an important ætiological factor in the congenital group of hemiplegias (23%).

Also difficult to differentiate from a case of acute infantile hemiplegia is the infant of good bodily health and nutrition, which, at a few weeks or months of age, commences to have a series of little fits or twitchings, or severer convulsions perhaps affecting one-half of the body, and accompanied very often by temporary want of movement of a limb or limbs. To a trained observer, such an infant may always have aroused suspicions of a want of interest or intelligence. Pneumoencephalography is the only method I know whereby the poverty of one or both hemispheres, in all the crudity of their maldevelopment, or possibly natal damage, can be revealed beyond dispute (fig. 1).

To return to the morbid anatomy of infantile hemiplegia, R. M. Stewart's cases are a selective group of hemiplegias with mental deficiency of institutional domicile. It is not always known when the amentia first declared itself, as at time of certification the parents' statements are often unreliable.

TABLE III.—(R. M. STEWART, 1947) HEMIPLEGIAS: AGE AT ONSET

	Male	Female

During 4th year ..	1	2
During 5th year ..	3	3

It will be noted that the majority, or 102 cases, male and female, were either congenital or occurred in the first three years of life. Many of these hemiplegias with onset after birth must have depended on natal or antenatal defects, although in some the hemiplegia was ushered in by convulsions soon after birth. 3 cases are of special interest with onset of convulsions and hemiplegia within the first two years of life, as they showed at autopsy sometime before their thirtieth years *hypoplasia* of one hemisphere. The small hemisphere showed no reduction in size of nerve cells, no vascular changes, no gliosis, no atrophy of convolutions, no widening of sulci. It must have been due to a developmental error in fetal life (fig. 2).

Speculation on autopsy material from patients dying years later than the onset of the hemiplegia is of limited value, as gliosis or scar-tissue will have blurred out the original traces. Multiple confluent petechial hæmorrhages, or necrotic areas due to asphyxial venous congestion at birth, may coalesce and lead to a large trabeculated cystic cavity in the central white matter of one hemisphere (fig. 3), or an initial softening with disappearance of cortical neurones may gradually be replaced by a secondary sclerosis or gliosis, ending in *lobar sclerosis*, or even *hemiatrophy* of the brain. Taylor held the view that as a result of vascular occlusion in childhood atrophy and shrinkage without death of the supporting tissues was a possibility (fig. 4).

Norman, from his study of these delayed forms of birth palsy in mental defectives at Stoke Park Colony, Bristol, aptly remarks that the original lesions spare sufficient cortical tissue to mask for the time being the inherent instability of the infant's motor apparatus. But as sclerosis gradually increases, epileptogenic foci are formed, convulsions begin, and hemiplegia is precipitated.

A common combination of central softening and secondary sclerosis, along with *état marbré* of the basal ganglia, accounts for the frequency of some degree of athetosis in the affected limbs of some young hemiplegics; infantile hemiplegia differing in this aspect from the adult form. The explanation lies in the lesions being in the territory of venous drainage of the great vein of Galen in the infantile form. As Eardley Holland showed, the venous tributaries draining the central white matter of the hemispheres are end-veins stopping short of the cortex, but having the corpus

fever and the complicating, though rare, hemiplegia. The method of association is still a matter of controversy. Possibly it is unwise to concentrate too rigidly on a conflict in one hemisphere, as both may be affected, either spontaneously, or following one of the specific fevers. The bilateral involvement then produces a diplegia, though often of unequal severity in the two halves of the body.

The following tables give some idea of the frequency of hemiplegia to diplegia; age of onset; and spontaneous onset as opposed to being a complication of a specific fever. These tables were compiled by notable physicians in the more spacious days of the past. Sachs and Peterson (1890) show the greater frequency of hemiplegia to

collected by Freud (1897), Osler (1889), and Taylor (1905). Freud's list contains hemiplegias from every conceivable source; Osler's, only 16 as complications of infectious fevers, and Taylor restricted his to such cases as are of apparently spontaneous onset. In all, the great preponderance in the first three years of life is clearly indicated. Gowers (1888) stated that seven-eighths of acute infantile hemiplegias had their onset in the first five years of life.

With the concentration of cases within the first three years, it is probable that many of those which suddenly develop hemiplegia of a permanent character, and are associated with mental deficiency, depend on antenatal and especially natal causes. The trigger that fires the explosion, the convulsion and hemiplegia, is not pulled, however, until some time after birth. In many of this type a history of prolonged, difficult labour and asphyxia of the infant at birth is obtained.

Before reviewing the morbid anatomy of acute infantile hemiplegia, and before looking for the reason of the delayed onset of hemiplegia of natal origin, the ground must first be cleared of some of the so-called congenital hemiplegias.

This is not always easy, as it may be several months before a unilateral weakness becomes obvious. Most of the activities of the newborn infant depend on reflex pathways in the brain-stem and spinal cord, and signs of pyramidal involvement of a higher level take a variable time to appear. Parents are unaware of any fault until their suspicions are aroused by the infant's retarded power of action. Most

A picture of unilateral sclerosis and cystic degeneration, probably of vascular causation, is depicted in figs. 5 and 6, from a case published by W. E. Le Gros Clark and Dorothy S. Russell (1940, *J. Neurol. Psychiat.*, 3, 123). It shows the shrivelled left hemisphere from a girl, previously in good health, who, at 8 years, suddenly became convulsed and developed an acute hemiplegia, and after some general improvement died at 13 years in a condition resembling status epilepticus. Here there was a conspicuous degree of atrophy and cystic degeneration of the left cerebral

FIG. 5.—Left lobar sclerosis, probably of vascular origin, in case of acute hemiplegia at 8 years (by courtesy of Professor Dorothy Russell).

FIG. 6.—Ventricular dilatation and cortical cystic degeneration.

(Figs. 5 and 6 are reproduced by permission of the Editor of *J. Neurol., Neurosurg. Psychiat.*)

cortex, with advanced demyelination and gliosis of the white matter of that hemisphere. There was no resemblance to Schilder's encephalitis. Two similar examples have been recorded by Bielschowsky.

The morbid anatomy of "acute infantile hemiplegia" as defined by Taylor, where the earlier history provides no suspicion of mental or physical defect, appears to depend almost entirely upon vascular changes, not in the form of gross bleeding or rupture of vessels, but in the form of vascular occlusions, arterial more often than venous, either by embolism or thrombosis; or in perivascular changes due to agents, toxins, and other antigens travelling via the blood-stream.

The anatomical lesions show great variety. In rapidly fatal cases, arterial occlusion is a common finding. Whether it be embolism or thrombosis is disputed. In 1 of my 7 cases, a child just under 2 years, in good health, suddenly developed convulsions, coma, right hemiplegia, and died within a week. At autopsy, the left anterior cerebral artery was occluded throughout its distribution. On cross section, the left frontal lobe showed a multitude of minute black vascular points. There was no disease found in the circle of Willis, nor in any other part of the body.

Ford and Schaffer (1927) record 16 cases with vascular occlusions, usually in the territory of the middle cerebral artery.

In some cases with previous good health coming to autopsy soon after the onset of hemiplegia, two types of encephalopathy have been described. The first appears to be a non-specific acute toxic encephalopathy occurring in many different diseases, probably as a result of bacterial toxins. Grinker and Stone have described the lesions varying from congestion, œdema, necrotic nerve cells and disintegration of cortical neurones to areas of cortical softening. Proliferation of the endothelium of the small cerebral vessels was observed, but an absence of signs of bacterial invasion. With lesions sufficiently extensive, a hemiplegia or diplegia may be produced. In cases of

striatum within the same venous system. With difficult prolonged birth and severe head moulding, the vein of Galen is kinked on the straight sinus and severe asphyxial congestion, œdema, diapedesis of red cells affect the central areas of the hemispheres and the basal ganglia. In the adult hemiplegia, the damage is in the arterial pathway, middle cerebral artery usually.

FIG. 1.—Occipito-posterior presentation, prolonged labour, asphyxia at birth. Twitchings, chiefly left-sided, from second month. Lumbar encephalogram at 7 months: cortical atrophy and ventricular dilatation.

FIG. 3.—Cystic cavity, false porencephaly: breech birth, hemiplegia of sudden onset at 2 months (R. M. Stewart's case).

FIG. 2.—Right hemiplegia acquired in second year; patient died aged 29, epileptic and mentally defective (R. M. Stewart's case). Hypoplasia left hemisphere.

FIG. 4.—Lobar sclerosis, hemiatrophy left hemisphere; congenital hemiplegia (R. M. Stewart's case).

One of my cases was probably of the above type; a boy born with some asphyxia and head moulding developed, in July 1947, a sudden convulsive episode with acute right hemiplegia and mental impairment. He improved for a time, but later grew worse and died in December of the same year. The C.S.F. had been normal. In November, Mr. McKissock had performed a lumbar encephalogram, which showed gross bilateral cortical atrophy with dilatation of the ventricles. The left cortex opposite the hemiplegia was more atrophic than the right.

Strümpell (1884), later supported by Marie (1885), that infection was the cause, and the infection probably polio-encephalitis, the counterpart of poliomyelitis. This must finally be abandoned. Recent research by Howe and Bodian in man and chimpanzee refers to the minor encephalitis accompanying the spectacular myelitis, meaning that the cerebral lesions lack the saturation of the spinal ones. Barring the brain-stem nuclear lesions causing most of the deaths in acute infantile paralysis, there is no authentic instance known of hemiplegia, nor of diplegia, due to the virus of polio. The initial stage of stupor, or of coma, seen in some cases of polio is ephemeral.

(2) A theory based on more solid ground is that of vascular occlusion, usually arterial, either by embolism or thrombosis. Some acute hemiplegias undoubtedly occur as a result of an infectious fever. I have mentioned those in diphtheria with cardiac weakness. Rolleston was able to collect in 1908 66 cases complicating scarlet fever, and in 6 out of 7 post-mortems embolism or thrombosis was found to be the cause. But this does not provide an answer why a child in apparent good health may suddenly be convulsed, become comatose, and show a hemiplegia. Yet in one of my cases already mentioned, the anterior cerebral artery on one side was thrombosed.

(3) More recently, other viruses, type unknown, are used as scapegoats to explain all cerebrospinal paralyses of obscure origin. There is little evidence to support this theory in regard to a permanent hemiplegia, or a diplegia. Viruses are selective, with preference for the nuclear masses of grey matter. In epidemic encephalitis, the preference is for nuclei in the brain-stem, and hemiplegia is an uncommon expression of this disease. Recovery from virus invasion of nuclear cells, also, is slow and often incomplete, so would not account for sudden hemiplegia with rapid recovery.

(4) In the third of all the acute infantile hemiplegias reckoned to follow the acute infectious diseases, I have already mentioned the non-specific encephalopathies, acute toxic and hæmorrhagic, which have been found in some cases. These it is thought are secondary processes to circulating bacterial and other toxins. No doubt on a grand enough scale, one or other type might produce a hemiplegia; or an acute cerebellar ataxia, if the vascular lesion is in the cerebellum.

(5) Lastly, there is the group of encephalopathies complicating vaccination, variola, measles, chicken-pox, rubella. In them the nervous complications are varied, but a hemiplegia or a bilateral paresis, temporary or permanent, has often been witnessed. In some cases the onset is spontaneous—acute spontaneous encephalomyelitis. In both the post-exanthematous and the spontaneous, the histological lesion is essentially the same. The characteristic anatomical lesion is perivascular demyelination in the central white matter of the hemispheres.

So far, no theory of how the demyelination is produced has stood its ground. At first, either the virus of the exanthem was accused, or a hypothetical neurotropic virus activated by the primary infection. Demyelination, however, is not a proved feature of virus infection in man, nor in the experimental animal, nor is it found as a result of generalized vaccinia. The secondary virus remains hypothetical and has escaped detection.

Recently, a more promising line of investigation into the production of demyelination is being perfected by the experimental pathologist. Briefly, this is the production of multiple lesions of demyelination in monkeys and other animals by injection, subcutaneously or intramuscularly, of homologous or heterologous white brain substance, combined with adjuvants, heat-killed acid-fast bacilli, &c. The adjuvants help to precipitate the reactions, but the injection of the adjuvants alone produced no results. This reaction is considered to be an immunological tissue response, or one due to allergy, or a specific brain antibody-antigen reaction. The similarity to the lesions in some of the post-infectious encephalopathies in man is considerable, and it is suggested that an infecting agent may stimulate formation of a cerebral

minor severity the damage is reversible and recovery may be gradual. This type of encephalopathy, as also the second type, is chiefly a complication of pneumonia, tonsillitis, scarlet fever, and other acute infectious diseases.

The second type sometimes found is called the hæmorrhagic encephalopathy. In this, as a result of bacterial or other circulating toxins (Alpers, 1928), small areas of congestion and necrosis surrounding small blood-vessels, which may have their lumen occluded by swollen endothelium, are found chiefly in the white matter of the brain. The circular areas are usually ringed by a hæmorrhagic zone. There is no evidence of bacterial invasion. Similar lesions may be produced following treatment with arsenical compounds.

The toxic and the hæmorrhagic encephalopathies are distinct anatomically from the type characterized by demyelination in the central white matter. In the latter form convulsions may be an initial symptom, but more often stupor sinks into coma. Hemiplegias, diplegias and other nervous signs occur in this type of encephalopathy, and may be either temporary or permanent.

It is, perhaps, necessary to state that gross or macroscopic hæmorrhage, intracerebral, is one of the rarest intracranial lesions in childhood. None of the cases presented was secondary to disease elsewhere in the body. So intracranial bleeding secondary to leukaemia, hypertension, bacterial endocarditis, spontaneous sub-arachnoid hæmorrhage, can be excluded. Nor were they due to diphtheria with severe cardiac involvement and dislocation of clot from the auricles.

Despite the excellent description of subdural hæmatoma in children from birth onwards by Ingraham and Matson, who collected 98 cases in six and a half years, I have, in the last two years, after diligent search by dural taps in all infants under 6 months in my ward with suspicions of cerebral disturbance, so far only found one in twenty examinations with a subdural hæmatoma. The condition occurs more often in children under 2 years of age, due to injury to the head. 2 recent ones I have had were in toddlers after an injury to the head from a fall. The bulging fontanelle, torpor, punctate hæmorrhages in the fundi, facilitated the diagnosis. One had extensive unilateral subdural clot, with contralateral paresis of the limbs, and

FIG. 7.—Tuberculoma of right hemisphere; left hemiplegia of sudden onset.

the other a large right cephalhæmatoma, fractured parietal bone, and gross underlying extradural extravasation, and mild paresis of the left arm. Nor should we expect the extradural or subdural hæmatoma to give rise to hemiplegia, unless the blood clot be excessively thick and extensive. The infant's cortex withstands an amazing amount of pressure without focal paralysis appearing. Paralysis, hemiplegia, is more likely to appear later as a result of atrophy of the cortex.

Only one other instance of confusion shall I cite; a boy of 1 year and 3 months, who developed a convulsion lasting four hours, followed by frequent twitching, fever, and a left hemiplegia. The optic fundi were normal. Mantoux skin reaction was strongly positive. X-ray of chest revealed miliary tuberculosis. At autopsy an enormous tuberculoma impinging on the right internal capsule was found, which had produced no inconvenience until convulsions occurred (fig. 7).

Theories of pathogenesis of acute infantile hemiplegia.—The pathogenesis of acute infantile hemiplegia I have reserved to the last. A review of the voluminous literature clearly shows how speculation has outrun fact.

(1) Of historical interest is the theory, so long-lived and widely accepted, of

Strümpell (1884), later supported by Marie (1885), that infection was the cause, and the infection probably polio-encephalitis, the counterpart of poliomyelitis. This must finally be abandoned. Recent research by Howe and Bodian in man and chimpanzee refers to the minor encephalitis accompanying the spectacular myelitis, meaning that the cerebral lesions lack the saturation of the spinal ones. Barring the brain-stem nuclear lesions causing most of the deaths in acute infantile paralysis, there is no authentic instance known of hemiplegia, nor of diplegia, due to the virus of polio. The initial stage of stupor, or of coma, seen in some cases of polio is ephemeral.

(2) A theory based on more solid ground is that of vascular occlusion, usually arterial, either by embolism or thrombosis. Some acute hemiplegias undoubtedly occur as a result of an infectious fever. I have mentioned those in diphtheria with cardiac weakness. Rolleston was able to collect in 1908 66 cases complicating scarlet fever, and in 6 out of 7 post-mortems embolism or thrombosis was found to be the cause. But this does not provide an answer why a child in apparent good health may suddenly be convulsed, become comatose, and show a hemiplegia. Yet in one of my cases already mentioned, the anterior cerebral artery on one side was thrombosed.

(3) More recently, other viruses, type unknown, are used as scapegoats to explain all cerebrosplinal paralyses of obscure origin. There is little evidence to support this theory in regard to a permanent hemiplegia, or a diplegia. Viruses are selective, with preference for the nuclear masses of grey matter. In epidemic encephalitis, the preference is for nuclei in the brain-stem, and hemiplegia is an uncommon expression of this disease. Recovery from virus invasion of nuclear cells, also, is slow and often incomplete, so would not account for sudden hemiplegia with rapid recovery.

(4) In the third of all the acute infantile hemiplegias reckoned to follow the acute infectious diseases, I have already mentioned the non-specific encephalopathies, acute toxic and hæmorrhagic, which have been found in some cases. These it is thought are secondary processes to circulating bacterial and other toxins. No doubt on a grand enough scale, one or other type might produce a hemiplegia; or an acute cerebellar ataxia, if the vascular lesion is in the cerebellum.

(5) Lastly, there is the group of encephalopathies complicating vaccination, variola, measles, chicken-pox, rubella. In them the nervous complications are varied, but a hemiplegia or a bilateral paresis, temporary or permanent, has often been witnessed. In some cases the onset is spontaneous—acute spontaneous encephalomyelitis. In both the post-exanthematous and the spontaneous, the histological lesion is essentially the same. The characteristic anatomical lesion is perivascular demyelination in the central white matter of the hemispheres.

So far, no theory of how the demyelination is produced has stood its ground. At first, either the virus of the exanthem was accused, or a hypothetical neurotropic virus activated by the primary infection. Demyelination, however, is not a proved feature of virus infection in man, nor in the experimental animal, nor is it found as a result of generalized vaccinia. The secondary virus remains hypothetical and has escaped detection.

Recently, a more promising line of investigation into the production of demyelination is being perfected by the experimental pathologist. Briefly, this is the production of multiple lesions of demyelination in monkeys and other animals by injection, subcutaneously or intramuscularly, of homologous or heterologous white brain substance, combined with adjuvants, heat-killed acid-fast bacilli, &c. The adjuvants help to precipitate the reactions, but the injection of the adjuvants alone produced no results. This reaction is considered to be an immunological tissue response, or one due to allergy, or a specific brain antibody-antigen reaction. The similarity to the lesions in some of the post-infectious encephalopathies in man is considerable, and it is suggested that an infecting agent may stimulate formation of a cerebral

antigen which reacts with specific antibody in perivascular tissues (Morgan, 1947; Kabat *et al.*, 1947).

The hypothesis is attractive, but can as yet only be advanced tentatively. Hurst (1944), working experimentally on demyelination, stated that the means by which it can be produced are diverse; further, its production under experimental conditions does not necessarily furnish a clue to the ætiology of those human diseases characterized by perivascular demyelination.

Such a theory, however, would go far to explain some of the cases of spontaneous hemiplegia and diplegia in childhood. Short of demyelination, which is irreversible, there is perivascular œdema and exudate. The process need not progress to its full development, and recovery can be expected. In 3 of my list of hemiplegias, 1, a child of 3 years and 10 months, developed acute infantile hemiplegia and was fully recovered in three months. In two others, with spontaneous hemiplegias coming on at 11 months and at 17 months of age (one being under the care of Dr. M. Edmunds), recovery has been almost complete, except for a slight clumsiness of the affected hand, in periods of three months and one year respectively. Such cases surely cannot be ascribed to vascular thrombosis, and are unlikely complications of virus invasion. The cerebrospinal fluid was normal in each. In a similar connexion I may mention a post-measles case of Dr. Sheldon's, a boy of 8½ years, exposed to measles beginning of April 1947, eight days later was given 5 c.c. measles convalescent serum, with subsequently a mild attack of measles. Seven days later he became drowsy, febrile, comatose, diplegic, but in eight days was completely well again. Even more suggestive was a case I saw of a girl of 7½ years, who, eight days after a normal vaccination, became irritable, stuporose, febrile and rigid, with bilateral extensor plantars, yet within five hours she was conscious, able to feed herself, and her spasticity had departed. To my mind, such cases speak, not for a bacterial agent, but for a specific tissue reaction, possibly antigen-antibody acting through vascular channels, and in these several instances, arrested in an early stage before irreversible damage had occurred. One last case, which I may mention through the kindness of Dr. Banks of the Park Hospital, a boy of 4 years had concurrently whooping cough and mumps, and became convulsed, unconscious for six days, with a left hemiplegia clearing up in eight days. The pathogenesis is more controversial here, as the possible nervous complications of mumps are varied, but, as Dr. Taylor said many years ago, it is likely the specific fever stands only as a predisposing cause.

There is obviously much still to be done to unravel the pathogenesis of acute infantile hemiplegia and diplegia. The examination of pathological material calls for close study by the morbid anatomist as the opportunity occurs. The chances of further light being thrown on the problem, in my opinion, lie largely in the hands of the research worker in experimental pathology.

Thiersch's Operation for Anal Incontinence

By W. B. GABRIEL, M.S.

THIERSCH's operation consists of the insertion of a silver wire into the perianal space, so as to encircle and narrow the anus; it was described by Thiersch in 1891, and was devised originally as a method for treating rectal prolapse. The operation is clearly described in Kirschner's *Operative Surgery*, in Professor Hartmann's work on the *Surgery of the Rectum*, and in Carrasco's monograph, "*Prolapsus du Rectum*". The use of other materials such as silk, fascia, kangaroo tendon and rubber has been described for this operation.

So far as I am aware, Thiersch's operation has fallen into disuse, at any rate in this country during the present century, and the object of this communication is to indicate that Thiersch's operation still has a sphere of considerable usefulness and that in fact it may prove to be the operation of election in one of the most difficult and intractable rectal conditions which we encounter.

Indications.—Women who develop relaxation of the anal sphincters have for many years been a most difficult problem, particularly since the cause of the condition is usually undetermined.

Examination reveals a somewhat patulous anus which can be made to gape widely by digital traction. The normal anal canal appears to be absent and the rectal mucosa seems to come right down to the anal margin; this must be due, I think, to fatigue or loss of the normal motor innervation of the internal sphincter (lumbar sympathetic).

The tone of the external sphincter is variable; some patients can manage some voluntary contraction, but many of the old, deaf subjects have no voluntary contractile power. In all cases the resting tone of the external sphincter is poor and it becomes worse towards the evening after the patients have been up and about all day.

The chief symptoms are those of anal incontinence, with inability to hold flatus, and a variable amount of faecal leakage, always associated with the mental distress and uncertainty that might be expected. In addition there is often a mucosal prolapse sometimes amounting to a short complete prolapse.

Treatment in these cases has hitherto been very unsatisfactory. Faradism sometimes helps a little but is often disappointing. A ligature operation to remove the prolapsing mucous membrane is doomed to failure and recurrence if the sphincter remains relaxed.

Owing to the advanced age of many of these patients a minor procedure is most desirable, and it is in such cases that Thiersch's operation is indicated.

One further indication for Thiersch's operation is when the sphincter remains patulous after operation for a complete rectal prolapse. There was one such case in this series, a woman aged 52, for whom I had previously done a Moschcowitz operation; her extremely patulous sphincter showed little sign of improvement, and after an interval of six months the beginning of a recurrent mucosal prolapse became evident and I decided to carry out a Thiersch's operation as a supplementary procedure. This has given great relief and has prevented any further development of her trouble although she has subsequently broken her wire on two occasions. (Case mentioned later.)

Technique.—The operation is performed for preference under continuous pentothal, with the patient in the lithotomy position. Strict aseptic technique is necessary: the skin is carefully cleaned and prepared with tincture of iodine and a dry gauze swab may be tucked into the anal canal in order to prevent leakage of mucus. A soft, easily malleable silver wire, No. 19 or 20 S.W.G. is then passed round the anus in the perianal space through a skin puncture 1 inch posterior to the anus. Doyen's needle has proved to be ideal for this operation. The anal lumen allowed by the wire should be such as will pass a forefinger easily; the assistant keeps his finger in the anal canal while the wire is being twisted in order to guard against the wire becoming tighter during the twisting. The twist is made posteriorly and the wire is then cut, leaving about $\frac{1}{4}$ inch of the twist which is bent posteriorly towards the coccyx and then tucked well away into the subcutaneous tissues. The skin punctures anteriorly and posteriorly are closed with Michel clips.

Post-operatively the bowels are moved with the aid of a glycerin suppository or enema about the fourth day, and a good deal of care has to be taken for the next week or two to overcome a tendency to faecal impaction. The patients only need to be in bed for two or three days and there is very little pain after operation.

Results.—In 11 cases treated to date by Thiersch's operation the results have been, with

one exception, very satisfactory. The patients were all females; their ages ranged from 44 to 79, 4 being over 70. After insertion of the wire the patients have remarked on their comfort and feeling of security and the cases with prolapse have found this to be completely corrected. Moreover, after operation patients are perfectly well able to continue with their sphincter and levator contractions and in some cases I have noted an improved contractile power with the wire in position.

My first three operations of this nature were done with stainless steel wire (2 or 4 strands) and in two of these the wire subsequently broke, one after one month, one after three and a half months, and I re-operated on both cases, this time putting in a silver wire. One of the cases again broke her wire in the course of defaecation seven and a half months later; she knew at once what had happened and without delay returned with a view to its reinsertion; I did this under pentothal after removing the silver wire which was found to have broken on one side just beyond the twist. (Wires demonstrated.)

There has been one case of sepsis; the patient was a stout woman, aged 49, for whom I did a Thiersch's operation with silver wire under local anaesthesia. Six days later an acute ischiorectal abscess on the left side had to be incised; the abscess rapidly cleared up but two weeks later the wire was seen to be exposed, so I removed it under pentothal.

As to the duration for which the wires can be left, I am proposing to leave them indefinitely so long as the symptoms are relieved and no untoward incident develops. Four of these cases have retained the wire for six months (including the case previously mentioned who broke her wire after seven and a half months).

Recto-Sigmoidectomy for Complete Prolapse of Rectum

By MICHAEL J. SMYTH, M.Ch., F.R.C.S.

PROLAPSE of the rectum up to a distance of 2 in. involves all the coats of the rectum. Beyond this the prolapse usually involves the pouch of peritoneum on the anterior surface; in fact a prolapse of greater dimension is regarded by some surgeons as a sliding hernia of the rectum. The greater the prolapse the more is the rectovaginal or rectovesical pouch involved. Ernest Miles used to say that prolapse could not be greater than 6 in., but I recall a case of a boy aged 10 years admitted to hospital with a sudden prolapse which was almost 12 in. long. In this case there was an intussusception of the pelvic colon which had come through the anus drawing the rectum with it completely, so that there was no sulcus at the anal margin. It was necessary to open the abdomen to effect reduction.

The condition of complete prolapse of the rectum occurs more frequently in the later decades of life and much more frequently in women than in men, but recently I have seen cases in the middle thirties and forties. It may be that wartime and post-war diet may have led to some laxity of the tissues.

Many operations have been advocated for prolapse of the rectum, both intra-abdominal and extra-abdominal or perineal operations, but in my opinion recto-sigmoidectomy is the best method. Miles standardized the operation in his report to the Society in 1933 (*Proc. R. Soc. Med.* (1933), 26, 1445). Briefly it amounted to amputation of the prolapse, and an entrance to the peritoneal cavity was inevitable. Yet it was remarkable that before the use of sulphonamides and penicillin, with ordinary care peritonitis rarely, if ever, occurred. In Miles' review of 32 cases he reported only one death, and this was due to intestinal obstruction—a knuckle of small intestine being involved.

Nowadays preliminary treatment with sulphathalidine is given. The operation is done with the patient in the lithotomy position, the table being given a slight Trendelenburg tilt. With the surgeon seated he will find it an advantage to have the instruments on a small tray in front of him. The amputation should leave not less than 1 in. of bowel above the mucocutaneous junction. In this way damage to the external sphincter is avoided and sufficient bowel is left for anastomosis to the pelvic colon. I have seen 2 cases in which the sphincter had been destroyed completely. When the peritoneum is opened it should be well divided on both sides: the pelvic colon can then be drawn down to its full extent so that when it is divided there may be no slack left, thus ensuring against recurrence of prolapse. The peritoneum is then carefully closed and stitched snugly around the wall of the pelvic colon as high up as possible. The amputation is completed by dividing the pelvic colon obliquely from before backwards, the line of section being higher in front than behind. In this way the lumen of the colon will more closely approximate to that of the rectal wall and so make anastomosis easier. It is wise to spray the line of anastomosis with sulphonamide-penicillin powder before returning it through the anus, in fact the spray can be used at any time throughout the operation where the surgeon may think it necessary. Finally a medium-sized tube surrounded by gauze soaked in flavine and paraffin is inserted through the anus and kept in place by skin stitches.

In a series of 27 cases there was no death and one recurrence. This latter was due to the fact that the pelvic colon had not been divided high enough. In this case the patient had been given a spinal anæsthetic, and I agree with the view expressed by Mr. Gabriel that a general anæsthetic is better, as spinal anæsthesia brings about retraction of the pelvic colon, and so it cannot be divided as high as one would wish.

[A film of the operation in colour was shown.]

Anorectal Malignant Melanoma

By RONALD W. RAVEN, O.B.E., F.R.C.S.

A STUDY of the morphology and properties of the malignant melanoma leads us into a number of fields of investigation including the complex system of the sensory nerve-endings, the wide distribution of chromatophores and pigment formation in the animal kingdom. In addition, this is the most deadly of all known tumours. There is still much to be learnt concerning its properties and it is important to record isolated cases, especially of sites in the body where it is less frequently seen.

The type cell.—The type cell of the malignant melanoma is the melanoblast which is polygonal in shape, with short, hair-like processes and a vesicular nucleus with several nucleoli especially in the more malignant types (fig. 1). As the cell differentiates it becomes racquet-shaped, developing one or more stout cytoplasmic tails and, passing through a fusiform stage, it becomes an enormously elongated filamentous structure. Protoplasmic fibrils are found within the cells; in the benign type they are localized in the cell processes, but in the malignant forms they may run throughout the cell cytoplasm. Some of the cells

FIG. 1.—Melanoblasts in growing tissue culture of chicken embryo. This is the type cell of the melanoma ($\times 150$).

FIG. 2.—A melanoblast seen under a high microscopic magnification. The middle of the cell is occupied by the nucleus: the cytoplasm is filled up with pigment granules. This is an autonomous unit ($\times 1,200$).

contain a considerable amount of melanin, while many others are free from it. There is evidence that the presence or absence of melanin does not affect the malignant properties of the cell. The melanoblast is an active cell, moving among the fibroblasts by amoeboid movement, throwing out branches which are sometimes long and attached to the main body by a very thin thread. The melanoblast (fig. 2) is an autonomous unit, it possesses the properties for survival and can reproduce a new colony of cells.

It is also important to stress the tendency of melanoma cells to separate from the main

body of the tumour and be carried away to commence a new tumour colony in another locality of the body (fig. 3). The chance of an active cell becoming detached is very great and cytological studies prove that it occurs (fig. 4). The single cell is able to pass through the larger lymphatic channels and it becomes arrested in the fine filtering system in the liver, lung (fig. 5) or bone-marrow. When a group of cells detach themselves they are arrested in the regional lymph nodes. This property of producing widespread metastases is one of the

FIG. 3.

FIG. 3.—Cytological study of a melanoma in a dog showing an area with dividing tumour cells near the blood-vessels. The large number of blood-vessels and lymphatics in close contact with the tumour cells increases the possibility of widespread and distant metastases ($\times 700$).

FIG. 4.—Cytological study of a transverse section of an artery whose lumen contains melanoblasts, leucocytes and erythroblasts ($\times 350$).

FIG. 5.—Cytological study of a section of lung at autopsy. The individual tumour cells have been separated with a solution of acetic acid (strength 45%). The nucleoli within the nuclei of some of the cells are demonstrated ($\times 700$).

FIG. 4.

FIG. 5.

outstanding features of the malignant melanoma, and the patient usually succumbs, not as a result of the primary lesion, which may be a small nodule in the skin, but from generalized metastases.

TABLE I.—MALIGNANT MELANOMA. THE METASTATIC PICTURE

Lymph nodes	Lungs Heart	Liver Pancreas Omentum Bowel	Structures Involved			
			Brain	Generalized	Skeletal: Pelvis Femur Tibia Metatarsals Metacarpals	Skin: Multiple nodules

Incidence.—Malignant melanoma is not found frequently in the alimentary tract. In the œsophagus it is extremely rare and as far as I can ascertain from the literature only 3 cases have been reported. The stomach is affected infrequently but it is more common in the small intestine; thus in 1945 Herbert and Manges collected 25 cases in the literature; in 9 cases the tumour was considered to be primary and in 16 cases metastatic. It is infrequent in the colon.

The anorectal region is the commonest site in the alimentary tract to be affected by malignant melanoma but the total number of cases reported in the literature is not large. Over

one hundred cases have been reported. Miles stated that he had only seen 3 cases in a series of more than 1,500 cases of carcinoma of the rectum.

Case records.—During the past fifteen years I have only found the case-records of 3 patients admitted to the Royal Cancer Hospital and Dr. John Waugh informs me that only 10 cases have been seen at the Mayo Clinic.

CASE I.—Male, aged 59, was admitted to the Royal Cancer Hospital on December 6, 1933, under the late Mr. Cecil Rowntree, complaining of increasing constipation.

History.—For nine months the patient had experienced increasing constipation and a sense of obstruction in the rectum. Morning diarrhoea was present and "rectal prolapse" occurred which was diagnosed elsewhere as "piles". The stools were ribbon-like in character: no blood or mucus was present. He had lost 11 lb. in weight.

Examination.—Patient's general appearance was healthy. The abdomen was distended in the region of the cæcum. There were hard shotty lymph nodes in the left groin. A growth was present in the posterior wall of the anal canal filling the lumen, the lower limit extending down to the level of the white line. Bleeding occurred on examination.

Operation (Mr. C. Rowntree).—Exploratory laparotomy. Multiple nodules were found involving the small intestine, a small hard nodule was present on the vault of the urinary bladder and two large masses were found in the pouch of Douglas. The anal tumour was excised locally and diathermy applied to the base.

Histology.—"The tumour is a malignant melanoma, pigment formation is minimal. The growth is composed mainly of cells of epithelial type but in one part shows a tendency to spindle form. Small strands of necrotic squamous epithelium, a few tubular mucus-secreting glands and occasional unstriated muscle fibres are the only traces of tissue of normal structure in the specimen."

CASE II.—Male, aged 39, was admitted to the Royal Cancer Hospital on November 22, 1946, under Mr. R. C. B. Ledlie, complaining of rectal bleeding and discharge.

History.—For four months the patient had experienced severe bleeding and discharge from the rectum with incontinence of fæces. He had also noticed a lump at the anus and there was also loss of weight.

Examination.—Patient appeared to have lost weight. The abdomen was distended: liver not palpable. A swelling protruded from the anal orifice, 4 × 3 cm. in size, purplish in colour and of firm consistency. It extended high up the anal canal and induration of the ischio-rectal fossæ was present. There were several lymph nodes in both groins, firm in consistency. Radiological examination of the chest showed no abnormality.

Operation (Mr. R. C. B. Ledlie).—Exploratory laparotomy; Liver was normal: a large growth involving the rectum was found with extension to the right side of the pelvis. A left inguinal colostomy was performed. Excision of the rectum was not possible. Nineteen days later the protruding mass was excised by diathermy.

Histology.—"The tumour is a malignant melanoma. There is a partial covering of the tumour by squamous epithelium which is partly hyperplastic, partly atrophic and partly ulcerated. The malignant parenchyma shows considerable heterogeneity and many parts are completely achromic. Other parts show melanin pigmentation in both melanoblasts and chromatophores. The component cells are sometimes fusiform or polyhedral but there are many circumscribed lobulated masses of cells of large spheroidal form bearing a striking resemblance to certain neuro-epithelial end-organs. Mitotic figures and examples of nuclear hyperchromia, reduplication and syncytium formation are abundant and the tumour is extremely malignant."

CASE III.—Male, aged 62, was admitted to the Royal Cancer Hospital on March 9, 1933, under Mr. C. E. Shattock.

History.—For three months the patient had experienced pain on sitting down and had passed blood from the rectum for six weeks. No constipation. No pain on defæcation. Weight decreasing. Six weeks previously colostomy had been performed elsewhere.

Examination.—Abdomen: Liver not enlarged. Spleen and kidneys not palpable. A purplish-brown tumour was present occupying the anus, extending outward to the buttock and upward along the full extent of the anal canal. The mucous membrane of the rectum beyond the tumour appeared normal. Consistency firm and the tumour did not bleed.

Operation (Mr. C. E. Shattock).—March 16, 1933: Perineal excision of rectum. April 5, 1933: Excision of left inguinal lymph nodes.

Histology.—"Histology of the primary tumour is that of an actively growing, intensively pigmented, malignant melanoma. There is massive infiltration of the regional lymph nodes by malignant melanoma, but the highest node removed shows no invasion. Lymph node from groin—there is metastasis of malignant melanoma. There is massive invasion of the inguinal lymph nodes by malignant melanoma."

The patient subsequently developed suppression of urine and died on May 9, 1933. Autopsy showed septicæmia and pyelonephritis to be the cause of death. There was no evidence of metastases.

Site of Origin.—Usually the tumour arises in the anal canal or at the anal verge. It is very exceptional for it to commence in the rectum but such a case is described by Chaliér

and Bönnet where the tumour occurred in the rectum 6 cm. from the anal orifice. There is good evidence that the malignant melanoma arises in the skin of the anal canal and involves the rectum secondarily by direct extension. It is of interest also to note that Kallet and Saltstein have described a case of malignant melanoma arising in a rectal polyp. The posterior wall of the anal canal is more often involved than the others, followed by the lateral walls; the anterior wall is the most infrequent site.

The tumour usually forms a single mass, but a second smaller growth is sometimes present separated by apparently normal tissue. There may be a small anal tumour with a larger one in the ampulla of the rectum; or the primary tumour may be surrounded by a number of small satellites. The size of a malignant melanoma in this region varies from a miliary nodule to a large tumour, with many intermediate varieties.

Types of tumour.—There are two main types, namely sessile and pedunculated. It is a feature of the malignant melanoma in this region to become pedunculated and this explains the frequency with which it prolapses through the anal orifice. A case is described in the literature of spontaneous extrusion of such a tumour after detachment had occurred at its base. The base of the tumour is frequently mobile over the deeper layers of the anal canal. The tumour is usually lobulated and there may be areas of superficial ulceration present. It is frequently black in colour due to the presence of melanin, although an amelanotic type is described. The consistency is firm and elastic; sometimes it feels semi-fluctuant.

Spread of the tumour.

(a) *Direct extension.*—Malignant melanoma commencing in the anal canal shows a marked tendency to spread upwards into the rectum along the submucous tissues. It also spreads outwards into the cellular tissues surrounding the anus and rectum but this type of extension appears to be halted by the fibrous fascia propria of the rectum. Contrary to the behaviour of adenocarcinoma in this region, malignant melanoma does not usually invade adjoining structures such as the urinary bladder, vagina or sacrum. Nodules of growth may be found in the ischio-rectal fossa or in the cellular tissues in the hollow of the sacrum.

(b) *Lymphatic spread.*—Owing to the site of the primary growth, the inguinal lymph nodes are frequently involved; if only one lateral wall of the anal canal is affected, the lymph nodes on that particular side may be involved, the others being normal. It is worth noting that the inguinal nodes are sometimes enlarged and resemble a mild form of lymphadenitis without containing tumour cells. Further, it is necessary to distinguish between the presence of chromatophores in the lymph nodes and actual malignant melanoma cells. When the rectum is involved, its lymphatics are invaded as in the case of adenocarcinoma. Usually these metastases are black in colour, although the primary growth may be amelanotic. Involvement of the lymphatic system may be more generalized and includes the thoracic duct, mesenteric, mediastinal and submaxillary groups of nodes.

(c) *Hæmatogenous spread.*—Invasion of the blood-vessels leads to widespread metastases, but in certain cases, as in malignant melanoma of the eye, dissemination may be delayed for a considerable period of time. The liver is involved most frequently; it assumes a large size and is nodular. These nodules may be black or amelanotic. The peritoneum may be studded with neoplastic nodules and secondary deposits may be present in the small intestines, great omentum and appendices epiploicæ. The lungs and pleura are also involved frequently. The subcutaneous tissues, kidney, brain and meninges, pancreas, spleen and thyroid gland may be affected.

Symptomatology.—A common symptom of the disease is the presence of a protruding mass from the anal orifice which may be mistaken for a prolapsed thrombosed internal hæmorrhoid. Bleeding and discharge are frequently present. There may be irregularity of bowel action with frequency of defecation and tenesmus. The protruding tumour can be seen, and is dark brown or black in colour, or a nodular pedunculated mass can be felt in the anal canal, and a blackish discharge may be noted on the examining finger. The regional lymph nodes in the groin may be enlarged and somewhat tender. In advanced cases a large mass of nodes are present and ulceration with suppuration may occur.

It is necessary to distinguish the primary tumour from a prolapsed, ulcerated internal hæmorrhoid and if there is any doubt concerning the true nature of the swelling a histological examination should be made after biopsy.

Treatment.—The treatment of malignant melanoma of the anorectal region is by radical surgical excision. An exploratory laparotomy is carried out to determine the situation as regards extensions of the growth and its operability. When conditions are favourable an abdomino-perineal excision of the rectum and anus should be performed. At a later date, three or four weeks afterwards, a bilateral block dissection is carried out to remove the lymph nodes in both groins.

Cytological studies carried out on malignant melanoma in animals before and after irradiation

tion with high-voltage X-rays of various doses (figs. 6, 7 and 8), and on malignant melanoma in patients, have shown that, on the whole, this tumour is not radiosensitive. Thus, wherever possible, radical surgical excision must be carried out.

ACKNOWLEDGMENTS

I wish to thank my colleagues at the Royal Cancer Hospital—Mr. C. E. Shattock, for allowing me to publish Case III; and Mr. R. C. B. Ledlie, for Case II; and Dr. P. C. Koller, for help in the cytological studies.

FIG. 6.

FIG. 7.

FIG. 8.

FIG. 6.—Cytological study of a biopsy specimen of a melanoma in a dog showing the histological variability of the tumour. The lower part of the section is rich in melanoblasts and chromatophores: the cells are long and spindle-shaped: some are large containing cytoplasm rich in pigment. The upper part contains round cells which are actively dividing: few pigmented cells are present ($\times 400$).

FIG. 7.—Cytological study of the same tumour shown in fig. 6, after X-irradiation with a total tumour dose of 2,500 r. No changes are present and actively dividing cells are shown ($\times 700$).

FIG. 8.—Cytological study of the same tumour shown in fig. 6, after X-irradiation with a total tumour dose of 3,500 r. No favourable irradiation reaction is present ($\times 400$).

Spreading Ulceration of the Skin Associated with Idiopathic Ulcerative Colitis

By E. C. B. BUTLER, F.R.C.S.

PROGRESSIVE ulceration of the skin is a rare but important complication of ulcerative colitis. In America Jankelson and McClure (1940) reported 7 cases, citing 12 others from the literature and Felson (1941) described 3 cases. Jankelson and McClure thought the condition was due to a vitamin deficiency while Felson ascribed it to an impaired resistance to infection. No British reference has been found so far.

CASE I.—A married woman aged 30 was admitted on August 8, 1942, to the London Hospital with the following history: Her first attack of ulcerative colitis, proved by sigmoidoscopy, occurred in 1934. In 1938 she had a further attack lasting for some months. She had remained well until six weeks before admission. Since then she has suffered from severe diarrhoea and rectal bleeding.

On admission there were no unusual signs. The stools contained blood and pus. No pathogenic organisms were isolated.

1.9.42; She complained of a small raised painful swelling on the left shin. Five days later a blood transfusion was given in the left arm by cutting down on the vein. Soon after an ulcer formed at the transfusion site.

7.9.42; The swelling on the leg broke down to form an ulcer which spread very rapidly. Although the discharge from the ulcer was profuse and purulent, repeated cultures remained sterile for some days. After this secondary infection occurred. Many organisms were then cultured from the ulcer; *Staph. aureus* predominated.

The base of the ulcer was composed of pus and sloughs but the infective process did not go beyond the deep fascia. The edge was raised, red, exquisitely tender and undermined. The skin surrounding the ulcer was red and indurated to a breadth of $\frac{1}{2}$ in. Spread of infection occurred in a very characteristic manner. The raised undermined edge rapidly dissolved away into pus leaving a fresh red area which, in turn soon became undermined and necrotic.

A similar ulcer also formed on the left arm at the site of the first blood transfusion.

The pain was so intense that the patient screamed whenever the dressings were changed or the affected limbs moved.

Local therapy consisted of hypertonic saline dressings, local sulphonamides and ultraviolet light. General measures included repeated blood transfusions, oral sulphonamides and a low residue, high vitamin diet. In giving the transfusions care was taken not to cut down on a vein.

The ulcers continued to spread until by October 14 all the skin of the leg had been destroyed from just below the knee to the level of the ankle (fig. 1). A similar ulcer had involved two-thirds of the left forearm. The patient was critically ill.

On October 15 the red growing edge of both ulcers was completely excised with a diathermy knife. The skin and superficial fat only were involved. Pathological report showed pyogenic infection. The next day pain had disappeared. The edge of the ulcers remained clean and clear-cut: there was no circumferential reddening of the skin. The discharge appreciably diminished and soon fresh epithelium grew in from the periphery (figs. 2 and 3).

Local treatment consisted in the repeated application of sulphathiazole powder. Whereas before operation local chemotherapy seemed inefficient post-operative treatment was successful. Possibly the pre-operative failure was due to the excessive discharge which rapidly rendered the sulphonamide powder inactive.

On October 19 an enormous rectal hæmorrhage occurred; the pulse-rate rose to 158. Five pints of blood were given. After this relapse secondary infection of the muscles of the arm occurred. On December 12 the left arm was amputated: two more pints of blood were given during the operation. The wound healed perfectly, no further spread occurred in the leg. Rectal bleeding ceased. In February 1943 she went home, her weight was rising, the ulcer was clean, her bowels were open twice daily and contained no blood.

In October 1944 the leg was grafted by Mr. Rainsford Mowlem with an excellent result.

In October 1945 she was readmitted to the London Hospital for delivery of a full-term child. While in hospital the leg remained healed although there was some further diarrhoea and hæmorrhage from the rectum. No further ulceration has occurred up to the present.

CASE II.—A woman aged 40 was admitted on November 11, 1944, to an Emergency Hospital with bilateral painful ulceration of the legs. She stated that the ulcerative colitis began in 1939 and in 1941 she had had a transverse colectomy, followed by a terminal ileostomy in 1942. In 1943, Mr. Hermon Taylor performed a partial colectomy, the ascending and part of the transverse colon were not removed.

On admission her condition was good: she had irregular pyrexia, the discharge from her colon had increased lately and consisted of blood and pus. On both legs there were large ulcers with raised red tender undermined edges. The bases were composed of pus and sloughs. *B. proteus* and *Str. hemolyticus* were obtained from cultures at different times. The treatment consisted of a high-vitamin low-residue diet. Systemic penicillin 120,000 units daily was given for a week. Penicillin

FIG. 1.—Left leg 1.10.42.

FIG. 2.—Left leg 2.11.42.

FIG. 3.—Left arm 2.11.42.

powder was applied locally. During this time her condition deteriorated and the ulcers doubled their size.

On December 3 the edge of both ulcers was excised with a diathermy knife, oozing was checked by elevating the legs during the operation. Another blood transfusion was given.

Post-operatively penicillin sulphonamide powder was applied locally. The remains of the colon was irrigated daily with a suspension of succinyl sulphathiazole.

The ulcers stopped spreading and the discharge from the colon practically ceased.

In January the patient was transferred to the care of Mr. Hermon Taylor. During the next month further discharge from the colon took place and the ulcers again became painful with renewed spread. In March Mr. Hermon Taylor excised the remainder of the colon.

Pathological report: Pyogenic infection of the colon with chronic inflammation of the lymphatic nodes.

After the operation the patient's general condition rapidly improved. The ulcers ceased to spread and gradually healed: skin grafts were not required.

In April 1945 she was sent home and has remained well since.

DISCUSSION

In both our cases the ulceration was severe but it is evident from the literature that all grades of skin involvement may occur in association with ulcerative colitis and we have met other mild cases where the ulcers were not painful and healing rapidly occurred with rest and chemotherapy. In this paper, however, we are chiefly concerned with the severe skin lesions since their clinical picture is so unmistakable and because they may be a danger to life.

Ætiology.—The ulceration seems to occur in patients who have suffered from colitis for some time; in both our cases and in others reported elsewhere the skin ulceration commenced during an exacerbation of the colitis as shown by pyrexia, diarrhoea and rectal bleeding.

We also noted that healing of the ulcers appeared to depend on the cessation of the active phase of the colitis, in one case following medical treatment and in the other after colectomy. It was noted in the second case that a relapse of the colitis was accompanied by an exacerbation of the skin ulceration.

These facts suggest that the skin lesions are clearly linked with the colitis but in what way is at present uncertain.

Spreading Ulceration of the Skin Associated with Idiopathic Ulcerative Colitis

By E. C. B. BUTLER, F.R.C.S.

PROGRESSIVE ulceration of the skin is a rare but important complication of ulcerative colitis. In America Jankelson and McClure (1940) reported 7 cases, citing 12 others from the literature and Felson (1941) described 3 cases. Jankelson and McClure thought the condition was due to a vitamin deficiency while Felson ascribed it to an impaired resistance to infection. No British reference has been found so far.

CASE I.—A married woman aged 30 was admitted on August 8, 1942, to the London Hospital with the following history: Her first attack of ulcerative colitis, proved by sigmoidoscopy, occurred in 1934. In 1938 she had a further attack lasting for some months. She had remained well until six weeks before admission. Since then she has suffered from severe diarrhoea and rectal bleeding. On admission there were no unusual signs. The stools contained blood and pus. No pathogenic organisms were isolated.

1.9.42; She complained of a small raised painful swelling on the left shin. Five days later a blood transfusion was given in the left arm by cutting down on the vein. Soon after an ulcer formed at the transfusion site.

7.9.42; The swelling on the leg broke down to form an ulcer which spread very rapidly. Although the discharge from the ulcer was profuse and purulent, repeated cultures remained sterile for some days. After this secondary infection occurred. Many organisms were then cultured from the ulcer; *Staph. aureus* predominated.

The base of the ulcer was composed of pus and sloughs but the infective process did not go beyond the deep fascia. The edge was raised, red, exquisitely tender and undermined. The skin surrounding the ulcer was red and indurated to a breadth of $\frac{1}{2}$ in. Spread of infection occurred in a very characteristic manner. The raised undermined edge rapidly dissolved away into pus leaving a fresh red area which, in turn soon became undermined and necrotic.

A similar ulcer also formed on the left arm at the site of the first blood transfusion.

The pain was so intense that the patient screamed whenever the dressings were changed or the affected limbs moved.

Local therapy consisted of hypertonic saline dressings, local sulphonamides and ultraviolet light. General measures included repeated blood transfusions, oral sulphonamides and a low residue, high vitamin diet. In giving the transfusions care was taken not to cut down on a vein.

The ulcers continued to spread until by October 14 all the skin of the leg had been destroyed from just below the knee to the level of the ankle (fig. 1). A similar ulcer had involved two-thirds of the left forearm. The patient was critically ill.

On October 15 the red growing edge of both ulcers was completely excised with a diathermy knife. The skin and superficial fat only were involved. Pathological report showed pyogenic infection. The next day pain had disappeared. The edge of the ulcers remained clean and clear-cut: there was epithelium grew in from the periphery (figs. 2 and 3).

Local treatment consisted in the repeated application of sulphathiazole powder. Whereas before the pre-operative failure was due to the excessive discharge which rapidly rendered the sulphonamide powder inactive.

On October 19 an enormous rectal hæmorrhage occurred; the pulse-rate rose to 158. Five pints of blood were given. After this relapse secondary infection of the muscles of the arm occurred. On December 12 the left arm was amputated: two more pints of blood were given during the operation. The wound healed perfectly, no further spread occurred in the leg. Rectal bleeding ceased. In February 1943 she went home, her weight was rising, the ulcer was clean, her bowels were open twice daily and contained no blood.

In October 1944 the leg was grafted by Mr. Rainsford Mowlem with an excellent result.

incidence of the former being variously reported between 25% and 75% and of the latter between 20% and 97·8%. Secondary disease may also follow the bursting into the rectum of gonococcal abscesses, e.g. from the prostate, Cowper's glands or fallopian tubes. The high incidence of secondary involvement in the female is due to the close proximity of the anus to the vagina, infection being more likely to occur during defaecation and menstruation. In spite of the advent of the sulphonamides and penicillin, the incidence of secondary disease in women has not lessened and in a recent series Nicol reported it to be 35%.

Primary disease, occurring more frequently in males than females, follows sodomy but many accidental infections due to the insertion of contaminated thermometers or enema nozzles have been reported. Stühmer (1921) described infections in 26 soldiers which had followed prostatic massage with a glove contaminated with gonococcal pus.

I have treated females with both primary and secondary involvement but the following observations concern 168 cases of primary disease in the male, contracted by sodomy.

Signs and symptoms.—Anorectal gonorrhœa may have an acute or subacute onset. In my experience the acute phase of the disease is rarely observed (it was noted in only 4 of my series) and a large majority of patients with positive findings will give no previous history of any acute manifestations. Acute signs and symptoms more often occur during the subacute phase when they are due either to perianal and ischio-rectal abscess (often leading to fistula) or to fissuring of condylomata acuminata.

The 4 cases in my series with early acute signs and symptoms complained of severe burning pain and tenesmus with blood in the stools and defaecation was extremely painful. Proctoscopy revealed a generalized redness of the rectal mucosa with localized areas of large red infiltrations similar to those of gonococcal urethritis, which bled on the least trauma and bulged into the instrument. Superficial erosions were seen in 2 cases but never ulceration—a pathological curiosity in all gonococcal inflammations. A frankly purulent discharge (hæmorrhagic on two occasions) was seen between the infiltrations on the rectal mucosa. There was no obvious involvement of anal canal in spite of the fact that gonococcal pus was present at the anal orifice.

Subacute inflammation was present in the majority of my cases and in 64% the disease was symptomless, an examination being requested because of anal warts or because the sexual partners had contracted a gonococcal urethritis. 40 in my series had noticed mucus or mucopus (occasionally hæmorrhagic) on the stools. Those with symptoms complained of moisture or itching in the region of the anus and, as already mentioned, acute symptoms due to perianal or ischio-rectal abscess, fistula and occasionally fissuring due to condylomata acuminata, were observed. (Painful fissuring, in my experience, is much more frequent in association with primary and early secondary lesions of syphilis.) Proctoscopy in the subacute phase of the disease shows more changes in the anal canal than rectum. Patchy areas of redness or more conspicuous submucous infiltrations, red or pale in colour, are seen on and between the columns of Morgagni, being especially well marked at the anorectal junction. Submucous infiltrations, pale in colour, are also seen on the rectal mucosa and I have occasionally observed their surface to be granular. Small superficial indurated areas are occasionally palpated in rectum and anal canal. There is an excess of adherent mucus on the mucous membrane of both the rectum and anal canal and occasional streaks (rarely clumps) of mucopus.

Complications.—Gonococcal inflammations in the subepithelial connective tissue of rectum, anal canal and skin of anus may cause local areas of induration which may either resolve or suppurate to cause perianal or ischio-rectal abscess with or without the subsequent development of fistula. 8 of my cases, at the first visit, were suffering from fistula and 3 of these had undergone surgical treatment. Gonococci were demonstrated in the discharge and all cases responded to specific treatment; no cases developed abscesses or fistula during treatment. It is interesting to note that 6 of Stühmer's cases developed abscesses and in 1 gonococci were demonstrated in the discharge five months after incision.

Condylomata acuminata, due to a concomitant virus infection, are present more frequently in anorectal than in urogenital gonorrhœa which is possibly explained by the fact that the anal canal is more liable to trauma than the urethra. The lesions, situated on the skin of the anus or in the anal canal as far as the anorectal junction, occurred in 40 (24%) of my cases and were the most frequent complication.

Superficial fissuring was only observed in 3 cases, all in association with condylomata acuminata.

The only blood-borne complication was arthritis which occurred in 2 cases, 1 with a positive complement-fixation test on the blood serum and in all probability gonococcal, and the other with a negative blood test and no doubt due to pleuropneumonia-like organisms or a virus.

Pathology.—During the last ten years I have studied the minute pathology of gonorrhœa
JULY—PROCT. 2.

It is possible that several factors play a part. First there may be a deficiency due to a lack of biosynthesis of certain vitamins in the diseased bowel; secondly the original skin lesion may be an allergic phenomenon similar to that which originally may have caused the colitis. This view is supported by the fact that in one of our cases the discharge from the ulcer was sterile for several days which was against a diagnosis of primary bacterial infection.

Thirdly, lowered resistance of the patient to infection coupled with secondary anaemia undoubtedly promotes the incidence of the severe secondary infection which so often occurs in these cases.

Bacteriology.—In our first case cultures from the lesion were sterile for some days before pyogenic infection occurred. The second case was not admitted to hospital until secondary infection was well established. Cultures from our cases showed at various times staphylococci, haemolytic streptococci, *B. proteus* and *B. pyocyaneus*.

The lesion commences as a raised red papule which rapidly breaks down to form a small ulcer. In mild cases no further spread may occur but in others the discharge becomes profuse and the ulcer rapidly increases in size. Severe pain is a predominant feature. The commonest sites for infection to occur are the limbs but any part of the body may be affected.

Unless the condition is checked the ulcer may spread until the patient is in danger of dying from toxæmia and anaemia. Spontaneous arrest may take place if there is a clinical improvement in the colitis but in severe cases energetic local and general treatment is required to halt the spread of the ulceration.

Once the infective process has been healed epithelium rapidly grows in from the edge of the ulcer but skin grafts may be required when the lesion has been extensive.

Treatment.—Severe cases must be treated vigorously; our first patient nearly died because the diagnosis was not made early enough.

If the colitis is in an acute stage (Case I) medical treatment will probably suffice. Diet should have a high protein content, a low residue and plenty of essential vitamins. Oral sulphonamides and systemic penicillin should be given but in our two cases the results from chemotherapy were disappointing. It is possible that larger amounts of penicillin, say one million units daily, might have had a more favourable result. Repeated blood transfusions are essential to combat the secondary anaemia.

If the patient does not improve ileostomy should be considered. In more chronic cases (as in Case II) surgical treatment may be required more frequently since the skin lesions may relapse with each exacerbation of the colitis. Ileostomy may be required and colectomy is often advisable. Locally we found that the treatment which appeared to stop the spread of the ulceration was excision of the whole of the edge with a diathermy knife. The result was dramatic, pain vanished, the edge of the ulcer became clean and clear-cut and the response to local chemotherapy was good. At operation the limbs should be raised to avoid considerable blood loss from venous oozing. These patients do not tolerate loss of blood and every effort should be made to prevent undue hæmorrhage. Blood transfusion is advisable during the operation. Excision with an ordinary knife might be equally satisfactory but the diathermy appeared useful in preventing blood loss. Complete excision of the whole ulcer, including the base followed by immediate skin grafting may be successful; this was done on one facial ulcer by Mr. C. L. Heanley with excellent results.

Post-operative therapy consists in repeated application of penicillin sulphonamide powder with early skin grafting if necessary.

Anorectal Gonorrhœa

By A. H. HARKNESS, M.R.C.S., L.R.C.P.

GOÑORRHŒA, syphilis and lymphogranuloma inguinale frequently involve the rectum and anal canal. Granuloma venereum and chancroid usually only cause lesions in skin of anus and skin of anal canal. I have seen also several cases of primary abacterial or Walsch urethritis (one subsequently developing Reiter's syndrome), contracted by sodomy, in which smears of the urethral discharge showed the presence of inclusions and cultures yielded pure growths of pleuropneumonia-like organisms. These organisms were isolated also in anal swabs of the only contact examined.

Anorectal gonorrhœa is a disease which is much more frequent than is generally supposed but owing to the mildness of its signs and symptoms it is often overlooked.

The disease may be primary or secondary. Secondary manifestations occur chiefly in women with primary urogenital involvement and in little girls with vulvo-vaginitis, the

Anæsthesia in Babies and Children

By R. W. COPE

DUBOIS and others have shown that from birth to puberty the metabolic rate is higher than at any other time during life, and is far higher than might be expected for the size of the organism. Running parallel with the curve of metabolic rate is that of oxygen demand and reflex irritability. Apprehension and fear are potent sources of raising the metabolic rate and it is by suitable premedication that the metabolic rate is reduced.

Premedication.—The value of bringing a child asleep to the operating theatre region is inestimable both to the child himself and to his parents. Let your own human feelings of sympathy for other people's fears be shown when you first approach a child about to have an anæsthetic. There are efficient methods now available to overcome those natural fears on the part of the patient, and briefly they are resolved into the following methods:

The rectal route.—*Paraldehyde:* The dose is $\frac{1}{4}$ to 1 drachm per 14 lb. (3 to 4 c.c. per 6.3 kilos) of body-weight in a 10% solution of normal saline, and should be given forty-five minutes pre-operatively. The sleep obtained after twenty minutes is very deep, and there is a marked diminution in the amount of anæsthetic drug which is necessary later. The post-operative sleep is quiet and will tide the child over the first few hours of pain arising from the surgical wound. Other methods of inducing pre-operative sleep are well known and will be only briefly mentioned:

By mouth: The oral barbiturates, such as nembutal or seconal.

By injection: The intravenous barbiturates, whose use may be limited only by the size of the patient's vein and his natural dislike of the prick of the needle from a strange doctor.

There is, however, one method of premedication by injection to which more attention might usefully be paid. This is by the administration of the opiates, morphia and scopolamine. Magill and Rowbotham, amongst many others, have described their effects. Bearing in mind the way in which morphia and hyoscine obtain sedation by a lowering of the body's metabolic rate, it can be appreciated how a child might respond particularly well to such a drug. The dose recommended has been calculated on a body-weight basis at morphia 1/30 grain per stone (2 mg. per 6.3 kilos) and scopolamine 1/1000 grain per stone (0.06 mg. per 6.3 kilos).

Induction and maintenance of anæsthesia.—Because the high metabolic rate has been lowered by premedication it is important to choose a method of anæsthesia which carries an adequate supply of oxygen. This fact has been recognized for many years but it is worth stressing lest there should become established some agent such as nitrous oxide which, if used without an adjuvant drug, may cause a dangerous degree of anoxia in the child.

It is true that nitrous oxide with minimal oxygen is employed in dental extraction clinics for children everywhere with great success, and yet I cannot help thinking that I am witnessing stages of asphyxia rather than anæsthesia when such a method is used. I believe the success of the method lies in the shortness of the operation.

Again during the start of an anæsthetic on an ill child he may change rapidly from a person who is breathing quietly and easily to one who has ceased to breathe, who passes quickly through the intense lividity due to respiratory obstruction to a flaccid, pale grey infant with dilated pupils, whose life is slipping quickly away. All these changes take place in a short space of time so that to the need for adequate oxygenation must be added the old-established fact of maintenance of a perfect airway.

For induction, therefore, it has seemed to us at Great Ormond Street that there is nothing safer than ethyl chloride or divinyl ether (vinesthene) sprayed on to an open or semi-open mask.

from biopsy material obtained by means of a punch (E. T. C. Milligan) from rectal mucosa, anal mucosa and skin of anal canal of 9 of my cases.

Rectum.—Several specimens show areas of disorganization and degeneration of the columnar mucus-secreting epithelium both on surface and in crypts of Lieberkühn and in some areas it is destroyed entirely with exposure of the subepithelial connective tissue. In the subepithelial connective tissue there is engorgement of capillaries which are surrounded by a cuff of polymorphs, lymphocytes, plasma cells and monocytes. Inflammatory cells are too numerous to show any evidence of exudate. Gonococci, chiefly extracellular in position, are seen in the necrosed mucous membrane. Intracellular organisms are seen more frequently in the subepithelial connective tissue and are particularly numerous beneath the necrosed mucous membrane. Their number diminishes as one approaches the muscularis mucosae and organisms were never seen in or beyond this structure.

Anal canal.—No changes are observed and no gonococci are seen in the stratified cuboid or modified squamous epithelium of anal canal, although the tissue reaction in the subepithelial connective tissue of the anal canal and the presence of gonococci both intra- and extra-cellular in position was similar to that seen in the rectum.

These investigations show that the portal of entry of gonococci in anorectal infections is the columnar epithelium of the rectum and that involvement of the subepithelial connective tissue of the anal canal is secondary. How high the infection travels by the subepithelial or surface route I do not know but Gant (1923) and Cress (1917) state that the inflammatory process extends upwards to involve the sigmoid and descending colon and the only evidence brought forward to support this is that of Cress who described a case "with tenderness on deep pressure over the left lower quadrant of the abdomen". Our opinion is that the infection never goes higher than the rectum but we hope to verify this by an examination of biopsy material from the sigmoid flexure of our next case.

Diagnosis.—Diagnosis depends on identifying gonococci by Gram's method in smears of the discharge or streaks of mucus. Smears, in my opinion, which is perhaps unorthodox, are superior to cultures in these cases as they are in urogenital infections. It is an easy matter, however, in certain cases, to obtain pure cultures of gonococci since the normal flora appear to be absent.

Proctoscopy is unnecessary for diagnosis in quite a large percentage of cases in which gonococcal pus is either present at the anal orifice or forced there by evertment, two or three times, the margins of the anus. Failure in diagnosis by this method demands proctoscopy and several slides are made of any suspicious secretions in rectum and anal canal. I have also had several cases in which a diagnosis was only made after an examination of mucus or pus on the stools.

The gonococcal complement-fixation test on the blood serum is, in my opinion, rarely helpful in diagnosis of primary anorectal disease as it was negative in 90% of my cases.

Differential diagnosis.—Granular proctitis is perhaps the only rectal lesion which may be confused clinically with gonorrhoeal proctitis. Both conditions cause a discharge but in granular proctitis the changes in the mucous membrane are much more marked in extent and intensity.

Treatment.—In all gonococcal infections I prescribe, in the first place, sulphonamide therapy (sulphathiazole or sulphadiazine 1 gramme six-hourly for five days) in view of the dangers of masking the development of a concomitantly acquired syphilis. Such a precaution is particularly important in the treatment of anorectal gonorrhoea as the rectum or anal canal is frequently the site of primary syphilis as is shown by the fact that in my series of 168 cases the Wassermann and Kahn reactions were positive in 60 (35%).

Penicillin, used only when the condition is sulphonamide-resistant, may be given parenterally (either one injection of 300,000 units in a delaying vehicle or five injections of 40,000 units two-hourly) or orally in tablets containing 20,000 units in 0.5 g. of disodium citrate (6 doses of 3 tablets three-hourly).

If the child appears cyanosed before induction starts, as for example in the case of a child with bronchopneumonia yet requiring an acute mastoid operation, then an open mask induction of ethyl chloride and ether followed by nitrous oxide, oxygen and ether will carry that child safely through the operation.

It is this use of ether, with its absence of post-operative complications, whether they be pulmonary or vomiting, which has kept this agent as the one most commonly used at Great Ormond Street.

Congenital hypertrophic stenosis and other congenital abdominal abnormalities needing laparotomy (for example exomphalos and duodenal atresia). At Great Ormond Street Rammstedt's operation is performed by one surgeon using local infiltration alone and he has used this method for many years. His mortality and morbidity results are first class. It is then found that three other surgeons, including the senior surgeon to the hospital point to a list of successful operations, equally long, performed under general anaesthesia. When general anaesthesia is used ether or divinyl ether or a mixture of the two using nitrous oxide and oxygen as its vehicle has been used. The same description applies equally to those other abdominal conditions requiring laparotomy. That of duodenal atresia must be mentioned again; it will be remembered that this operation must always be of long duration and necessitates the performance of a gastro-jejunostomy when the primary condition has been verified. These facts made me first realize that the baby's condition might be improved if the depth of the anaesthesia could be lightened during the course of the operation and then deepened rapidly without any outward sign from the patient. In such a young baby control of the airway by a pharyngeal airway was often unsatisfactory in my hands. Glottic spasm would occur rapidly if the depth of the anaesthesia at the moment of incising the peritoneum in the epigastrium was ill-judged, and having once occurred was more difficult to overcome than in an adult. For both these reasons I began to pass a No. 00 Magill tube under direct vision, in all these babies undergoing laparotomy, as soon as surgical anaesthesia was established.

The quiet respiration which is obtained throughout an abdominal operation in an adult

FIG. 1.

by this manoeuvre is well known, and the depth of anaesthesia can be safely lightened during the performance of an intestinal anastomosis. As might be expected the same type of respiration is apparent when intratracheal anaesthesia is used on a baby.

To assist further in producing a quiet respiration in babies undergoing abdominal surgery, a method of carbon-dioxide absorption has been tried recently which indicates further trial. A few well-known types of circle apparatus for carbon-dioxide absorption have not been entirely satisfactory, perhaps due to the increase of the dead space of the patient. Stimulated by a communication from Kaye of Melbourne, an attempt was made to build a light canister for soda lime of about the same capacity as the vital capacity of a baby. At 12 months this is found to be 150 to 200 c.c. The next step was to realize that the smallest size of baby's face mask was not designed to fit the baby's face accurately. In a baby there is underdevelopment of the chin compared with the adult chin, and yet a baby's facemask is nothing more than an exact copy of an adult mask on a reduced scale. Accordingly a mask was made by hand for me by Mr. Charles King, in which there is a slight lip to the lower margin of the mask, and this will now fit snugly on to the baby's face. Similarly the breathing bag has been reduced to the size of a BLB oxygen mask (see fig. 1).

The role of curare in abdominal surgery in children.—Though ether still remains the most common agent in producing relaxation in children there are still a few conditions in which perfect relaxation with a quiet respiratory movement is difficult to obtain. Splenectomy in children of 4 years and over is not uncommon and surgical manipulations could be better assisted if there was a very peaceful respiratory movement. To produce this result, in my last 4 cases tubarine in varying doses has been used. The difference in the appearance of the abdomen as the surgeon worked to deliver the spleen from under the costal margin was striking. Exomphalos is another rare condition in which very great relaxation is needed in order that the surgeon may close the abdominal wall, a procedure as difficult as closing the abdominal wall after having returned the contents of a large diaphragmatic hernia to the abdomen. In a recent case, aged 36 hours, the mass was almost the whole liver and many coils of intestine. The body-weight was 7 lb. 6 oz. An intravenous drip was in position. It should be remembered that a blood transfusion is often necessary due to tearing of the liver surface with consequent excess bleeding. After inducing anæsthesia with cyclopropane and oxygen, an intratracheal tube was passed and the baby's canister mask reapplied. 1-mg. of tubarine was then injected intravenously. Profound relaxation without complete paralysis was obtained throughout the operation, recovery was uneventful.

Harelip and cleft palate repair.—The age at which the first operation for the complete repair of a harelip is performed is from 2 months onwards. The keynote for success in these operations lies in producing a quiet operating field for the surgeon combined with safety for the baby, and the following points are of value: (1) The use of a wide-bore intratracheal tube. (2) Careful packing of the oropharynx, preventing blood from running down into the air passages or stomach. (3) Care taken to ensure that the baby has recovered all his reflexes by the end of the operation.

At Great Ormond Street, looking at the figures for deaths on the operating table before intubation was used as a routine for these operations, it was found that in 1924, 1925 and 1929 there were 5, 4 and 6 deaths in each year. On examining the causes of death we find that the harelip cases occur in the following order: 1, 1 and 2. After intubation became routine practice the total death figures for 1939 and 1945 drop to 1 and 2, and harelip conditions do not enter into any of these cases.

In 1920 Magill first began to pass an intratracheal tube on a baby. By reason of the very small size of tube necessary, a new anxiety has arisen for the anæsthetist. This is kinking and obstruction of the tube as it passes over the dorsum of the tongue. Two types of tube designed by Magill are used by us at Great Ormond Street to overcome this difficulty. One is an ordinary rubber tube strengthened by sliding over it a thin outer rubber tube and only the single or inner tube is passed through the vocal cords. The other is a Magill armoured tube consisting of a finely coiled spring covered with rubber, to whose proximal end is attached a double funnel opening. The anæsthetic vapour is directed to the fine tube, while the broad funnel end is left open to the air. This entry and exit for the anæsthetic gases achieve exactly the same purpose as Ayre's T-piece. My own preference is to use the armoured tube for all harelip and cleft-palate operations.

Intubation.—The chief factors which have given me trouble in passing a tube through the tiny opening of the larynx are: First, the opening into the mouth may be considerably obstructed by a round knob of tissue, the freely mobile premaxilla. In order to get this mobile proboscis out of the way Denis Browne designed a special blade for the Magill laryngoscope. The curved shelf of this blade is designed to keep the premaxilla out of the way of the groove down which the tube is to pass.

My own feeling is that this blade is too large for the mouth and it is my practice to use the Shadwell laryngoscope designed by Gillespie. In order to prevent the blade falling into the cleft, or the premaxilla obstructing the groove of the instrument, it has seemed easiest to insert the blade into the right-hand corner of the mouth and to keep it there throughout the manipulation while the cords are visualized.

The anatomy of the infantile larynx.—It will be remembered that in the newborn the distance from the gums to the glottis is 2 in. and the distance from the glottis to the bifurcation of the trachea is a further 2 in.

Epiglottis: There is a marked difference in contour between the infantile epiglottis and that of the adult. In the latter the epiglottis is a leaf-like structure, quite flat in the antero-posterior plane. In the infant this is not the case, the lateral margins of the epiglottis are rolled slightly on themselves towards the mid-line. This appearance will decrease the size of the visible epiglottis even more, and this fact should be recognized when the laryngoscope is used to lift the tip of the structure forward. Then will appear the tiny opening of the larynx through which the tube must be gently introduced.

After careful insertion of the gauze packing the baby requires very little ether to keep the cough reflex abolished and the body still. It should be your aim to lighten the anæsthetic so much that by the time the tube is removed there is a vigorous cough reflex and a good cry is produced before the baby leaves the theatre.

The removal of tonsils and adenoids by dissection is still the commonest operation performed in surgery, and for that reason it is pertinent to mention the method of anæsthesia used at the Hospital for Sick Children, Great Ormond Street. At that hospital neither the technique of the operation nor of the anæsthetic has changed greatly since 1907. In that year Waugh began to dissect the tonsils and curette the adenoids under deep chloroform, administered through a Junker's inhaler. Later a change was made to deep ether, using air from a foot-bellows, or oxygen as its vehicle. The vapour is delivered to the patient's mouth by a hooked metal tube, whose design has not changed since Waugh first described the operation. The airway is maintained by placing a sandbag beneath the shoulders, opening the mouth with Waugh's gag and then the tongue is drawn firmly out of the mouth by a pair of tongue forceps held by a nurse. Throughout the operation the surgeon wishes to have the patient at a deep plane of anæsthesia with no sign at all of movement of the palate or fauces, and this level is maintained while the adenoids are removed at the end of the operation. The child is returned to bed in the semi-prone position with the tongue forceps still in place, and these are removed when the cough reflex is brisk.

Anæsthesia for major thoracic surgery.—The scope of this surgery has increased rapidly in special units and I claim no recent personal experience of this work. My colleague, B. G. B. Lucas of Great Ormond Street and University College Hospital has kindly shown me his methods. He employs the same principles of physiology and anæsthesia in children undergoing pneumonectomy or lobectomy as he would use in adults. The use of intra-bronchial suction and of carbon-dioxide absorption with controlled respiration when required, sum up the technical procedures carried out.

THE ROLE OF ANÆSTHESIA IN THE STUDY OF AUTONOMIC NERVOUS SYSTEM IMBALANCE

A few words on this subject should be included here, for it has seemed to me that anæsthetists may assist and carry out useful research in at least two major surgical conditions of children.

(1) *Congenital megacolon (Hirschsprung's disease).*—It will be remembered that the large bowel receives its motor fibres from the parasympathetic system through the right and left vagus nerves and the second, third and fourth sacral roots. The sympathetic system supplies the inhibitory fibres which are given off from the spinal cord in the anterior roots of the fifth dorsal to the third lumbar segment.

In 1912 in the *Guy's Hospital Reports* Sir Arthur Hurst began to describe a theory of imbalance between these two nervous systems as the causation of this disease. In 1939 Telford first used spinal analgesia as a possible method of cure; the explanation of this treatment lay in the fact that by giving a spinal anæsthetic injection the whole of the sympathetic supply of the colon could be paralysed, so allowing the parasympathetic to supply an uninhibited field of action. Such an injection must, of course, reach as high as the fourth dorsal segment. It is found in many cases that there is a spontaneous bowel action soon after injection and it might be thought that the colon would relapse as soon as the paralysing action of the drug has passed. But such is not the case, for normal bowel-control sometimes remains for months after the initial spinal injection.

Telford's work has been repeated and I am familiar with the work of Hawksley at Great Ormond Street. In 1944 she described 12 personal cases in detail and her results were encouraging.

(2) *Congenital hydro-ureter.*—It has been thought that paralysis of the sympathetic system may assist these massive ureters and kidney pelves to contract so that there have been attempts at injection of the splanchnic ganglia with local anæsthetic solution. Scholefield and Chivers reported 5 such cases and their results have warranted further trial. It has, however, seemed to me that paralysis of the splanchnic ganglia is obtained more accurately by injecting the drug into the theca rather than attempting to inject it into and around the ganglia themselves.

Hawksley and I have used nupercaine 1/1500 as the spinal anæsthetic drug. The dosage has been determined by Howard Jones' method of measurement of the spine. Having determined the dose it has been my practice to make the injection in the third to fourth

lumbar space with the child sitting up, and from the moment of starting the intrathecal injection the patient is held vertical for the next fifty seconds. After this time a change is made to a 15 degrees Trendelenburg tilt and this is maintained for the next fifteen minutes. During this time the child is carefully examined for the height of skin anæsthesia developing, if this does not reach at least as high as the nipple line, it is reasonable to suppose that the sympathetic supply of the colon has not been completely paralysed. The injection should then be repeated in 48 hours' time.

This brings to an end the description of some points of anæsthesia you may find applicable in your own practice. For my own part I would especially like to thank my colleagues at the Hospital for Sick Children, Great Ormond Street, both Surgical and Anæsthetic, those who have gone before and those who in their varying capacities still labour there. All have taught me some of that quality of kindness in approaching that most important person in the operating theatre, the little child.

Dr. T. Cecil Gray considered that Dr. Cope was right in his advocacy of intubation. Even in tiny infants this undoubtedly conduces to a smoother and more trouble-free anæsthesia. Provided it was performed with extreme gentleness and with great care in the adequate sterilization of laryngoscopes and tubes it was not followed by harmful results. It appeared that in the type of closed circuit apparatus for children which Dr. Cope had described the soda-lime canister was situated directly above the facepiece and there might be a danger of inhalation of irritant dust. Dr. Gray asked whether Dr. Cope took any special precautions to ensure that this did not occur. In his experience children tolerated curare well provided one adhered to a dose for weight scale—2 mg. per stone (0.3 mg. per kg. body-weight).

Dr. Rex Binning admitted the advantages of employing parenteral premedication in children but stressed the need for some rule of thumb premedication for the routine tonsil list when it was often impossible for the anæsthetist to see each patient beforehand. He himself used seconal but post-operative restlessness was sometimes troublesome.

Dr. B. Kenton said that on the question of intubation each case had to be decided on its merits depending on the type of operation, the state of the child, &c. One had to remember, however, that the tidal volume in children was sometimes smaller than the sum total of physiological plus mechanical dead space. With intubation therefore the dead space is considerably decreased and thus tidal exchange facilitated.

Ayre's method was not mentioned though it was of great assistance in preventing CO₂ accumulation and obviating resistance to respiratory efforts. It would be interesting to know how it compared with Dr. Cope's CO₂ absorber.

Dr. Kenton drew attention to the use of seconal as a basal narcotic or the principal anæsthetic agent for minor surgery in children as advocated by Poe and Karp in America (*Current Researches in Anæsthesia and Analgesia*, 1946, 25, 152). The authors used doses of seconal of 0.1 to 0.14 grain per pound (6 mg. to 8.5 mg. per half kilo) of body-weight (with a maximum of 6 grains) given orally or rectally (in 5 c.c. of tap water) thirty to sixty minutes before the operation. Dose was decreased in anæmic and lethargic children. Nitrous oxide and oxygen in equal parts was used as a supplementary agent. The method was found useful by the speaker for such procedures as encephalography and ventriculography in children.

Dr. R. E. Pleasance stated that he had hoped to hear Dr. Cope's views on anæsthesia for the operation for strabismus in children.

Personally he had made use of small doses of curare, 5 mg. or less, and light anæsthesia. Relaxation of the eye muscles was almost immediate, and added materially to the ease with which the operation could be performed. Furthermore, the effect of the curare on the eye muscles lasted for some time after this had worn off in other parts of the body, thus allowing the traumatized muscles a valuable period of rest.

Small doses were essential, otherwise the muscles became too relaxed, and the surgeon complained that the eye felt like a ball of cotton-wool.

Dr. O. P. Dinnick found nembutal and seconal to be unreliable premedicants chiefly because digestion of the capsule is frequently inhibited—presumably owing to the child's anxiety. Splitting the capsule and disguising the taste with jam or honey gave better results, but he had largely abandoned these drugs in favour of sodium thiopentone administered rectally. The ordinary 5% solution was used and presented several advantages over other drugs administered rectally, namely, small bulk of solution, ease of preparation. A test for decomposition was unnecessary, and the drug was inoffensive. The dose was 1 gramme per 50 lb. body-weight (23 kilos)—slightly less in wasted or over-fat children—and was given an hour before operation using a record syringe and a very fine catheter inserted as high in the rectum as was comfortably possible. A preliminary bowel washout was not essential as it was found that with a very slow rate of injection the small amount of solution used seldom acted as an enema, especially if the buttocks were approximated with a strip of elastoplast.

He would like to stress that in infants the possibility of post-operative hyperpyrexia was a very

After careful insertion of the gauze packing the baby requires very little ether to keep the cough reflex abolished and the body still. It should be your aim to lighten the anaesthetic so much that by the time the tube is removed there is a vigorous cough reflex and a good cry is produced before the baby leaves the theatre.

The removal of tonsils and adenoids by dissection is still the commonest operation performed in surgery, and for that reason it is pertinent to mention the method of anaesthesia used at the Hospital for Sick Children, Great Ormond Street. At that hospital neither the technique of the operation nor of the anaesthetic has changed greatly since 1907. In that year Waugh began to dissect the tonsils and curette the adenoids under deep chloroform, administered through a Junker's inhaler. Later a change was made to deep ether, using air from a foot-bellows, or oxygen as its vehicle. The vapour is delivered to the patient's mouth by a hooked metal tube, whose design has not changed since Waugh first described the operation. The airway is maintained by placing a sandbag beneath the shoulders, opening the mouth with Waugh's gag and then the tongue is drawn firmly out of the mouth by a pair of tongue forceps held by a nurse. Throughout the operation the surgeon wishes to have the patient at a deep plane of anaesthesia with no sign at all of movement of the palate or fauces, and this level is maintained while the adenoids are removed at the end of the operation. The child is returned to bed in the semi-prone position with the tongue forceps still in place, and these are removed when the cough reflex is brisk.

Anaesthesia for major thoracic surgery.—The scope of this surgery has increased rapidly in special units and I claim no recent personal experience of this work. My colleague, B. G. B. Lucas of Great Ormond Street and University College Hospital has kindly shown me his methods. He employs the same principles of physiology and anaesthesia in children undergoing pneumonectomy or lobectomy as he would use in adults. The use of intra-bronchial suction and of carbon-dioxide absorption with controlled respiration when required, sum up the technical procedures carried out.

THE ROLE OF ANAESTHESIA IN THE STUDY OF AUTONOMIC NERVOUS SYSTEM IMBALANCE

A few words on this subject should be included here, for it has seemed to me that anaesthetists may assist and carry out useful research in at least two major surgical conditions of children.

(1) *Congenital megacolon (Hirschsprung's disease).*—It will be remembered that the large bowel receives its motor fibres from the parasympathetic system through the right and left vagus nerves and the second, third and fourth sacral roots. The sympathetic system supplies the inhibitory fibres which are given off from the spinal cord in the anterior roots of the fifth dorsal to the third lumbar segment.

In 1912 in the *Guy's Hospital Reports* Sir Arthur Hurst began to describe a theory of imbalance between these two nervous systems as the causation of this disease. In 1939 Telford first used spinal analgesia as a possible method of cure; the explanation of this sympathetic supply of the colon could be paralysed, so allowing the parasympathetic to supply an uninhibited field of action. Such an injection must, of course, reach as high as the fourth dorsal segment. It is found in many cases that there is a spontaneous bowel action soon after injection and it might be thought that the colon would relapse as soon as the paralysing action of the drug has passed. Unilateral Bony Swelling of the Maxilla

By Professor R. W. SCARFF, M.B., and D. GREER WALKER, M.B., M.Dent.Sc., F.D.S.

THIS paper presents some facts concerning a unilateral, bony swelling of the maxilla (figs. 1, a, b, c).

(a)

(b)

(c)

FIG. 1.

Different investigators have considered the lesion to be (I) a local or focal osteitis fibrosa; (II) a neoplasm; or (III) a hyperplasia.

(I) Knaggs (1926), who favours the diagnosis of osteitis fibrosa, says that: (a) The disease commences during childhood or during the growing period, and if left to itself may last a lifetime. (b) There is reason to believe it may become stationary or even go on to a spontaneous cure. (c) There is a complete absence of any periosteal bony deposit. (d) The affected bone is enlarged giving the impression of a swollen bone. "The resemblance to the normal bone remains, but the salient points that give the latter its 'expression' disappear." Davis (1941) differentiated between focal osteitis fibrosa and a tumour as follows: In focal osteitis "the enlargement is confined to the outer surface of the alveolus and its inner surface shows no swelling. On the other hand, a tumour expands the whole alveolus, forming more or less a globular tumour in the palate. This distribution of the swelling is a distinguishing feature between a tumour and osteitis".

(II) That this bony lesion of the maxilla is a neoplastic process can be concluded from the work of Thoma (1944), Phemister and Grimson (1937), and Furedi (1935). The term osteofibroma seems to be generally accepted. Phemister and Grimson in describing 13 cases of fibrous osteoma of the jaws (4 in the maxilla, 8 in the mandible, and 1 in both bones) say that, in general, the tumours are slow-growing, and when starting in childhood tend to become stationary in adult life. No case has been

real danger, and he would warn against the excessive use of mackintoshes and towels on the operating table, and a surfeit of wrapping and clothes post-operatively.

It was a common practice with adults to spray the larynx with local anæsthetic to facilitate endotracheal anæsthesia. He had found this technique of equal value for children and the cleft palate infants.

Dr. Cope had rightly stressed the difficulty of intubating infants with cleft palates. Dr. Dinnick suggested that if twenty minutes have been spent in two or three vain attempts at intubation, it is wise policy, incurring no loss of prestige, to cancel the operation for that day.

In his experience infants in the first forty-eight hours of life withstand operation and anæsthesia surprisingly well—it is in the ensuing few weeks until their birth-weight is regained that they are such poor risks. He would like to know if the greater experience of Dr. Cope confirmed this view.

He would hesitate to criticize Dr. Cope's CO₂ absorption technique without having seen it used, but felt there must be—as in all absorbers—a certain resistance to respiration and a significant amount of "dead space". His own experience was that infants tire quickly if they have to breathe against even the slightest obstruction, or were allowed to build up CO₂ under the mask. He therefore avoided the use of a facepiece as much as possible, preferring to maintain anæsthesia by oral insufflation or an Ayre's "T" piece if an endotracheal tube were used.

Dr. A. H. Galley said that it was a continual source of wonderment to him that babies and small children so often maintained an adequate airway when no pharyngeal airway was used at all; the supporting finger must not, however, migrate from the region of the symphysis mentis as pressure on the soft tissues of the submental region readily obliterated the airway. When administering spinal analgesia to babies (for therapeutic reasons) he had discarded lumbar-puncture needles. He mounted a needle as for venepuncture, advanced until he felt the needle-tip pierce the ligamentum flavum, withdrew the plunger to verify that the needle was well in the subarachnoid space and then made the injection.

Dr. H. Bruce Wilson said that he was pleased to hear that Dr. Cope underlined the prime importance of the maintenance of a clear airway during anæsthesia in children, and the necessity for adequate sedative premedication. He agreed that if a good airway could be maintained without intubation, that was to the good, but if difficulty were encountered he had no hesitation in intubating children of any age. The question of premedication had been exercising the attention of himself and his assistants at the Royal Aberdeen Hospital for Sick Children, and they had employed nembutal, rectal pentothal, paraldehyde, omnopon and scopolamine in an endeavour to determine which was most satisfactory. They had much satisfaction from oral nembutal and their success with this, compared with the experience of some of the other speakers in the Discussion, was perhaps due to the fact that they gave a small dose of nembutal the night before operation in addition to the dose before operation—probably the first dose had some "hangover" effect and made more certain of the action of the second dose. The drawback to nembutal was the period of restlessness and excitement during recovery. For this reason they had tried rectal pentothal and, being a shorter acting and more rapidly excreted drug, they found the period of post-operative restlessness very much more transient. The drawback to rectal pentothal was the need for close supervision and for a competent nursing staff.

Dr. J. D. Laycock asked if Dr. Cope could tell him how to give an anæsthetic to a child for a lipiodol bronchogram with due regard to explosive risks.

Dr. R. W. Cope in reply said: Dust from the close proximity of the small canister to the face mask was a real danger recognized at the start of its use. The speaker's own baby was induced to breathe into the new canister-mask in the early stages of experiment, and it was found that the baby's nose, lips and tongue were soon covered with a fine layer of lime dust. This dust formation had been prevented by taking care to add about 2 teaspoonfuls of water to the soda lime immediately before use. No further precautions had been necessary.

Ayre's method and the speaker's canister had not been compared either clinically or experimentally for an evaluation of the alveolar carbon-dioxide accumulation.

The suggestion of using small doses of curare to paralyse the eye muscles during operations for strabismus would seem to be valuable and the speaker was grateful for being told about the idea and the possibility of making the eyeball like cotton-wool would be borne in mind.

With regard to general anæsthesia for lipiodol bronchograms conducted in the X-ray department, there had been several techniques tried at Great Ormond Street. For some months the Anæsthetic Registrar had found the following method entirely satisfactory. Induction and maintenance were carried out with gas, oxygen and trilene. A Magill intratracheal catheter was passed through the mouth, and then the dose of lipiodol was introduced with syringe and record needle by injection through the wall of the tracheal tube. Anæsthesia could be maintained without anxiety during this manœuvre and while the pictures in different positions were being taken.

The cases seen early in life presented extremely healthy mouths as might well be expected. Those seen later had had teeth removed at various stages, on account of simple caries, and not for any gross infection. One case, aged 27, dates the swelling since the age of 7; at the age of 17 all his teeth were removed except an upper third molar (which presumably was unerupted) on account of caries.

The last clinical observation is the natural arrest of the condition. It is agreed that these lesions are arrested when the growth of the maxilla is complete. This is borne out by clinical evidence and is an important matter as far as treatment is concerned. We have not been able to follow these cases over a sufficiently long time to ascertain if they enter the realm of Paget's or leontiasis conditions as suggested by some authorities. Our view is in common with that of others who do not regard the lesion as belonging to either of these conditions.

X-ray examination is of the greatest value in the diagnosis of these conditions. It must, however, be stated that apart from X-ray and histological examinations no other special investigation revealed any data of value.

Histology.—In this group of swellings of the maxilla, histologically one must consider three different conditions:

A. True tumour: Rarely there occurs a true tumour in this region which appears to be locally invasive. This has been described by one of us (R. W. S.) previously. Its true nature is not yet determined, and for the present it must remain anonymous. This condition shows a characteristic histology: a cellular spindle-cell stroma, the cells of which are arranged around areas of calcification and areas of bone formation. It is possible that this condition is an atypical form of cementoma, but its behaviour is somewhat different. Although encapsulated in the early stages, if left alone it will invade and destroy the bones. The tumour appears to be radio-sensitive.

B. A lesion of the bone akin to, if not identical with, Paget's disease: There were 2 such cases in our series and fig. 2a shows the typical appearances, i.e. irregular bone formation, marked osteoclastic activity and a loose connective tissue stroma. This condition, too, would appear to be progressive.

C. Osteofibrous enlargements: This group contains 7 of our 9 cases. Although this lesion would appear to constitute an entity its nature is still in doubt. Histologically the condition shows fibrous tissue which varies considerably in cellularity in different cases and in different portions of the tissue from the same case. The bone present varies in amount and much of it is fully-formed lamellar bone with a trabecular arrangement. Fig. 2b shows a low-power view of such a case and gives some idea of the variation in cellularity of the fibrous tissue. Figs. 2c, d, are high-power views showing the great variation, and it will be noted that the bone is fully-formed lamellar bone.

The nature of these masses is in considerable doubt. They have been described by various authors as: chronic osteitis, localized osteitis fibrosa, Paget's disease, osteofibromata and hyperplasia. Chronic osteitis is not supported by the histology as the lesion shows no evidence of inflammatory infiltration. Even if one admits that localized osteitis fibrosa (Knaggs) is a positive entity the appearances of these masses do not correspond with this condition.

They show little osteoclastic activity; cyst formation is uncommon and much of the bone that is laid down is fully formed lamellar bone. The same is true of Paget's disease; the typical cases show none of the features of this disease. But in contradistinction to true tumours they are not localized and they become static after a certain stage of growth has been reached. Many workers have stated that there is frequently a history of trauma but that has not been our experience. We should prefer to regard the condition as a developmental hyperplasia possibly associated with trauma and analogous to osteochondritis juvenilis of the cartilage bones.

recorded which has become malignant. Blood calcium and phosphorus were determined in 4 cases and found to be normal. The lesion appears to be a true neoplasm and not a form of osteitis fibrosa, hyperostosis or chronic inflammation.

Thoma makes the following comments on fibro-osteoma: "This benign osteogenic tumour heretofore has been described under the name of localized osteitis, osteofibroma, ossifying fibroma, fibrous osteoma, or osteoid osteoma. The reason for all these names is easily understood when we consider the varied appearance and the changeable proportion of soft and hard tissue . . . I feel now that the terms localized osteitis fibrosa and osteodystrophia fibrosa are not in keeping with the pathological condition found. In the first place there is no evidence of osteitis as seen in Paget's disease, and second, the term fails to designate that the disease is an expansive new formation."

(III) It is perhaps a little unfortunate that most authorities have grouped this so-called tumour with similar though not identical lesions occurring in the mandible. This no doubt accounts for the multiplicity of terms. Furedi has stated that the maxillary tumour is somewhat of a different nature; and in speaking of osteofibromata of the maxilla questions whether they are true tumours or hyperplasias of probable inflammatory origin. In 1913 Westmacott reviewed 8 cases under the title "Chronic Hyperplasia of the Superior Maxilla". The ages of the patients ranged from 17 to 30 and he noted the following details: (1) The swelling is limited anteriorly by the premaxilla; (2) the alveolus is first affected and then the outer wall of the maxilla towards the malar process.

This brief review of the literature reveals the confusion that exists in describing these conditions. In this paper we make the following observations on 9 cases:

Age, sex and incidence.—The condition would definitely appear to begin in childhood. 5 cases were seen in patients under 20 years of age when the lesion had attained a considerable size; 3 under 30 years of age and 1 case aged 52. 5 of the cases occurred in female patients. It is extremely difficult to assess the degree of incidence. In reviewing several hundred cases of tumours our total of 9 cases over some ten years is low. There is no evidence of any hereditary tendency.

History.—No history of trauma could be obtained. This particular lesion is symptomless; many of the cases present themselves solely for cosmetic reasons or because in early life the parents notice the swelling, or when the swelling interferes with the making of a denture.

Examination.—The condition presents a definite clinical entity. The lesion appears to begin in the buccal aspect of the upper alveolus opposite the first molar and second premolar tooth—it extends in an upward direction involving the outer antral wall. This wall appears to become thickened and posteriorly the tuberosity is also involved. There is no anterior spread beyond the canine tooth. Later the extension occurs palatally but before this is discernible the "bending" of the medial raphe can be noted with its maximum concavity opposite the site of origin. The anterior part of the mid-line is not altered as in the more extensive bony lesions involving other facial bones. There is no encroachment on the nasal passage, fronto-malar synchondrosis, or zygomatic arch. The zygomatic bone shows involvement in the more extensive lesions as also does the anterior part of the floor of the orbit which may be slightly raised. On the affected side the eye will appear to be on a slightly higher plane but there is no disturbance of vision; the buccal mucosa is normal. The swelling is bony, hard, and painless; it is not well defined, and the bone rather gives the appearance of a "swollen bone". In only 1 case was the occlusal plane of the teeth affected. In this the maxillary teeth were displaced palatally and downwards. No alteration in size and shape of the teeth was noted, but slight spacing of the teeth has been noticed in the larger swellings, and the teeth themselves showed little evidence of infection.

case with Paget's disease. The lesions as they affect the palate and teeth have markedly distinguishing features as can be seen in figs. 3a, b, c. Of the more localized lesions producing a swelling of the maxilla we must consider soft tissue, dental and bony lesions. Soft tissue tumours (as for example carcinoma or mixed parotid tumours involving the antrum in whole or part) are easily differentiated from these bony lesions. Radiographs will exclude all soft tissue tumours and most tumours of dental tissues. The large odontomes are composed of calcified dental tissues. The appearance of these again shows characteristics which differ from the condition we have under consideration. The last group we have to exclude comprises the true osteomata, a tumour described by one of us previously (Scarff, 1947), and perhaps some early pagetoid cases. The true osteoma is more of an encapsulated tumour with all its inherent characteristics. It does not conform with the shape of the maxillary bone tending to lessen its marks of "expression". The tumour described by R. W. S. can also be excluded with the clinical difference that it is more localized in the early

(a) Leontiasis ossea.

(b) Paget's disease.

(c) Osteofibrosis.

FIG. 3.

stages with a later tendency to invasion, and to recurrence following removal. Some of the early cases of Paget's disease seen by us have shown alveolar changes which are distinct. These have been described by Sir Frank Colyer. One case, however, showed some swelling of the malar bone but again, we repeat, no other pathology conforms with the anatomical arrangement we have outlined. The recognition of this lesion as a definite clinical picture is borne out by the history, examination, and special investigations.

Treatment.—The treatment is usually conservative. There is no need for radical surgery in view of the nature of the lesion. Its correction for cosmetic reasons is justifiable; again, the making of a denture may necessitate some correction of the deformity. In either case a surgical trimming is all that is necessary.

We are indebted to Professor Kilner, Messrs. R. Vaughan Hudson, E. W. Peet, and J. W. Schofield for permission to include some of their cases, and to the radiologists of the Middlesex Hospital, particularly Dr. Campbell Golding, for their interest and help.

This paper is published by permission of the Director General of Medical Services of the Ministry of Pensions.

Differential diagnosis.—We have already outlined the anatomical position and this excludes the leontiasis ossea group, which is not confined to the maxilla alone as is the

or of the face alone in which the condition of the teeth was not reported or in which accelerated eruption but not tooth-enlargement was noted, and a few others in which the teeth appeared normal at the time of examination.

CASES OF UNILATERAL HYPERPLASIA OF THE FACE IN WHICH TOOTH-ENLARGEMENT WAS REPORTED

There appears to be no record of such a case before 1863. In that year Friedrich published under the title "Unilateral congenital head-hypertrophy" the description of a girl of 16 in whom there was some unilateral enlargement, present from birth, of the face below the eyes, including chin, cheek, lips, tongue, tonsil and ear. He noticed pigmentation and more hair on the enlarged cheek, and found no difference in the bones except inside the mouth, where the alveolar processes on that side were much wider. Of the teeth he said: "The teeth of the right upper jaw, in particular degree the canine and the cheek-teeth, are much thicker, longer, and broader than on the left side . . . also in the lower jaw the teeth are more strongly developed than on the left." He observed that the teeth on the large side encroached across the apparent mid-line and that the gum was hyperplastic in both jaws on that side. Friedrich appended notes of another case which Heumann had seen seven years before but had not made known. This was a boy of 5 years in whom, since birth, there had been one-sided enlargement of the cheek, both jaws, and tongue. The teeth on that side were described as double the size of the others and wider apart, and the parents had noticed that the first teeth had erupted several weeks earlier on the large side than on the smaller.

There is a little uncertainty to what extent the findings as regards tooth-enlargement in this and some other cases are valid, for the following reason. It will be shown later that the eruption of the permanent teeth is sometimes so precocious on the enlarged side that by the age of 5 years the permanent teeth may be seen in the mouth on that side while the deciduous teeth are still in place on the other. To an observer who expected to find enlargement it might not be apparent that the difference in size on the two sides was due to this cause.

Passauer (1866) (fig. 1) found the size of the left cheek and the left side of the lips and tongue greatly enlarged in a boy of 11 years, and the teeth on the same side larger and spaced further apart. The left alveolar processes of the jaws were also wider. The mention by this author that the upper canine tooth was not only much larger on the left but was of

FIG. 4.—Cast of mandible of Barwell's case.

abnormal shape is strong evidence in favour of his view that the tooth was enlarged, though the permanent canine on the other side may well have been still unerupted.

The next case was recorded by Barwell (1881) (fig. 2), a boy of 7 years. His reference to the teeth was ambiguous: "The baby teeth (on the left) form a strange contrast with the great incisors and molars on the right." However, the boy died of secondary hæmorrhage following an operation for ligation of the common carotid artery, and his skull was preserved in the museum of Charing Cross Hospital until about 1923. Keith (1923) studied it before its disappearance and had casts made which unfortunately were destroyed by bombs in 1941 (figs. 3 and 4). It was perhaps the only skull in which the condition could be studied, and Keith considered the bony development on the large side closely to resemble that found in acromegaly.

Examination of the few drawings and photographs remaining in the possession of Sir Arthur Keith which he kindly placed at my disposal enabled me to form an opinion as to

JOINT MEETING WITH THE SECTION OF ODONTOLOGY OF THE BIRMINGHAM
MEDICAL INSTITUTE, AT BIRMINGHAM

A Dental Abnormality of Size and Rate

By MARTIN A. RUSHTON, M.D., F.D.S.

THE size of the teeth and the rate of their development and eruption are matters of considerable importance in dental practice and attributes which we should often like to alter. Unfortunately they are characters very insusceptible to any influences which we may exert, and this applies particularly to tooth size. It is of some interest, therefore, to study a condition in which a striking abnormality of tooth size occurs, accompanied by an abnormality in the rate of development and by certain related disorders in the neighbouring tissues. Let us consider a moment what are the factors which are able to influence the size of teeth. There are genetic factors connected with family and race. Then in the direction of smallness we have the effects of radium and X-rays, certain genetic disorders affecting the mesodermal part of the tooth as in osteogenesis imperfecta and hereditary opalescent dentine, and perhaps some local inflammatory disorders such as osteomyelitis. In addition, in some forms of pituitary dwarfism of early onset the teeth may be on the small side of normal. In the direction of largeness the only suggestion of any factor other than genetic comes from the experimental work of Putnam, Teel and Benedict (1929) in which an alkaline extract of anterior pituitary gland was injected into 11-weeks-old puppies. The teeth were said to be larger than in the control and though unfortunately no measurements were published some of them certainly appear so in the illustrations. Downs (1930) in a similar experiment in which only slightly older puppies were used found no enlargement on measurement although other expected effects were obtained.

As regards rate of development of the teeth and rate of eruption we know of more factors. Clinically it appears that these rates can be accelerated by additional thyroid or anterior pituitary hormone and retarded by deprivation of these substances, and there is considerable experimental support for this belief. In addition there is a striking group of cases showing dental as well as other precocity in association with hyperplasia or neoplasms of the adrenal cortex.

The cases of Ogle (1865 *a, b*), Linser (1903), Gordon and Browder (1927), and Richardson and Doll (1939) and others show that the dental precocity may correspond to many years but is usually less than the apparent bone-age. The teeth are, of course, of normal size and the affection bilateral. It must be added that there are also cases of juvenile adreno-genital syndrome in which the state of formation and eruption of the teeth is nevertheless normal, such as that cited by Thoma (1943), suggesting that we are concerned not only with the presence of circulating hormone-like substances but also with considerable variations in the reactivity of the dental system towards them. It is unfortunate, however, that in the majority of the many cases of the syndrome reported the condition of the teeth is not described. The same is true of pineal gland tumours and other varieties of precocious development on record. We are all aware, of course, that precocious dentition may occur also to some extent in children who are in all other respects apparently normal, and that there is a difference between the means for the two sexes.

It has been known for many years that congenital hyperplasia of one side of the face or of the whole body may be accompanied by precocious eruption of the deciduous teeth on the same side; and in other cases it has been noticed that some of the teeth on the same side may be enlarged. It has been said that the latter condition—unilateral hyperplasia of the teeth—is one of the rarest of dental abnormalities, and reference books only note two or three cases. But the rarity is probably much exaggerated. It is likely that at least five such patients are living in the British Isles to-day: I have seen 3 and Sir Frank Colyer and Mr. A. E. W. Miles have each reported one. Since reported cases have never been collected and compared I thought it worth while to do this, the more so in that there is a remarkable resemblance in detail between the various known examples. It is evident that the abnormality develops according to some very precise laws, and even if one cannot say what they are it is worth examining their effects.

To begin with we must note that two different congenital disorders must be distinguished. In one there is hyperplasia of the whole or most of one side of the body including some of the teeth. Of this variety there are very few dental records. In the other kind the hyperplasia is confined to one side of the face only, including the teeth, and of this sort there are excellent dental records in certain cases. I shall chiefly refer to this group. It must be added that there is on record also a large number of cases of hyperplasia of one side of the body

I will illustrate the condition by mentioning some cases which I have been able to observe (two of them under the surgical care of Sir Harold Gillies) and will then discuss the dental features of the whole group of facial cases.

CASE I.—The patient was a boy of 5½ years in whom enlargement of the right side of the face had been noticed soon after birth (fig. 5). No other members of the family were malformed; and his health was good. The structures enlarged were the upper and lower lips, cheek, nostril, tongue, and ear on the right side, the upper and lower right alveolar processes; and certain teeth. The right side of the palate was wider, and the same side of the tongue carried globular elevations and appeared deficient in papillæ. The teeth erupted were $\frac{e43c21}{654321} | \frac{abcde}{1bcde}$ (fig. 6). The eruption of $\frac{432}{6543} | 1$ was incomplete, but in spite of this those on the right side were in contact with their opponents in the other jaw. $\frac{65}{7} | \frac{1234567}{234567}$ were present unerupted, but $\frac{7}{1}$ was congenitally absent.

The state of dental development of the left side was normal for the age both as regards calcification and eruption: that on the right showed in both respects a precocity on the whole equivalent to five or six years more than the real age. As regards size, comparison by measurement of homologous teeth on the two sides was only possible in the case of $e | e$ since the permanent teeth on the left were not erupted. $e |$ was very much enlarged: 12×14 mm. compared with 7.5×9.5 mm. on the left (normal mean: 9×9.5 mm.). By means of good radiographs and measurement of the erupted teeth the following conclusions were formed. The incisors were not enlarged, but the upper and lower right canines were enlarged and of abnormal shape, having the nipple-like tip described by Pagenstecher. The root formation of the lower canine was about seven years precocious but its

FIG. 5.—Case I.

[Reproduced by permission of the Editor of the *British Dental Journal*.]

FIG. 6.—Case I. Models after extraction of enlarged $e |$.

eruption only five. The premolars were probably a little larger on the right and the lower first molar certainly was so and had abnormal roots, the posterior one being strangely recurved. A similar root formation in the lower first molar was later described by Miles in his case. On the other hand the second molar was smaller than on the left though more advanced in development.

It is noteworthy that although $e |$ was huge the succeeding tooth $5 |$ was only slightly enlarged if enlarged at all.

CASE II.—The patient was a boy of 16 in whom enlargement of the face had been noticed at birth. No malformation was known to have occurred in the family. His general health was excellent. The head at the level of the eyes and above was symmetrical. The left cheek and the left side of both lips were enlarged but without undue pigmentation or hæmangiomas; and there were two button-like nodules on the lower lip (fig. 7). There was no difference in the hairiness or texture of the skin on the two sides. The left ear was longer and broader and about twice as thick as the right; it was also set a little lower. The malar bone and zygomatic arch were much more prominent on the left, but the anterior surface of the upper part of the maxilla and the infra-orbital border were symmetrical on the two sides. The body of the mandible on the left felt thicker from above downwards. Within the mouth, the anterior part of the tongue was much broader and rather longer on the left and was covered with irregular nodular and papillary elevations. The inner surface of the cheek and lower lip had also numerous soft polypoid excrescences, some an inch in width. On section these proved to be composed of connective tissue with rather numerous and large lymph vessels.

The alveolar processes of both jaws were much wider on the left, especially the upper, but in both cases were rather shorter on that side. The morphological mid-line of both jaws was deviated to the patient's right. Several of the upper teeth on the left were enlarged, the canine particularly (figs. 8 and 9). The teeth present and erupted were $\frac{7654321}{7654321} | \frac{123456}{123456}$; $\frac{8}{7}$ had been extracted. $\frac{8}{8} | \frac{7}{78}$

the dental conditions, though the various documents are not absolutely in agreement. The following teeth appear to have been present and erupted: $\frac{6e4321}{6e\ 321} \mid \frac{de6}{1cde6}$ The tooth occupying the expected position of $\overline{1}$ is probably $\overline{1}$ which has drifted across owing to its premature eruption. There were also three empty sockets from which $\overline{1bc}$ seem to have fallen out.

While the state of development on the left side is normal for the age, that on the right is precocious by two to four years. To some extent, therefore, Barwell may have been contrasting the "baby teeth" on the left with permanent teeth on the right. However, measurement from the scaled drawings and from enlarged photographs calibrated from the drawings shows that some of the teeth on the right were abnormally large. $e \mid$ seems to have been about 12×13 mm. (normal mean 9×9.5); and $e \mid$ about 12×12 (normal mean 10.5×8.7). $6 \mid$ also appears to have been very large, about 13×13 ; and $4 \mid$ was probably enlarged. It is impossible to say whether the upper canine was enlarged or not, but its shape appears abnormal and reminiscent of that found in some other cases.

The other teeth on the right, $\frac{21}{6321} \mid$, seem to have been within normal limits, though the shape of $\overline{6} \mid$ was abnormal and its enlargement cannot be excluded. Doubt must remain on some points, such as the nature of the small tooth which occupies the position of the upper left second deciduous molar.

Clerc (1904) reported another case in a boy who had been watched from 3 to 10 years of age. He was the first to state precisely which teeth were enlarged and which were not, among those visible to him. In particular he showed that of the deciduous dentition only the second molars were enlarged in his case. He also observed precocious eruption of the first dentition on the large side, and was the first to publish photographs of casts of the teeth in this condition.

Port (1904) and Werner (1905) described a further case. They published for the first time comparative measurements of the crowns of teeth on both sides, though not of all teeth. They also published the first radiographs of the facial bones in this condition, and these though very dim have some comparative value. In their case the frontal bone was among those enlarged, and excessive bone growth was still continuing in the malar region at twenty years.

Pagenstecher (1906) described a woman of 35. His case is noteworthy for some aberrations in form which he found in the teeth. Unfortunately he gave no measurements and his illustrations are very poor; but from the latter it seems probable that the upper lateral incisor was among the teeth enlarged, a thing only once recorded since.

These last 3 cases are the ones usually mentioned in reference books.

No further reports appeared until 1923 when Paterson and Reynolds recorded a probable case. The remaining case-reports, some detailed and some scanty, are by Colyer and Sprawson (1931), Masten (1936), Peyrus (1936), Rushton (1937 and 1942), Miles (1944), and Rudolph and Norvold (1944). I have since seen one further case but unfortunately not before most of the teeth had been extracted. Another probable case was published by Arnold (1936).

(Cases in which tooth enlargement was said to accompany hyperplasia of the whole of one side of the body were reported by Milne (1894), Arnheim (1898), Gesell (1921) and Wiseberg (1931).)

Altogether there are records of 19 cases in which there is probability or certainty that some teeth on the hyperplastic side were larger than those on the other. In 15 of these the facial region only was enlarged (11 male, 4 female; 7 right and 8 left). In 4 most of one side of the body was enlarged (1 male, 3 female; 3 right and 1 left). On the general question of asymmetry and tooth size we may note that Ballard (1944) found that of 500 normal persons 408 showed slight difference (0.5 mm. or more) between the diameters of some homologous right and left teeth.

As a general description of the condition one can say that the facial asymmetry is always noticed soon after birth. As the infant grows the disparity becomes more marked and it is presently found that some or all of the following parts on one side are enlarged: lips, cheek, anterior part of the tongue, ear, uvula, tonsil, nostril, upper and lower jaws especially as to the alveolar processes, teeth, malar bone, and sometimes the mastoid process and frontal bone. There are occasionally pigmentary and vascular abnormalities of the skin, or neurological disturbances.

The teeth may develop and erupt earlier on the enlarged side and some of them may also be enlarged: this applies to both dentitions. The asymmetry of the face may continue to increase as late as the age of 20 years: it varies from a relatively slight condition to the enormous disproportion seen in Barwell's case.

I will illustrate the condition by mentioning some cases which I have been able to observe (two of them under the surgical care of Sir Harold Gillies) and will then discuss the dental features of the whole group of facial cases.

CASE I.—The patient was a boy of 5½ years in whom enlargement of the right side of the face had been noticed soon after birth (fig. 5). No other members of the family were malformed; and his health was good. The structures enlarged were the upper and lower lips, cheek, nostril, tongue, and ear on the right side, the upper and lower right alveolar processes; and certain teeth. The right side of the palate was wider, and the same side of the tongue carried globular elevations and appeared deficient in papillæ. The teeth erupted were $\frac{e43c21}{654321} \mid \frac{abcde}{1bcde}$ (fig. 6). The eruption of $\frac{432}{6543} \mid 1$ was incomplete, but in spite of this those on the right side were in contact with their opponents in the other jaw. $\frac{65}{7} \mid \frac{1234567}{234567}$ were present unerupted, but $\frac{7}{7}$ was congenitally absent.

The state of dental development of the left side was normal for the age both as regards calcification and eruption: that on the right showed in both respects a precocity on the whole equivalent to five or six years more than the real age. As regards size, comparison by measurement of homologous teeth on the two sides was only possible in the case of $e \mid e$ since the permanent teeth on the left were not erupted. $e \mid$ was very much enlarged: 12×14 mm. compared with 7.5×9.5 mm. on the left (normal mean: 9×9.5 mm.). By means of good radiographs and measurement of the erupted teeth the following conclusions were formed. The incisors were not enlarged, but the upper and lower right canines were enlarged and of abnormal shape, having the nipple-like tip described by Pagenstecher. The root formation of the lower canine was about seven years precocious but its

eruption only five. The premolars were probably a little larger on the right and the lower first molar certainly was so and had abnormal roots, the posterior one being strangely recurved. A similar root formation in the lower first molar was later described by Miles in his case. On the other hand the second molar was smaller than on the left though more advanced in development.

It is noteworthy that although $e \mid$ was huge the succeeding tooth $5 \mid$ was only slightly enlarged if enlarged at all.

CASE II.—The patient was a boy of 16 in whom enlargement of the face had been noticed at birth. No malformation was known to have occurred in the family. His general health was excellent. The head at the level of the eyes and above was symmetrical. The left cheek and the left side of both lips were enlarged but without undue pigmentation or hæmangiomas; and there were two button-like nodules on the lower lip (fig. 7). There was no difference in the hairiness or texture of the skin on the two sides. The left ear was longer and broader and about twice as thick as the right; it was also set a little lower. The malar bone and zygomatic arch were much more prominent on the left, but the anterior surface of the upper part of the maxilla and the infra-orbital border were symmetrical on the two sides. The body of the mandible on the left felt thicker from above downwards. Within the mouth, the anterior part of the tongue was much broader and rather longer on the left and was covered with irregular nodular and papillary elevations. The inner surface of the cheek and lower lip had also numerous soft polypoid excrescences, some an inch in width. On section these proved to be composed of connective tissue with rather numerous and large lymph vessels.

The alveolar processes of both jaws were much wider on the left, especially the upper, but in both cases were rather shorter on that side. The morphological mid-line of both jaws was deviated to the patient's right. Several of the upper teeth on the left were enlarged, the canine particularly (figs. 8 and 9). The teeth present and erupted were $\frac{7654321}{7654321} \mid \frac{123456}{12345}$; $\frac{8}{8} \mid \frac{7}{7}$ had been extracted.

were present unerupted and $\bar{8}$ was congenitally absent. One cusp only of $\bar{7}$ had erupted in an abnormal position on the medial side of the alveolus.

There was no record of the order of eruption of the teeth, but it is evident that the eruption of the two left second molars was retarded about four years already. With regard to size, in the upper jaw the incisors on the two sides are equal but the left canine is very large and of globular shape; it has no root. The left premolars are enlarged and have no roots, and the first molar is enlarged and has only one defective root. In the lower jaw the incisors on each side are equal, the left canine slightly larger. The second molar is smaller on the left.

The patient was re-examined in 1946 at the age of 21. The asymmetry of the soft tissues had in the meantime been greatly reduced by plastic surgery.

Radiographs of the facial bones showed no abnormality at the level of the orbits and above.

FIG. 7.—Case II.

FIG. 8.—Case II. Model of right upper teeth.

FIG. 9.—Case II. Model of enlarged left upper teeth.

The upper parts of the maxillæ do not differ much from each other; the left is probably a little wider and the right somewhat denser. The left malar bone carries an abnormal downward and outward prominence, and the left zygomatic arch is thicker. The left alveolar process of the maxilla has now increased in length and is of equal length with that of the right. The quality of the bone of the new-formed maxillary tuberosity is abnormal showing no cortex in intra-oral films. There is also an increased boss of bone posterior and medial to the first molar tooth. The latter, which previously only had one root, now seems to have lost this also. The mandible is rather more massive on the left side. Its canal is much enlarged and the mental foramen is twice the normal diameter (fig. 10). The second molar is still unerupted, and the third is not only unerupted but is covered

FIG. 10.—Case II. Radiograph of left mandible at 21 years.

by a proliferation of bone carrying an upward spur. The lower third molar on the right is now erupted. The hyoid bone appears equal on the two sides.

Comparing these with the previous findings one may say that an osteolytic process has destroyed the roots of the upper teeth from the canine backwards to the first molar on the left; that eruption on that side has ceased; and that abnormal bone apposition is proceeding on the posterior ends of the alveolar processes of both jaws. These are the parts in which one would expect still to find some bone growth at this age, but of quite a different kind and connected with the eruption of the third molars.

CASE III.—In a third case, a young woman under the care of Mr. Patrick Clarkson, most of the teeth had already been extracted but the other deformities, including in this instance the frontal bone, were well shown.

The following are some of the principal dental findings in the whole group of facial cases.

(a) *Size.*—Of the deciduous dentition only the second molars are known to have been enlarged and then only in 3 cases (Barwell; Clerc; Rushton, 1937). In Clerc's case the other deciduous teeth were normal but in most cases none remained at the time of examination owing to their very early loss on the large side.

The greatest enlargement found amongst the permanent teeth occurs in the canines and does not exceed an increase in diameter of 50%; next in the first molars and first premolars; then in the second premolars. The upper central incisors are never enlarged which may be connected with their development in tissue derived from the fronto-nasal process. The upper lateral incisors and the lower incisors are rarely enlarged and then slightly. A second molar has only once been found enlarged (Colyer) and these teeth are sometimes smaller than those on the normal side. Little is known of the condition of the third molars.

(b) *Rate of development.*—Eruption of the deciduous teeth may be and perhaps usually is precocious to the extent of several months on the large side. And precocious eruption of the permanent teeth on that side is usually a striking feature: there may be a precocity of five years at the real age of 5 or 6. After that age it diminishes; and in some cases the eruption of those teeth which should normally erupt late, the second and third molars, is retarded compared with normal expectation or fails completely. It is estimated that in these cases a retardation of eruption has begun before the age of 10 years. The state of formation of the teeth is comparable with the state of eruption at any time except in the case of the second and third molars where any retardation of eruption is not accompanied by retarded formation. In contrast with the distribution of size-abnormality those teeth which are formed in tissue derived from the fronto-nasal process and those formed in tissue derived from the first visceral arch are equally affected as regards accelerated formation and eruption. It is also clear that this acceleration affects indifferently those teeth on the large side which are hyperplastic and those which are not. The second molars may show accelerated formation even though their size be diminished; or a normal state of formation though their eruption be retarded.

(c) *Alveolar bone.*—The distribution of areas of increased and diminished growth of alveolar bone is usually the same as that of areas in which accelerated and retarded eruption occur, and does not correspond closely with the distribution of tooth enlargement. The alveolar bone growth is not only precocious but also excessive and disorderly. Abnormal absorption of tooth roots has been reported in 2 cases (Rushton, 1942; Miles, 1944).

(d) *Tooth form.*—The enlarged teeth often have an alteration in form as if they had been inflated. This may be due to a greater overgrowth of the mesodermal than of the ectodermal elements, a thing several times observed in other organs at autopsy in cases of partial gigantism (Hornstein, 1893; Arnheim, 1898; Cagiati, 1907).

The various hypotheses which have been put forward to explain the syndrome of congenital unilateral hyperplasia as a whole have been summarized by many authors and recently by Schwartzman, Grossman, and Dragutsky (1942). Of these the suggestions of chromosome or gene abnormalities probably accord best with the dental evidence.

I am not competent to discuss the nature of such a genetic defect: reference to such a paper as that of Grüneberg (1935) shows that the number of possible interpretations of asymmetrical development is large. Suggestions of somatic mutation and of non-disjunction have been made, but there is one record (Rudolph and Norvold, 1944) which claims that the facial enlargement, though not necessarily that of the teeth, was present in three generations, and if this was so those suggestions are not likely to be correct. An alternative is to suppose a hereditary factor with a very low manifestation rate.

The distribution of the whole abnormality corresponds to a considerable extent with that of structures derived from the first visceral arch but the correspondence is not precise: areas outside that zone are often affected and some areas and teeth within it are not. If the malformation be considered an abnormal gene effect it is one of the diffusely localized variety. The localization in respect of increased organ-size and of precocity is not exactly the same in extent: and these two abnormal influences are effective at different periods—

were present unerupted and $\bar{8}$ was congenitally absent. One cusp only of $\bar{7}$ had erupted in an abnormal position on the medial side of the alveolus.

There was no record of the order of eruption of the teeth, but it is evident that the eruption of the two left second molars was retarded about four years already. With regard to size, in the upper jaw the incisors on the two sides are equal but the left canine is very large and of globular shape: it has no root. The left premolars are enlarged and have no roots, and the first molar is enlarged and has only one defective root. In the lower jaw the incisors on each side are equal, the left canine slightly larger. The second molar is smaller on the left.

The patient was re-examined in 1946 at the age of 21. The asymmetry of the soft tissues had in the meantime been greatly reduced by plastic surgery.

Radiographs of the facial bones showed no abnormality at the level of the orbits and above.

FIG. 7.—Case II.

FIG. 8.—Case II. Model of right upper teeth.

FIG. 9.—Case II. Model of enlarged left upper teeth.

The upper parts of the maxillæ do not differ much from each other; the left is probably a little wider and the right somewhat denser. The left malar bone carries an abnormal downward and outward prominence, and the left zygomatic arch is thicker. The left alveolar process of the maxilla has now increased in length and is of equal length with that of the right. The quality of the bone of the new-formed maxillary tuberosity is abnormal showing no cortex in intra-oral films. Smallpox 1947. [Abridged]

By W. H. BRADLEY, D.M., M.R.C.P.

DURING 1947 the diagnosis of smallpox was confirmed in 79 persons infected in England and Wales. 15 of these died. Although the numbers are small the experience deserves comment for three reasons. First, the number of cases was the highest since 1934 when there were 179, mainly of variola minor, with 6 deaths only. Secondly, we must recognize the great importance of the fact that in 1935 endemic variola, both major and minor, had completely disappeared from these Islands. During 1947 in one area of Staffordshire the infection persisted through nine generations and at one time there appeared to be a real threat that smallpox might again establish endemicity. Thirdly, the experience was sufficiently small to permit some close-up observations from which there are some lessons to be learnt.

In each of the years 1939, 1940, 1942, 1944 and 1945 there was a single importation of smallpox. In 1946, in consequence of the return of our Forces from the East, there were 15 importations (discussed by Boul and Corfield 1946, Peirce 1947, Conybeare 1946, Stallybrass 1947). In 1947 there were two importations; the source of the first was not proved, the second originated in India. The geographical spread is discussed elsewhere (Murray and Bradley, 1948).

FIRST IMPORTATION

Two old men, aged 85 and 75, resident in a common lodging house at Grimsby, became ill on February 8 and 13 and were subsequently diagnosed in the Public Assistance Hospital as smallpox. When lists of contacts were made several of the mariners and tramps who frequented the lodging house had disappeared. There is little doubt that amongst them was the source case. It may be significant that at the time an unprecedented blizzard virtually isolated Grimsby by road and rail for several days and that vessels from French ports were lying at Grimsby. A case of smallpox was reported from Paris with onset on February 10 and 32 cases followed there as well as cases in other parts of France. Also among those who disappeared was the unknown man who transported the disease to Stepney where a resident member of the staff of a seamen's hostel (273 beds) sickened on March 3. He was removed from the hostel before the rash appeared but was in a ward of an East London general hospital till March 9 when a pustular rash was diagnosed smallpox. Contact listing, surveillance and vaccination were speedily undertaken and only one secondary case occurred in a contact under observation in the hospital.

At Grimsby there were 13 cases in the second generation, 2 being in members of the Public Health Department staff, others in contacts in the Public Assistance Hospital and in the inmates of the lodging house. Some of these inmates absconded from surveillance. Two moved to a dosshouse in Scunthorpe, 28 miles from Grimsby, where on March 2 a permanent resident developed a rash. He was removed to the infectious diseases hospital on March 25 as a case of chickenpox. It may be assumed that suspicion of smallpox arose because material was sent to the laboratory, but no precautionary measures other than isolation were taken nor was a second opinion consulted until after the laboratory reported variola virus present on April 1. Subsequent cases included 4 inmates of the common lodging house, a nurse in the infectious diseases hospital and the Acting Medical Officer of Health. Once again tramps from the lodging house absconded and were probably the means of conveying the virus to Doncaster and Barnsley. It was found that tramps moved between these towns and London by jumping lorries.

increased size from before 5 or 6 months of foetal life until perhaps 1½ to 2 years, and precocity from birth until 9 or 10 years with a maximum at 5 or 6.

The precocity which occurs is of the same order as has been found bilaterally in some endocrine disturbances but in facial hemihyperplasia there is no evidence of any excess of such hormones and the contralateral teeth are normal. It appears reasonable to think that such an abnormal effect may operate through an abnormal reactivity in the affected area to normal influences promoting growth at any time, and that the normal variation in these may determine the very different effects produced at different age-periods. States in which there is failure of localized areas to react in the expected manner to various hormones, whether bilaterally or not, are recognized, also the different reactivity of various parts at the same or different times. Dana's case (1893) of acromegalic gigantism in which the whole body except one side of the face was affected could be regarded as a kind of opposite to the cases here discussed.

It appears that in these cases of facial and dental hemihyperplasia we see the result of removal of one or more of the factors which normally control in a certain area the rates of cell-proliferation and of morpho-differentiation and the relationship between the two determining in the normal environment the ancestral rate of development and size of the dental organs. Perhaps the most surprising thing is that among so many known genetic abnormalities in this one almost alone in man can enlargement of the crowns of a series of teeth occur, and then only during a period of two or three years. While variations in tooth number and partial dichotomy or partial fusion are common, also such modifications of growth gradients as will produce either increased complexity or extreme simplification of form, the upper limit of size of teeth of approximately normal pattern seems most insusceptible to either environmental or genetic disturbance.

VACCINATION

Vaccination did not fail us although it was used sparingly. In spite of some uncertainty at times concerning the prospect of control of the Bilston outbreak by surveillance and vaccination of contacts alone, the Ministry of Health's Medical Officers did not advocate mass vaccination. A high proportion of the population chose to be vaccinated and this may to some extent have affected the course of the outbreak. Yet I believe that the Ministry's advice was sound and am very doubtful about the statement made by the Commissioner of Health for New York City that "whenever a case of smallpox occurs in a community the only safe procedure is for every person in that community to be vaccinated without delay" (Weinstein, 1947). All the 12 patients in the 1947 outbreak in New York were in the direct line of contact and the outbreak terminated with the second generation of cases. 9 of the patients were unvaccinated and 3 had been vaccinated more than forty years previously. It is difficult to see how the mass vaccination of some 6 million New Yorkers affected the outcome. Vaccination on this scale was a remarkable achievement but any benefits which accrued must be set against a serious disadvantage. 50 cases of post-vaccinal encephalitis were reported and in 46 the diagnosis was considered probable; 8 of these died and 3 other deaths were reported from complications of vaccination. Weinstein comments "tragic as these incidents were, it must be borne in mind that had vaccination not been carried out, there very likely would have been thousands of cases (of smallpox) and hundreds of deaths". Our experience in this country suggests that it was not very likely, and past history confirms that the evolution of an epidemic of smallpox is relatively slow (Bradley, 1947).

COMMENTS

There was a difference between the outbreaks resulting from the two 1947 importations. In the Grimsby series the difficulty of handling the freedom-loving tramps led to dispersal over a wide area. Nevertheless, early detection and removal of cases together with vaccination and close surveillance of contacts brought control within two generations at each of the foci which resulted and it was possible to conjecture the route of spread except in the one late case at Barnsley.

In Staffordshire, on the other hand, the great difficulty in diagnosing the highly modified disease in the early cases and hesitation in accepting a laboratory diagnosis postponed action until thirty-four days after the onset in the original case. Although the disease remained confined to adjacent towns, nine generations of cases occurred before it was controlled and the route of spread to many cases could not be discovered.

The first lesson to be learnt is that if Wanklyn's question "Can this be smallpox?" cannot be answered with a firm negative, suspicion remains and routine smallpox precautions must start immediately. The second lesson is the great value of the Public Health Laboratory Service Smallpox Reference Laboratory at Colindale. A positive report from the laboratory must on no account be ignored. (A negative report must be treated with reserve if clinical suspicion remains.) Other lessons are: vaccinate everyone who enters a smallpox hospital, see that lists of contacts are comprehensive and make surveillance the main line of defence. Do not expect vaccination after contact to overtake the established infection or eliminate all risk of infectivity. Lastly, look to the vaccinal state of Public Health staff and ensure that contacts among them submit to surveillance no less rigorous than that applied to the general public.

So long as homing Britishers move around the world these Islands are at risk from imported smallpox, and we must aim at a high level of immunity obtained by routine infant vaccination with re-vaccination at suitable intervals. The appearance of the virus here should not be the signal for panic mass vaccination. Rather should all our resources, which are by no means limitless, be thrown into that reconnaissance,

Doncaster's singleton case was an assistant master at a preparatory school. The onset of his illness was sufficiently severe to send him to bed but clinical diagnosis of his highly modified rash was difficult and became confident only after laboratory examination.

At Barnsley the original source of infection was probably present in a common lodging house occupied by 93 men, women and children from April 30 till May 7. This focus of infection was detected only when it was found that a case with an early rash diagnosed in Bermondsey on May 16 had stayed at a common lodging house in Barnsley on the conjectured date of infection. Inquiries revealed 3 persons with early rashes, 2 in the lodging house and 1 in the Municipal Hospital. The inmates of the lodging house were immediately vaccinated and after 2 more cases in the first wave, making a total of 5, there were only 2 in the second wave. Despite extraordinary efforts to keep the residents together a few tramps absconded. They were probably the source of infection of an isolated case at Wakefield and possibly carried the infection to Sheffield. In the Municipal Hospital at Barnsley there were 5 secondary cases in ward contacts. One of these was in a child admitted for one night only and discharged on May 16 when the smallpox scare started. The parents refused vaccination. This case illustrates the importance of making comprehensive lists of contacts. The last case in Barnsley occurred a month after the last case in the town outside any known line of contact and within half a mile of the hospital. This type of unexplained case near smallpox hospitals seems to occur more frequently than could be due to chance (Millard, 1944).

The singleton case at Wakefield was in a night watchman who frequently entertained vagrants round the fire in his hut. Vaccination of contacts in the lodging house where he lived was performed early and their surveillance was relatively easy.

The primary case in Sheffield was in a child of 11 years who was confined to bed on May 1, developed a rash on May 4 and was diagnosed and removed only on May 9. Vaccination at this time could offer little protection, and the contacts, all members of the family, were persuaded to enter a quarantine house. The father and an aunt, both unvaccinated prior to contact, later developed the disease. The cost of the quarantine house was amply justified.

SECOND IMPORTATION

An Army sergeant arrived from India at Heath Row by air on February 23 and proceeded to his home at Bilston in Staffordshire on the next day. On March 1 he was unwell but remained ambulant until a rash was reported on March 6. Expert opinion diagnosed chickenpox both in this patient and in his mother and a visitor to the house who developed rashes on March 21 and 25. On April 1 material was sent to the laboratory where variola virus was found to be present, but the experts remained incredulous. Contacts were vaccinated on April 3, and 2 who were then ill developed rashes on April 5 and 7. Only on April 8 were routine smallpox precautions put into operation. The development of this outbreak to involve 24 cases and its spread to the contiguous district of Coseley (4 cases) have been described by Simpson Smith (1948).

A few interesting points can be added. Despite careful investigation the line of spread into 8 of the 13 families could not be discovered. In two instances the link in the chain of infection was not a diagnosable case of smallpox but was nevertheless a human being. Healthy carriers may occur although there is ample epidemiological evidence that they and cases of variola sine eruptione are much less infectious than patients with the exanthem. A singleton case from Dudley reported by Simpson Smith (1948) as a case of relapsing smallpox was more probably a hospital infection. The patient had been vaccinated in infancy forty-five years previously and was not revaccinated on admission to the smallpox hospital. The only case exported from the Bilston area was in a medical student at Birmingham who was allowed to see the cases without being adequately protected by recent vaccination.

They were able to show that the causal factors include sustained malnutrition or ill-health and poor posture, and that the disease is closely related to the geographical distribution and incidence of dental fluorosis. There is some evidence that those who are affected derive benefit from a better diet and improved social conditions.

Dr. W. T. Russell briefly reviewed the importance of the statistics of occupational mortality and indicated the greater precision now made by the Registrar-General in their evaluation. Having stressed the care necessary in their interpretation, especially on account of the possible influence of selective physical recruitment to particular occupations, he then emphasized the importance of industrial accidents since they represent direct occupational risks. He gave figures from the Chief Inspector of Factories' Annual Report, 1945, which indicated that there were 223,000 reported accidents in that year, and quoted the Chief Inspector's statement on the action deemed desirable for their prevention.

He described an investigation now being made at the Institute on the incidence of accidents in the three large factories in the Oxford Area. All accidents, minor and major whether involving lost time or not, are included in this study. Slides illustrating the statistics of the injuries, their type, causal agents and the correlation between incidence and age of worker were shown.

Dr. Russell concluded by indicating the broad character of this study which is a co-operative effort by the factory doctors, safety engineers and the Institute, in which they aim also to correlate the sickness records of the workers with their accident statistics, in the hope that further light may be shed on accident proneness.

Dr. Alice Stewart and Dr. J. P. W. Hughes: Mortality statistics over the last fifty years were given which showed that there is an excessive mortality from pulmonary tuberculosis in the boot and shoe industry, corresponding with the high morbidity rate found in a recent mass radiography survey in Northamptonshire (Smith, C. M., 1946, Northamptonshire County Council, Mass Miniature Radiography, 1945-1946, S. L. Hunt, Rushden, Northants).

The present survey was planned in order: (1) to exclude effects likely to be caused by home, racial, familial or immunological considerations; (2) to discover whether there were specific factory conditions which might account for the high incidence of the disease.

The findings in respect of the first part of the investigation suggest that boot and shoe factory operatives differ little if at all from other factory workers in the county. The second part of the investigation revealed both evidence of selective recruitment into the industry and the presence of unfavourable working conditions. For instance, examination of nearly ten thousand health records of men called up into the Services revealed a lower proportion of physically fit men in the boot and shoe industry as compared with other factory workers in Northamptonshire and Leicestershire. Secondly, working records of men known to have had tuberculosis showed that these men are more often employed in the boot and shoe industry than in other trades in Northamptonshire.

Further analysis of the mass radiography records possessed by Dr. Smith showed that workers in the large boot and shoe factories contracted the disease more frequently than workers in small factories, and that there was a close relationship between size of factory and the incidence of pulmonary tuberculosis. There was no evidence that this was due either to differences in sex and age of the factory populations or to the factories being situated in towns or villages. It was concluded, therefore, that size of factory (and hence size of workshop) was the main factor determining the incidence of tuberculosis.

Some of the factories had already been graded into good, fair and poor by the factory inspectorate. When the "factory grade" was compared with the tuberculosis morbidity rates it was found that although the poor factories produced

clinical and epidemiological, which reveals the distribution of the virus and enables us to apply deliberately, step by step, calculated counter-measures. This and the public demand for vaccination will keep us busy enough.

MEETING HELD IN THE INSTITUTE OF SOCIAL MEDICINE, OXFORD

SUMMARY

Professor J. A. Ryle, in an introductory talk, described the origins and purposes of the Institute, which was opened in April 1943. He and his staff were predominantly occupied with socio-medical research programmes, but they had also assumed responsibility for undergraduate teaching during the first clinical year. The course included (1) lectures on the historical and theoretical aspects of the subject by himself and his immediate colleagues; (2) lectures on public health practice, industrial medicine, epidemiology and social case-work by members of the local health departments, a factory medical officer, the public health bacteriologist and the senior almoner of the Radcliffe Infirmary; (3) eight classes in medical statistics; (4) socio-medical case-conferences; and (5) field visits. Approximately fifty hours were devoted to the course. Wherever possible the close inter-relationships of clinical and social medicine were stressed.

The main sections of the Institute were concerned with: (1) Occupational Disease and Hygiene (the Assistant Director, Dr. Alice Stewart); (2) Child Health (Dr. Cicely Williams); (3) Student Health (Dr. R. W. Parnell); (4) Vital Statistics (Dr. W. T. Russell); (5) Radiology (Dr. F. H. Kemp). Reference was also made to the associated Bureau of Health and Sickness Records (Mr. H. Cotton).

The investigations undertaken were, in the main, epidemiological and ætiological and were based upon a variety of surveys, involving collaborations between physicians, statisticians, a medical social worker and a radiologist, on the one hand, and others in the fields of public health, industrial medicine, the school medical service, the maternity and child welfare services, &c., on the other.

Current researches included (1) a study of health and sickness experience and growth in the pre-school child, based upon a sample of upwards of 500 babies drawn from all social groups; (2) a study of student health; (3) an investigation into the high rate of tuberculosis in the boot and shoe industry; (4) sickness and accidents in factories; (5) hospitalized accidents; (6) the morbidity and mortality of appendicitis; (7) the health of the housewife.

After brief discussion the meeting was later resumed and short communications were given by Dr. F. H. Kemp and Dr. D. Wilson (*Social and nutritional factors in juvenile osteochondritis of the spine*); by Dr. W. T. Russell (*Occupational morbidity and accidents*); and by Dr. Alice Stewart and Dr. J. P. W. Hughes (*Tuberculosis in the boot and shoe trade*).

Dr. F. H. Kemp and Dr. D. Wilson reported a series of investigations which they had conducted into the ætiology of osteochondritis of the spine (Scheuermann's disease).

it becomes common. A similar series was also collected without difficulty in a general military hospital in England during the next winter (Copeman, 1942) in the absence of any outbreak of meningitis.

Peripheral mononeuritis.—Another outbreak of which the symptomatology was at first considered to be rheumatic was described by Spillane (1943) who pointed out that although polyneuritis with the exception of the diphtheritic form was rare in the M.E.F., a number of cases of paralysis, mostly affecting single muscle groups, were being seen in the military hospitals. The groups affected were mostly those of the shoulder girdle. Such cases had not been observed before the war, so far as he was able to ascertain. The cases seen fell into two groups; in the first the affection of the shoulder girdle developed while the patient was in hospital convalescing from some other illness. Sometimes they had even been transferred to a convalescent depot, and always they were afebrile. No common causative factor could be detected and evidence of faucial or cutaneous diphtheria was lacking. In the second group, the illness began whilst the victim was on duty with a sharp pain in the shoulder which sometimes radiated down the arm, and which lasted up to fourteen days, after which weakness and later wasting became prominent. In most cases this wasting became considerable and Spillane records that he never saw any certain regeneration of muscle in such cases, although improvement occurs in milder cases.

The uniformity of the clinical findings in this and similar series seems to suggest, although it does not prove, a common causation. In respect of these patients, two considerations spring to mind: first the number of injections to which their upper arms had probably been subjected, and the ever-present possibility of trauma in soldiers on active service. In connexion with this latter condition, Spillane states that he never saw a typical case in an officer, although such have been recorded. The differential diagnosis was chiefly from localized poliomyelitis, but pathological investigation established its difference. As the result of much further investigation it was concluded that neither severe injection nor trauma was causative. No certain aetiology can therefore as yet be invoked for these cases which later were seen in many theatres in the war.

Jaundice.—Infective hepatitis, with a small mortality, constituted, after malaria, one of the principal man-power problems which confronted us in the Middle East and the C.M.F. The epidemiology of this condition has never been established with certainty, and each outbreak encountered, therefore, presented a fresh challenge to the amateur epidemiologist. The accepted method of spread of infective hepatitis has always been by droplet spray amongst close contacts, or even personal contact; this could but rarely have been the case, however, in the outbreaks noted amongst units and individuals scattered about the deserts of the M.E.; whilst the extreme rarity with which, if ever, it appeared to be transmitted to nursing sisters seemed also to throw some doubt on this method of transmission. Wits (1944) in reviewing this problem as it appeared amongst the troops around the Mediterranean, where the disease is endemic, did not discard the belief prevalent amongst the troops that a potent cause was imperfectly washed communal crockery. This hypothesis was thought by many M.O.s on the spot to explain the increased incidence of the disease noticed amongst officers as compared with men. Findlay and Willcox (1945) later produced typical cases in volunteers following the oral ingestion of faeces or urine from spontaneous cases, which seems to favour the view, to which I personally found myself attracted by the evidence, that an insect vector must be the transmitting mechanism.

It was during the late war also that post-inoculation jaundice was established as an entity *sui generis*. Findlay, summarizing the evidence in 1940, decided that the agent, although probably differing from the filtrable virus believed to be the cause of infective hepatitis, is of the same nature. Later he proved that this agent was present in the nasal secretion of sufferers amongst the N. African Force, and was

more cases than the good factories, this effect was not sufficient to overcome the effect of size; for instance, in a "poor" small factory the incidence of this disease was less than in a "good" large one, whilst in the "poor" large factories the incidence of the disease was higher than in any other group.

After further discussion demonstrations were given (1) of recording methods and the design of record cards for survey work, and (2) of the Powers-Samas Machine Room.

Clinical Epidemiology

PRESIDENT'S ADDRESS

By W. S. C. COPEMAN, O.B.E., M.D., F.R.C.P.

EPIDEMIOLOGY is the study of disease prevalent amongst communities at special times, and was initiated by the Father of Medicine himself when he observed that certain climatic variations were associated with certain prevalent diseases (Hippocrates, Epidemics i and iii). Epidemiology has in all ages perforce been a major interest of the physician, but it became developed as a special branch of Medicine with the evolution of the scientific method which was introduced by Harvey and John Hunter, and later, with the application of statistical methods to medical practice, by pioneers such as Snow and William Budd. Since the middle of the last century it has tended to be regarded exclusively as a branch of Public Health and the professional epidemiologist is now rightly regarded as an important unit of the team responsible for the corporate health of the community.

In isolated districts, and more particularly in time of war, small communities often find themselves circumscribed in medical conditions in which epidemiological knowledge and technique are desirable. It not infrequently happens, however, that the situation has to be handled by someone trained only in clinical medicine. We need only turn to the communications of Pickles prior to the late war (many of them to this Section) to realize that even in such circumstances our knowledge has not infrequently been advanced.

It is to such a combination of circumstances that I apply the term "Clinical Epidemiology", and it is mostly to some personal wartime experiences that I propose to refer.

Chronic meningococcal septicæmia.—During the winter of 1939–40, during the period of the "phoney war", some cases were noticed in one of the tented hospitals in France which presented an acute pyrexial onset followed rapidly by severe migratory joint and muscle pains often with effusion, and in most cases followed by a somewhat inconspicuous rash, which sometimes however simulated erythema nodosum. They mostly ran an irregular or remittent fever subsequent to the onset. In spite of all this, the patients rarely seemed to feel seriously ill. It was found that sulphonamides were a prompt and effective remedy, which cast doubt on the diagnosis of rheumatic fever or influenza, with which they had mostly been admitted. At this time a small epidemic of meningococcal meningitis had been reported in the Army. In view of the association of chronic meningococcal septicæmia with acute outbreaks of meningitis in America reported by Appelbaum (1937) and by Binns and Clancy (1939) in children, a series of blood cultures was undertaken in these cases. This resulted (not without difficulty) in positive cultures for this organism being obtained in some 17 of the cases within a period of nine weeks. These cases were carefully analysed (1940) by Stott and Copeman who stated their belief that chronic sporadic meningococcal septicæmia, although not widely recognized, is not rare, but that whenever meningococcal meningitis is prevalent in a community

it becomes common. A similar series was also collected without difficulty in a general military hospital in England during the next winter (Copeman, 1942) in the absence of any outbreak of meningitis.

Peripheral mononeuritis.—Another outbreak of which the symptomatology was at first considered to be rheumatic was described by Spillane (1943) who pointed out that although polyneuritis with the exception of the diphtheritic form was rare in the M.E.F., a number of cases of paralysis, mostly affecting single muscle groups, were being seen in the military hospitals. The groups affected were mostly those of the shoulder girdle. Such cases had not been observed before the war, so far as he was able to ascertain. The cases seen fell into two groups; in the first the affection of the shoulder girdle developed while the patient was in hospital convalescing from some other illness. Sometimes they had even been transferred to a convalescent depot, and always they were afebrile. No common causative factor could be detected and evidence of faucial or cutaneous diphtheria was lacking. In the second group, the illness began whilst the victim was on duty with a sharp pain in the shoulder which sometimes radiated down the arm, and which lasted up to fourteen days, after which weakness and later wasting became prominent. In most cases this wasting became considerable and Spillane records that he never saw any certain regeneration of muscle in such cases, although improvement occurs in milder cases.

The uniformity of the clinical findings in this and similar series seems to suggest, although it does not prove, a common causation. In respect of these patients, two considerations spring to mind: first the number of injections to which their upper arms had probably been subjected, and the ever-present possibility of trauma in soldiers on active service. In connexion with this latter condition, Spillane states that he never saw a typical case in an officer, although such have been recorded. The differential diagnosis was chiefly from localized poliomyelitis, but pathological investigation established its difference. As the result of much further investigation it was concluded that neither severe injection nor trauma was causative. No certain ætiology can therefore as yet be invoked for these cases which later were seen in many theatres in the war.

Jaundice.—Infective hepatitis, with a small mortality, constituted, after malaria, one of the principal man-power problems which confronted us in the Middle East and the C.M.F. The epidemiology of this condition has never been established with certainty, and each outbreak encountered, therefore, presented a fresh challenge to the amateur epidemiologist. The accepted method of spread of infective hepatitis has always been by droplet spray amongst close contacts, or even personal contact; this could but rarely have been the case, however, in the outbreaks noted amongst units and individuals scattered about the deserts of the M.E.; whilst the extreme rarity with which, if ever, it appeared to be transmitted to nursing sisters seemed also to throw some doubt on this method of transmission. Witts (1944) in reviewing this problem as it appeared amongst the troops around the Mediterranean, where the disease is endemic, did not discard the belief prevalent amongst the troops that a potent cause was imperfectly washed communal crockery. This hypothesis was thought by many M.O.s on the spot to explain the increased incidence of the disease noticed amongst officers as compared with men. Findlay and Willcox (1945) later produced typical cases in volunteers following the oral ingestion of fæces or urine from spontaneous cases, which seems to favour the view, to which I personally found myself attracted by the evidence, that an insect vector must be the transmitting mechanism.

It was during the late war also that post-inoculation jaundice was established as an entity *sui generis*. Findlay, summarizing the evidence in 1940, decided that the agent, although probably differing from the filtrable virus believed to be the cause of infective hepatitis, is of the same nature. Later he proved that this agent was present in the nasal secretion of sufferers amongst the N. African Force, and was

able to transmit the disease to three volunteers by the instillation of washings into their nares.

Another type of jaundice, which follows the injection of arseno-benzine preparations, was also much seen, particularly in the Italian campaign where the V.D. rate was high. It seemed from the careful reports of the local M.O.s that this type was probably transmitted by imperfectly sterilized syringes or needles being used for the injection of arsenicals into successive patients. This view has now been generally adopted. (Medical Research Council War Memo. No. 15, 1945.)

In all cases of jaundice occurring in endemic areas, it is obviously very important to exclude Weil's disease, and the story of its identification in the B.L.A. in France and Holland has been told by my colleague Dr. E. Bulmer (1945). The occurrence of the disease had not been unforeseen in view of the known presence of rats which had been found to harbour the spirochæte in the urine and the conditions which were prevalent in the earlier part of the campaign. The first case to be recognized occurred in Caen in July 1944, and the report which was at once circulated to all physicians in the Force rendered the arrival of each case of jaundice something of an adventure. In all, Bulmer estimates that about 100 cases must have occurred, although as some were without jaundice more may have been missed. It seemed that the source of infection was almost certainly the water which was used by the men for washing, since all drinking water was sterilized by the usual efficient Army methods. For washing, the men were forced to draw water from the wells and streams. It is, however, probable that they also cleaned their teeth in such water. Bathing in the streams was allowed, the alternative—if it could have been enforced—was that the men should remain dirty and unrefreshed during the rather dreary period prior to the advance, during which it was often exceedingly hot. On some sectors they perforce lived in damp rat-infested ditches and the risk, such as it was, was taken therefore advisedly. It is interesting to note in this connexion that the leptospira isolated in this outbreak were found by Brigadier J. S. K. Boyd to be moderately penicillin-sensitive, and subsequent treatment of some 36 cases with this substance yielded results which were thought to be worthy of further and more extended trial.

Epidemic myalgia.—Bornholm disease has generally been considered as the only recognized example of an infective myalgia. During the winter 1940–41, however, a number of cases of "fibrositis" were seen from a single isolated military unit. All these cases were of similar onset and type and affected the neck, shoulder-girdle, and arms of the sufferers. On further investigation it appeared that the condition showed some signs of being of an epidemic nature. About that time the American Harvard Red Cross Unit arrived under the charge of Dr. (now Professor) Paul Beeson whose assistance was sought in this matter. Subsequently to this he and his team investigated in all four similar outbreaks during 1941–42. He described the results of this work before this Section the same year, and included the cases which actually occurred within his own staff. I will quote some of his observations on the epidemiology of this interesting and unusual investigation. In October 1941 several cases of "stiff neck" occurred among members of the staff of this unit. All persons in the community were therefore canvassed in order to determine the prevalence of the condition. This revealed that a considerable number of persons (up to 24% of those who were resident) had suffered an attack of myalgia in the neck or shoulder regions within the preceding two months period. Similar cases of myalgia were reported in a near-by factory and also among a unit of A.T.S. billeted in the neighbourhood. Systematic inquiries revealed a recent high incidence of acute myalgia in these two groups. A fourth survey was then made amongst a detachment of soldiers, and the incidence of myalgia in that community was found to be considerably less than that in other groups. A full study was made of these four groups and it was concluded (Beeson and Scott, 1942) that the evidence obtained indicated that

the prevalence of the condition fluctuated in a manner similar to that of communicable disease, and certain types were defined. Most affected persons had a mild self-limited illness of fairly uniform course, but occasionally the disease passed into a chronic form and extended to other parts of the body, and eventually produced the clinical syndrome of generalized fibrositis. These chronic cases would not ordinarily be identified as having originated from an epidemic of benign myalgia of the neck. Transmission experiments seemed to promise some success but were not, by the time the unit disbanded, conclusive. It will be seen therefore that the evidence of this investigation supports the concept that acute "fibrositis" of the neck and shoulders may sometimes present as an infectious disease. This work should undoubtedly be followed up and repeated.

A further very small epidemic which occurred elsewhere and was independently reported by Houghton and Jones (1942) may be quoted, as the occurrence of epidemic forms of fibrositis is not well known. Seven members of the nursing staff of a hospital developed sore throat, this was followed in eight to eleven days in six of them by severe pains in the muscles and headache. These pains and some mild pyrexia persisted for up to five months, menstrual disturbances and spontaneous epistaxis were also reported although the E.S.R. remained normal throughout. The explanation put forward by the observers was that the condition was due to a myotropic strain of virus, although no extensive epidemiological investigations were made in this outbreak. Other rather similar outbreaks are on record, and two others are within my own recollection, although unpublished.

Cutaneous diphtheria.—Northern Palestine was, in 1941, an area where the skin lesions known as desert sore had become increasingly frequent and Cameron noted that this rise had coincided with a small outbreak of faucial diphtheria. Craig had reported in 1919 that a large proportion of cases of desert sore investigated by him in the Sinai Peninsula were found to yield the Klebs-Löffler bacillus, and Cameron therefore undertook an investigation with Muir (1942) into the cases of desert sore in his area. He found that the unit showing the highest incidence of this affection was a Yeomanry Regiment. Soon after arrival from England during June-August 1940, 12 cases of faucial diphtheria had broken out in the unit. After this a carrier had been found and after his isolation no further trouble had been reported. Both before and after this outbreak, desert sores were reported to be numerous in the unit. Subsequent to the diphtheria outbreak, however, swabs and scrapings were taken from the bases of the ulcers after removal of the overlying scabs, and the presence of the diphtheritic bacillus was proved in 66 cases. Later this state of affairs was shown to exist in all parts of Palestine. When this report was circulated, my unit was in the desert south of Baghdad, and as 40 cases of desert sore were at that time in hospital, they were immediately investigated on the same lines, with the discovery of the Klebs-Löffler bacillus in 28 of these cases, although no clinical differentiation from non-diphtheritic-infected sores seemed to be possible. In 2 of the cases mild palatal paralysis subsequently developed after the sores had healed. This had also occurred in a number of Cameron's cases, and a knowledge of the preceding epidemiological investigation thus explained what would otherwise have become an obscure neurological problem. The routine use of diphtheritic antitoxin in all intractable cases after 1942 served to prevent a recurrence of this problem.

Typhus broke out in Naples at the end of 1943. It was here that louse-borne typhus, from time immemorial the scourge of every combatant army, met its Waterloo in the shape of the then newly invented D.D.T. The 1946 edition of the Army Manual on medical diseases of the tropics states as the result of this experience that "There is now no reason why a properly equipped modern army need fear typhus".

It is generally accepted since the work of Mackenzie (1941) that the appearance of the exanthematic variety of typhus in a community is due to the previous existence

able to transmit the disease to three volunteers by the instillation of washings into their nares.

Another type of jaundice, which follows the injection of arseno-benzine preparations, was also much seen, particularly in the Italian campaign where the V.D. rate was high. It seemed from the careful reports of the local M.O.s that this type was probably transmitted by imperfectly sterilized syringes or needles being used for the injection of arsenicals into successive patients. This view has now been generally adopted. (Medical Research Council War Memo. No. 15, 1945.)

In all cases of jaundice occurring in endemic areas, it is obviously very important to exclude Weil's disease, and the story of its identification in the B.L.A. in France and Holland has been told by my colleague Dr. E. Bulmer (1945). The occurrence of the disease had not been unforeseen in view of the known presence of rats which had been found to harbour the spirochæte in the urine and the conditions which were prevalent in the earlier part of the campaign. The first case to be recognized occurred in Caen in July 1944, and the report which was at once circulated to all physicians in the Force rendered the arrival of each case of jaundice something of an adventure. In all, Bulmer estimates that about 100 cases must have occurred, although as some were without jaundice more may have been missed. It seemed that the source of infection was almost certainly the water which was used by the men for washing, since all drinking water was sterilized by the usual efficient Army methods. For washing, the men were forced to draw water from the wells and streams. It is, however, probable that they also cleaned their teeth in such water. Bathing in the streams was allowed, the alternative—if it could have been enforced—was that the men should remain dirty and unrefreshed during the rather dreary period prior to the advance, during which it was often exceedingly hot. On some sectors they perforce lived in damp rat-infested ditches and the risk, such as it was, was taken therefore advisedly. It is interesting to note in this connexion that the leptospira isolated in this outbreak were found by Brigadier J. S. K. Boyd to be moderately penicillin-sensitive, and subsequent treatment of some 36 cases with this substance yielded results which were thought to be worthy of further and more extended trial.

Epidemic myalgia.—Bornholm disease has generally been considered as the only recognized example of an infective myalgia. During the winter 1940–41, however, a number of cases of "fibrositis" were seen from a single isolated military unit. All these cases were of similar onset and type and affected the neck, shoulder-girdle, and arms of the sufferers. On further investigation it appeared that the condition showed some signs of being of an epidemic nature. About that time the American Harvard Red Cross Unit arrived under the charge of Dr. (now Professor) Paul Beeson whose assistance was sought in this matter. Subsequently to this he and his team investigated in all four similar outbreaks during 1941–42. He described the results of this work before this Section the same year, and included the cases which actually occurred within his own staff. I will quote some of his observations on the epidemiology of this interesting and unusual investigation. In October 1941 several cases of "stiff neck" occurred among members of the staff of this unit. All persons in the community were therefore canvassed in order to determine the prevalence of the condition. Similar cases of myalgia were reported in a near-by factory and also among a unit of A.T.S. billeted in the neighbourhood. Systematic inquiries revealed a recent high incidence of acute myalgia in these two groups. A fourth survey was then made amongst a detachment of soldiers, and the incidence of myalgia in that community was found to be considerably less than that in other groups. A full study was made of these four groups and it was concluded (Beeson and Scott, 1942) that the evidence obtained indicated that

(h) A well-equipped organization is essential. Adequate staff, equipment, and transport must be available.

Dr. Oswald Savage referred to the excellent work done by the Americans in Naples in combating typhus. They split up their team of typhus workers into three sections. The first was a diagnostic section which went out and ascertained that a given case was typhus. The second section surrounded the plague spot and sprayed everybody in the tenements and dwellings. The third section rounded up the inhabitants of Naples and got them into shelters and other places and sprayed them before they were allowed in the streets again. In the British hospitals at Naples a team went round once a week to spray all civilians. Only one case of typhus, he believed, was reported in the troops, and that was in a soldier who broke out of gaol and was missing for forty-eight hours.

Dr. Allan McFarlan referred to the transmission of the virus in infective hepatitis. Personally he felt inclined to think that in infective hepatitis the virus might be transmitted from the faeces or from the throat, though it was true that the virus had not been shown definitely to appear in pharyngeal washings. Occasionally epidemics were preceded by upper respiratory infections in the community. One got a picture of contact spread after an incubation period of about thirty days, but whether the spread was by droplet or from faeces could not yet be stated. He was not sure that their methods of epidemiological inquiry at the moment helped them to draw a proper distinction.

Dr. W. H. Bradley said that unfortunately the professional epidemiologist had to spend his time working on notifiable diseases almost exclusively and there was less information about other communicable diseases which had a distinct economic bearing. Here he mentioned "epidemic wry-neck" or fibrositis, and syringe-transmitted jaundice. He hoped the President would tell them whether now, in retrospect, he felt that the type of fibrositis which Beeson and McNair Scott transmitted amongst their colleagues at the Harvard Hospital, Salisbury, during the war, was in fact typical of the disease which was so prevalent in this country that most of us got an attack at some time or other in our lives. He had been privileged to see Beeson and Scott's transmission experiments, and although they did not carry them to the point at which they could demonstrate the actual presence of an agent, he was sure it was significant that they did succeed in transmitting serially through six passages in the human. This seemed to be almost as convincing as anything could be that in the blood of patients there was an agent capable of communicating the ordinary fibrositis seen commonly in this country.

As to syringe-transmitted jaundice, he expected that Dr. Copeman's own experience in rheumatic clinics would have caused him to see a good deal of this in patients receiving gold therapy. Did he feel that there was in this jaundice a factor other than that known as homologous serum jaundice? Did he think it was merely syringe transmission of an agent from patient to patient, or did the gold itself play a part in the production of jaundice in rheumatic clinics where chrysotherapy was practised?

Dr. Maurice Mitman said that he particularly appreciated that part of the President's Address which dealt with the possibility of the infective origin of various myalgias, such as Bornholm disease, epidemic wry-neck, erythema nodosum associated with pain in the joints, and so forth. There had been a tendency to pick out from amongst acute and often chronic joint pains a number of infective conditions which were now fairly clearly defined. Erythema nodosum was an interesting example because, for a long time, it was undecided whether it was a streptococcal disease, a tuberculous condition, a disease *sui generis*, or an allergic disorder. The subject became more complicated when it was discovered that meningococcal septicaemia might have as one of its manifestations erythema nodosum, and that some sulphonamides might produce a similar reaction. Did the

in that community of mild murine typhus, and the infestation of its members with lice. The lice feed upon the murine-infected blood, and after a few "passages" through the louse-man cycle, they appear to take on exanthematic properties and the disease becomes epidemic.

The Naples epidemic broke out simultaneously in all the poorer sections of the city and by March 1944 about 1,500 cases had been notified. The peak was reached in January and a sharp fall in daily incidence occurred in the middle of this month. The factors which were underlying the occurrence of the outbreak were evidently numerous, but Stuart-Harris (1947) lists the refugee conditions prevailing amongst the civilian population, the use of overcrowded air-raid shelters as homes, and the shortage of first-class protein in the dietary. Their public health system had entirely broken down, as had the ordinary sanitary services of the city. Throughout the epidemic the younger age-groups were involved to a greater extent, but the mortality, as is usual, was greater in proportion to age. It was soon realized by the Army hygiene officers that the health of the civilian population in such circumstances was intimately connected with that of their troops with whom it was impossible to prevent more or less intimate contact, and co-operation with civilian practitioners was organized by them. About the middle of December, a scheme for the treatment of contacts by means of D.D.T. (and other insecticides) was put into operation by means of the American "six-shot" method of application by use of a dust-gun. This method does not entail the removal of clothes, and thus very large numbers of cases can be dealt with in a comparatively short time. Towards the end of the month, public dusting stations for this purpose were opened all over the city, and by the end of February 1944 over 2,250,000 people had been dealt with in this way. Much of the credit for this achievement must go to the American Typhus Commission under the energetic leadership of Brigadier-General Fox and assisted by 17 selected officers from the R.A.M.C. Towards the end of March, the epidemic finally petered out. The important lessons which we learnt from this rather dramatic episode are tabulated by Chalke (1946) as follows:

- (a) An epidemic of typhus can be terminated in the winter months even in a city where conditions are most favourable for its spread.
- (b) Intensive searching for cases and the disinfection of contacts and the general public were the most important measures adopted. Other public health measures must not be overlooked—in particular the control of movement.
- (c) An army can live and work in a typhus-ridden city with almost complete impunity, provided discipline is maintained and prophylactic dusting is carried out efficiently and regularly.
- (d) The principle of dusting fully clothed people, using hand or power-dusting apparatus, is a notable advance on former methods of dealing with lousiness in a community. Its use in the Army allows cumbersome steam and hot-air apparatus to be done away with.
- (e) Any efficient insecticide powder applied in this way will be successful in guarding against infestation and reinfestation, as well as in treating it. The method is without equal for dealing quickly with large groups of people. Its worth was proved at a later date in disinfecting immense numbers of prisoners and refugees.
- (f) D.D.T. is a new weapon in preventive medicine. It does not kill lice quickly, but is non-irritant and persistent, having residual action which prevents reinfestation. It is particularly valuable where people are not under strict discipline and washing and laundry arrangements are defective.
- (g) Civilian inoculation was not of much importance in the extinction of the epidemic. The British Army, which escaped with one case, contained a large number of uninoculated troops at the peak stages.

Section of Neurology

President—C. WORSTER-DROUGHT, M.D.

[March 4, 1948]

DISCUSSION ON RUPTURE OF THE INTERVERTEBRAL DISC IN THE CERVICAL REGION

Dr. W. Russell Brain: *Anatomy.*—Disc protrusions are common in the cervical and lumbar regions and rare in the thoracic. The cervical and lumbar regions of the spine both exhibit a secondary lordotic curve which, in the cervical region, is largely contributed by the intervertebral discs. They are both sites of much greater mobility than the thoracic spine, and they are each especially exposed to trauma, the lumbar spine to the stresses and strains imposed by weight-lifting and by falls on the buttocks; the cervical spine to the effects of violent movements of the head. In the cervical spine the intervertebral discs are larger relative to the vertebrae than in the lumbar spine, and they are related to the spinal cord as well as to the nerve roots. The cervical spinal cord is anchored fairly firmly by means of the ligamenta denticulata and the roots run a short and direct course to the intervertebral foramina, the uppermost running slightly upwards, the mid-cervical roots transversely and the lowermost beginning to run slightly downwards.

The posterior longitudinal ligament expands opposite each intervertebral disc but does not reach to the lateral margins of the disc. Its central fibres are the weakest and this probably accounts for the two main sites of disc protrusion. If the central fibres are ruptured the disc protrudes straight backwards in the middle line. If this does not happen, or if the disc protrudes slightly to one side, it extends laterally to emerge at the outer edge of the ligament.

In addition to the anterior and posterior spinal arteries the cord is supplied by the lateral spinal arteries which pass in through the intervertebral foramina and in the cervical region are derived from the vertebral arteries and the ascending cervical branch of the inferior thyroid artery. In the veins the blood flow is upwards and the longitudinal venous plexuses of the spinal cord itself anastomose through the veins of the spinal roots with the internal vertebral venous plexuses lying between the dura mater and the ligaments of the spine and these again communicate through the intervertebral foramina with the external vertebral venous plexuses which lie outside the vertebral column.

No doubt the earliest changes produced by a protruded intervertebral disc are circulatory and these must be important at all stages. The veins with their thin walls and low pressure would naturally be compressed first and since the flow in them is upwards an œdema of the anterior or anterolateral region of the cord at and for some segments below the site of compression would cause symptoms related to these segments. Similarly, œdema would be produced in the spinal roots compressed. Arterial blood supply is likely to suffer late, if at all, but obstruction of the lateral spinal artery at the foramen would tend to cause ischæmia of the lateral region of the cord. The anterior spinal artery might conceivably be compressed by a mid-line protrusion, and in severe cervical spondylitis the vertebral artery and vein may undergo compression in their foramen.

Pathogenesis.—The material upon which this paper is based consists of 10 surgically verified cases from one of which post-mortem material is also available.

These patients were mostly middle-aged or older. 2 were between 30 and 40, 3 between 40 and 50, 2 between 50 and 60 and 3 were over 60. Only 2 had symptoms of the radicular type alone, in the remaining 8 the spinal cord was compressed. This, of course, does not represent the relative frequency of the two clinical pictures, for patients with spinal cord compression are much more likely to be operated upon than those with symptoms of a root lesion alone. In this series trauma was unimportant as a cause and appeared to have been a possible factor in only 2 cases. On the other hand osteo-arthritis was present in the cervical spine in 7 out of 10, and in 1 other, though the neck appeared normal, there was osteo-arthritis in the thoracic spine. The osteo-arthritis may be fairly diffuse or limited to the articulations adjacent to one intervertebral disc. In one patient the protrusion occurred during pregnancy.

While it may not be possible sharply to distinguish traumatic disc protrusion from protrusion associated with chronic osteo-arthritis, since the two may overlap, I believe that at the two extremes there are cases in which the protrusion is primarily traumatic and those in which osteo-arthritis is the main causal factor. In the former group it has been suggested that some congenital weakness of the disc may be present, since the precipitating trauma may be very slight, and that is perhaps supported by the fact that I have seen several patients—one in this series—with sciatica as well.

The patients in whom trauma plays a part in the ætiology appear to be younger than those with osteo-arthritis and to be more likely to develop radicular than spinal cord compression.

President consider that these conditions were allergic, or were just picked specific clinical entities from a group which was very mixed beforehand?

Dr. H. J. Parish thought that until the recent war they had probably overlooked skin sores or wounds as manifestations of diphtheria infection. The historical accounts of Trousseau and others showed that cutaneous diphtheria was formerly a most serious condition. The President had spoken of the infected desert sores seen in Palestine during the war, and many skin lesions were also found in prison camps in the Far East. Bacteriological examination was not carried out in these camps, but several patients developed various paralyses; in retrospect, diphtheria could be diagnosed with confidence. There was no doubt that this type of infection had to be reckoned with from time to time.

Secondly, the President had mentioned the transmission of viruses by injections. The need for good inoculation technique was thus emphasized. A separate syringe and needle should be used for each intravenous injection or withdrawal of blood.

Sir Weldon Dalrymple-Champneys said that they heard much talk nowadays about getting the preventive aspect into the minds of the young practitioner by encouraging physicians and surgeons in teaching hospitals to look at all their cases from a preventive standpoint, and to get their students to do the same. Parallel with that, there was also, as the President had demonstrated that afternoon, the great desirability of getting their students to look at things from the epidemiological point of view. They were all conscious of the fascinating problems waiting to be solved and the important discoveries waiting to be made.

It was curious that whereas it was well recognized in tropical countries that there were one-day fevers and two-day fevers, and so on, most of them were attributed to some virus infection, and most of them were so mild that no one worried about them but took them as one of the ordinary commonplaces of life. In temperate climes they did not seem to have paid much attention to these things. They liked to go on studying well-recognized diseases or more serious diseases, and all these "colds" and "influenzas" were occurring and unless they could find the virus they were being allowed to drift past them. Personally he hoped that in the future more attention would be paid to these matters, and as a result some of the discoveries to which the President had referred would be made.

With regard to epidemic myalgia, he was struck at the time by the fact that some of these cases did become chronic. They were not all trivial things. He would have thought it very probable that many of these "trivial" illnesses included a certain residue of cases which had become chronic and which generally were quite unrecognized except in the hands of the able epidemiologist.

The President said that Dr. Bradley had asked whether he could have told that the cases of fibrositis of Beeson and McNair Scott were not typical ones. Of those he saw he was quite unable to say which of them had become chronic owing to natural causes and which had arisen out of the epidemic. Some became very severe, two of them at least had to be sent back to America as they seemed quite intractable to treatment, and that might indicate some degree of differentiation.

The transmission experiments were interesting. This was also done in a case of rheumatic fever, and again, something happened, that is to say, quite definite "rheumatic" symptoms arose in four generations of inoculation from this case of rheumatic fever. They were unable, however, to carry the matter further at that time.

In reply to Dr. Mitman, his view was that a large group of cases in the whole field of the rheumatic diseases—not only in the non-articular type—still awaited further classification. There was still a large field for purely clinical observation and he felt sure that they would, bit by bit, sort out that field.

With regard to gold-produced jaundice it was very rare in rheumatic clinics, so that he thought it must be considered sporadic rather than homologous, and probably something specifically to do with the gold itself.

Sir Allen Daley said that the advances for which they hoped could come about only with the closest co-operation between the clinician and the professional epidemiologist, if he might use that term. The professional epidemiologist might be able to throw some light on the problems, but he was not sufficiently close to them, and it was the practising physician, the clinician, who, if he had in his bones the elements of epidemiology, could ascertain that there was a problem there. Many clinicians neglected this entirely. Therefore the Section was very fortunate in having as President a man who had done a large amount of clinical work with the Army in the field, and had drawn attention to numerous and most interesting epidemiological studies which had arisen there.

lesion was fairly common. Posterior column sensibility was rarely affected. (d) Fasciculation was occasionally seen in the upper limbs, but muscular wasting was inconspicuous except in the hands where it was several times noted even with a lesion as high as C2 to C3. This may be the result of a circulatory change produced by compression of spinal veins, but if so this region of the cord must be especially vulnerable.

(4) *The cerebrospinal fluid:* The C.S.F. was examined in 9 cases and was abnormal in composition in 7. The protein was between 60 and 80 mg. % in 3 and between 100 and 140 mg. % in 4. Queckenstedt's test yielded evidence of subarachnoid block in 4 in one of whom the composition of the fluid was normal. Thus in 8 out of 9 the investigation of the C.S.F. yielded some abnormality.

(5) *X-ray examination:* X-rays may show no abnormality, or merely a narrowed disc space, but in this series osteo-arthritic changes were present in the neck in 7 out of 10 cases and myelography yielded positive results in all 6 cases in which it was carried out.

(6) *Movements of the neck:* Some limitation of neck movement is often present. In the more acute cases a very slight movement may cause pain: in some cases with chronic osteo-arthritis on the other hand neck movement may be surprisingly full and painless.

Diagnosis.—In patients with radicular symptoms only the main problem in diagnosis is to distinguish a protruded disc from cervical spondylitis with a root lesion due to narrowing of the intervertebral foramen. In both osteo-arthritic changes may be present with loss of disc-space and hence a narrowed foramen. A raised protein in the C.S.F. may occur with a disc protrusion compressing the roots only but not in arthritis. In doubtful cases only myelography will settle the question.

The diagnosis of a protruded disc from other extramedullary tumours can be made only when the characteristic X-ray changes are present in the cervical spine.

Prognosis and treatment.—As with herniated lumbar discs recovery from radicular symptoms may be achieved by conservative measures. Prolonged immobilization with the neck between sandbags or with traction extension or support from a plaster or leather collar should be tried and operation carried out only for persistent pain in the neck or upper limb, or severe muscular wasting and weakness. Spinal compression always calls for surgical exploration.

Mr. G. C. Knight: In the cervical canal the neural structures are relatively immobile and small herniations may therefore produce compression, not only of an adjacent nerve root but also of half, or the whole, of the anterior aspect of the spinal cord.

Each cervical root runs almost transversely across the face of the disc to reach its point of exit, each root crossing only one disc. Compression of two roots by a single protrusion is therefore rare. Evidence of compression of two roots almost invariably means two compressing agents, and these are not necessarily discs.

Although Stookey in his original description divided cases of cervical disc protrusion into three groups, those showing root compression, or root compression with hemi-cord compression, or mid-line compression of the front face of the cord, there is reason to believe that cervical disc protrusion may at times be a progressive lesion: cases passing progressively from root compression alone to root compression with hemiparesis, and finally to paraparesis. The interval elapsing before the development of symptoms of cord compression may be long, as in a case recorded by Michelson and Mixter in which pain in the arm and shoulder preceded by twenty-three years the onset of paraparesis.

Symptomatology of acute traumatic protrusion.—Minor injuries in the cervical region may be followed by the instantaneous development of traumatic paraplegia. Such an injury may be inflicted by a fall down a few stairs, by an elderly patient falling on his face when walking along the pavement, and has followed sudden movement of the neck if a patient is pitched forward by the sudden arrest of a car. X-ray examination in such cases may reveal no evidence of cervical spinal fracture or dislocation. It has been suggested that in cases of this nature dislocation of the spine has occurred but the bones have rebounded into their normal position. Such a state of affairs is impossible owing to interlocking of the articular facets. Certain cases of this type are attributable to cervical cord contusion produced by hyperextension of the spine and rupture of the anterior common ligament, but others are clearly due to a sudden protrusion of a cervical disc, the effect of which will depend upon the degree of contusion inflicted on the cord at the moment of herniation. If the herniation produces a lesion in the anterior spinal artery at the site of impact the case will be irrecoverable; there is an immediate quadriplegia, the level of anaesthesia extends up to the arms, and gradually ascends to a still higher level, as the result of anterior spinal thrombosis which may even produce phrenic palsy within twenty-four hours.

Less serious cases are observed in which the cord escapes severe vascular injury; in these there is a substantial prospect of recovery. There may be an immediate quadriplegia, but the sensory loss extends only to the thorax and tends to pass off quickly. Within a matter

The role of osteo-arthritis in causation is obscure: it is in this group that the protrusion is likely to be osteophytic in part, and possibly some of these swellings are not derived from the disc. In the one case with post-mortem material—a patient with cervical and thoracic spondylitis from whom a left antero-lateral protrusion at the level of C4 to C5 had been removed—three out of four adjacent intervertebral discs in the thoracic region were the site of a cartilaginous nodule. Histological examination showed at the site of the operation the remains of a cartilaginous protrusion beneath a greatly thickened dura fused with the posterior longitudinal ligament, while in the thoracic region there was a degenerated intervertebral disc which had ruptured into the body of one vertebra. In such a case herniation of a disc is clearly only an element in a diffuse degenerative spondylitis. In this series the disc between C5 and C6 was involved five times, that between C4 and C5 twice and C2 and C3, C3 and C4 and C6 and C7 once each.

I am indebted to Mr. Northfield for kindly allowing me to use his notes. He operated upon 9 of these 10 patients, and the 10th was operated on by Sir Hugh Cairns.

SYMPTOMATOLOGY

(1) *Mode of onset*: The disorder may manifest itself by: (a) an acute onset of symptoms, especially pain, involving the neck and one upper limb; (b) an insidious and, perhaps, remittent onset of the same character and distribution; (c) an insidious onset with radicular symptoms referred to one upper limb together with evidence of a lesion of the spinal cord; or by (d) an insidious onset of symptoms of a spinal cord lesion alone. The acute onset of symptoms with a spinal cord lesion with or without radicular symptoms is much less common.

(a) An acute onset of symptoms involving the neck and one upper limb is most often seen after trauma which may be quite slight. For example, a woman of 50 twice within ten days sustained a blow on the chin. Six weeks after the second incident she "felt something go in her neck", and developed such intense pain that she could not move it. The pain was felt at the base of the neck and across the shoulders. Four days later the neck could be moved rather stiffly and lateral flexion was painful. The only neurological abnormality was diminution of the left biceps jerk. X-rays showed reduction of disc space between C7 and D1. In another patient, a woman of 49, the symptoms dated from an electric shock which rendered her unconscious. X-rays showed a narrowed disc space between C5 and C6 with a slight crush of adjacent bodies and lipping.

(b, c, d) The other modes of onset need no special discussion, except to mention that the history of symptoms of spinal cord compression was often short, namely two months, three months, four months, six months and nine months. In the other 3 cases it was two years, two and a half years and ten years.

(2) *Radicular symptoms*: Radicular symptoms may occur alone or in association with symptoms of compression of the spinal cord. The most prominent radicular symptom is pain corresponding in distribution to the root involved. It is shooting or burning in character and when severe may be described as agonizing. Characteristically it is made worse by coughing and by movements of the neck and sometimes of the affected upper limb. The patient may be unable to lie on either side in bed, especially the affected side. It is common for periods of exacerbation to be followed by periods of relative remission. The pain may be accompanied by feelings of numbness or tingling referred to the affected dermatome and most noticeable when one of the roots C5, C6 or C7 is involved. The pain, however, as is the rule with pain due to root irritation, is much more extensive than the distribution of the dermatome, radiating widely into the muscles innervated by the affected root and, since the upper limb but also muscles from the neck to the chest wall and scapula, the pain may be very widespread. Hyperalgesia may occur.

Sensory loss is usually slight and rather patchy within the dermatome, involving cutaneous rather than deep sensibility. The tendon-jerks innervated by the affected root are likely to be diminished or even lost. Muscular fasciculation may occur and there may be slight wasting, weakness and hypotonia of the muscles innervated by the affected root, but gross muscular wasting and weakness are unusual.

(3) *Spinal cord symptoms*: There are certain noteworthy points in the spinal cord symptomatology. (a) There were 8 patients with symptoms of spinal cord compression: 4 with an incomplete Brown-Séquard syndrome, 4 with bilateral spinal cord symptoms. Yet 7 of the 8 had a laterally placed protrusion and the 8th an anterior one. Hence 3 of the patients with a lateral compression gave no clinical evidence of its laterality. (b) Signs of pyramidal tract involvement were the most severe. (c) Sensory fibres appeared less vulnerable. Only one patient showed much damage to the spinothalamic tracts, but bilateral cutaneous sensory impairment over several dermatomes at and below the level of the

lesion was fairly common. Posterior column sensibility was rarely affected. (d) Fasciculation was occasionally seen in the upper limbs, but muscular wasting was inconspicuous except in the hands where it was several times noted even with a lesion as high as C2 to C3. This may be the result of a circulatory change produced by compression of spinal veins, but if so this region of the cord must be especially vulnerable.

(4) *The cerebrospinal fluid:* The C.S.F. was examined in 9 cases and was abnormal in composition in 7. The protein was between 60 and 80 mg. % in 3 and between 100 and 140 mg. % in 4. Queckenstedt's test yielded evidence of subarachnoid block in 4 in one of whom the composition of the fluid was normal. Thus in 8 out of 9 the investigation of the C.S.F. yielded some abnormality.

(5) *X-ray examination:* X-rays may show no abnormality, or merely a narrowed disc space, but in this series osteo-arthritic changes were present in the neck in 7 out of 10 cases and myelography yielded positive results in all 6 cases in which it was carried out.

(6) *Movements of the neck:* Some limitation of neck movement is often present. In the more acute cases a very slight movement may cause pain: in some cases with chronic osteoarthritis on the other hand neck movement may be surprisingly full and painless.

Diagnosis.—In patients with radicular symptoms only the main problem in diagnosis is to distinguish a protruded disc from cervical spondylitis with a root lesion due to narrowing of the intervertebral foramen. In both osteo-arthritic changes may be present with loss of disc-space and hence a narrowed foramen. A raised protein in the C.S.F. may occur with a disc protrusion compressing the roots only but not in arthritis. In doubtful cases only myelography will settle the question.

The diagnosis of a protruded disc from other extramedullary tumours can be made only when the characteristic X-ray changes are present in the cervical spine.

Prognosis and treatment.—As with herniated lumbar discs recovery from radicular symptoms may be achieved by conservative measures. Prolonged immobilization with the neck between sandbags or with traction extension or support from a plaster or leather collar should be tried and operation carried out only for persistent pain in the neck or upper limb, or severe muscular wasting and weakness. Spinal compression always calls for surgical exploration.

Mr. G. C. Knight: In the cervical canal the neural structures are relatively immobile and small herniations may therefore produce compression, not only of an adjacent nerve root but also of half, or the whole, of the anterior aspect of the spinal cord.

Each cervical root runs almost transversely across the face of the disc to reach its point of exit, each root crossing only one disc. Compression of two roots by a single protrusion is therefore rare. Evidence of compression of two roots almost invariably means two compressing agents, and these are not necessarily discs.

Although Stookey in his original description divided cases of cervical disc protrusion into three groups, those showing root compression, or root compression with hemi-cord compression, or mid-line compression of the front face of the cord, there is reason to believe that cervical disc protrusion may at times be a progressive lesion: cases passing progressively from root compression alone to root compression with hemiparesis, and finally to paraparesis. The interval elapsing before the development of symptoms of cord compression may be long, as in a case recorded by Michelson and Mixter in which pain in the arm and shoulder preceded by twenty-three years the onset of paraparesis.

Symptomatology of acute traumatic protrusion.—Minor injuries in the cervical region may be followed by the instantaneous development of traumatic paraplegia. Such an injury may be inflicted by a fall down a few stairs, by an elderly patient falling on his face when walking along the pavement, and has followed sudden movement of the neck if a patient is pitched forward by the sudden arrest of a car. X-ray examination in such cases may reveal no evidence of cervical spinal fracture or dislocation. It has been suggested that in cases of this nature dislocation of the spine has occurred but the bones have rebounded into their normal position. Such a state of affairs is impossible owing to interlocking of the articular facets. Certain cases of this type are attributable to cervical cord contusion produced by hyperextension of the spine and rupture of the anterior common ligament, but others are clearly due to a sudden protrusion of a cervical disc, the effect of which will depend upon the degree of contusion inflicted on the cord at the moment of herniation. If the herniation produces a lesion in the anterior spinal artery at the site of impact the case will be irrecoverable; there is an immediate quadriplegia, the level of anaesthesia extends up to the arms, and gradually ascends to a still higher level, as the result of anterior spinal thrombosis which may even produce phrenic palsy within twenty-four hours.

Less serious cases are observed in which the cord escapes severe vascular injury; in these there is a substantial prospect of recovery. There may be an immediate quadriplegia, but the sensory loss extends only to the thorax and tends to pass off quickly. Within a matter

The role of osteo-arthritis in causation is obscure: it is in this group that the protrusion is likely to be osteophytic in part, and possibly some of these swellings are not derived from the disc. In the one case with post-mortem material—a patient with cervical and thoracic spondylitis from whom a left antero-lateral protrusion at the level of C4 to C5 had been removed—three out of four adjacent intervertebral discs in the thoracic region were the site of a cartilaginous nodule. Histological examination showed at the site of the operation the remains of a cartilaginous protrusion beneath a greatly thickened dura fused with the posterior longitudinal ligament, while in the thoracic region there was a degenerated intervertebral disc which had ruptured into the body of one vertebra. In such a case herniation of a disc is clearly only an element in a diffuse degenerative spondylitis. In this series the disc between C5 and C6 was involved five times, that between C4 and C5 twice and C2 and C3, C3 and C4 and C6 and C7 once each.

I am indebted to Mr. Northfield for kindly allowing me to use his notes. He operated upon 9 of these 10 patients, and the 10th was operated on by Sir Hugh Cairns.

SYMPTOMATOLOGY

(1) *Mode of onset:* The disorder may manifest itself by: (a) an acute onset of symptoms, especially pain, involving the neck and one upper limb; (b) an insidious and, perhaps, remittent onset of the same character and distribution; (c) an insidious onset with radicular symptoms referred to one upper limb together with evidence of a lesion of the spinal cord; or by (d) an insidious onset of symptoms of a spinal cord lesion alone. The acute onset of symptoms with a spinal cord lesion with or without radicular symptoms is much less common.

(a) An acute onset of symptoms involving the neck and one upper limb is most often seen after trauma which may be quite slight. For example, a woman of 50 twice within ten days sustained a blow on the chin. Six weeks after the second incident she "felt something go in her neck", and developed such intense pain that she could not move it. The pain was felt at the base of the neck and across the shoulders. Four days later the neck could be moved rather stiffly and lateral flexion was painful. The only neurological abnormality was diminution of the left biceps jerk. X-rays showed reduction of disc space between C7 and D1. In another patient, a woman of 49, the symptoms dated from an electric shock which rendered her unconscious. X-rays showed a narrowed disc space between C5 and C6 with a slight crush of adjacent bodies and lipping.

(b, c, d) The other modes of onset need no special discussion, except to mention that the history of symptoms of spinal cord compression was often short, namely two months, three months, four months, six months and nine months. In the other 3 cases it was two years, two and a half years and ten years.

(2) *Radicular symptoms:* Radicular symptoms may occur alone or in association with symptoms of compression of the spinal cord. The most prominent radicular symptom is pain corresponding in distribution to the root involved. It is shooting or burning in character and when severe may be described as agonizing. Characteristically it is made worse by coughing and by movements of the neck and sometimes of the affected upper limb. The patient may be unable to lie on either side in bed, especially the affected side. It is common for periods of exacerbation to be followed by periods of relative remission. The pain may be accompanied by feelings of numbness or tingling referred to the affected dermatome and most noticeable when one of the roots C5, C6 or C7 is involved. The pain, however, as is the rule with pain due to root irritation, is much more extensive than the distribution of the dermatome, radiating widely into the muscles innervated by the affected root and, since the fifth, sixth and seventh cervical segments between them innervate not only muscles of the upper limb but also muscles from the neck to the chest wall and scapula, the pain may be very widespread. Hyperalgesia may occur.

Sensory loss is usually slight and rather patchy within the dermatome, involving cutaneous rather than deep sensibility. The tendon-jerks innervated by the affected root are likely to be diminished or even lost. Muscular fasciculation may occur and there may be slight wasting, weakness and hypotonia of the muscles innervated by the affected root, but gross muscular wasting and weakness are unusual.

(3) *Spinal cord symptoms:* There are certain noteworthy points in the spinal cord symptomatology. (a) There were 8 patients with symptoms of spinal cord compression: 4 with an incomplete Brown-Séquard syndrome, 4 with bilateral spinal cord symptoms. Yet 7 of the 8 had a laterally placed protrusion and the 8th an anterior one. Hence 3 of the patients with a lateral compression gave no clinical evidence of its laterality. (b) Signs of pyramidal tract involvement were the most severe. (c) Sensory fibres appeared less vulnerable. Only one patient showed much damage to the spinothalamic tracts, but bilateral cutaneous sensory impairment over several dermatomes at and below the level of the

lesion was fairly common. Posterior column sensibility was rarely affected. (d) Fasciculation was occasionally seen in the upper limbs, but muscular wasting was inconspicuous except in the hands where it was several times noted even with a lesion as high as C2 to C3. This may be the result of a circulatory change produced by compression of spinal veins, but if so this region of the cord must be especially vulnerable.

(4) *The cerebrospinal fluid:* The C.S.F. was examined in 9 cases and was abnormal in composition in 7. The protein was between 60 and 80 mg. % in 3 and between 100 and 140 mg. % in 4. Queckenstedt's test yielded evidence of subarachnoid block in 4 in one of whom the composition of the fluid was normal. Thus in 8 out of 9 the investigation of the C.S.F. yielded some abnormality.

(5) *X-ray examination:* X-rays may show no abnormality, or merely a narrowed disc space, but in this series osteo-arthritic changes were present in the neck in 7 out of 10 cases and myelography yielded positive results in all 6 cases in which it was carried out.

(6) *Movements of the neck:* Some limitation of neck movement is often present. In the more acute cases a very slight movement may cause pain: in some cases with chronic osteo-arthritis on the other hand neck movement may be surprisingly full and painless.

Diagnosis.—In patients with radicular symptoms only the main problem in diagnosis is to distinguish a protruded disc from cervical spondylitis with a root lesion due to narrowing of the intervertebral foramen. In both osteo-arthritic changes may be present with loss of disc-space and hence a narrowed foramen. A raised protein in the C.S.F. may occur with a disc protrusion compressing the roots only but not in arthritis. In doubtful cases only myelography will settle the question.

The diagnosis of a protruded disc from other extramedullary tumours can be made only when the characteristic X-ray changes are present in the cervical spine.

Prognosis and treatment.—As with herniated lumbar discs recovery from radicular symptoms may be achieved by conservative measures. Prolonged immobilization with the neck between sandbags or with traction extension or support from a plaster or leather collar should be tried and operation carried out only for persistent pain in the neck or upper limb, or severe muscular wasting and weakness. Spinal compression always calls for surgical exploration.

Mr. G. C. Knight: In the cervical canal the neural structures are relatively immobile and small herniations may therefore produce compression, not only of an adjacent nerve root but also of half, or the whole, of the anterior aspect of the spinal cord.

Each cervical root runs almost transversely across the face of the disc to reach its point of exit, each root crossing only one disc. Compression of two roots by a single protrusion is therefore rare. Evidence of compression of two roots almost invariably means two compressing agents, and these are not necessarily discs.

Although Stookey in his original description divided cases of cervical disc protrusion into three groups, those showing root compression, or root compression with hemi-cord compression, or mid-line compression of the front face of the cord, there is reason to believe that cervical disc protrusion may at times be a progressive lesion: cases passing progressively from root compression alone to root compression with hemiparesis, and finally to paraparesis. The interval elapsing before the development of symptoms of cord compression may be long, as in a case recorded by Michelson and Mixer in which pain in the arm and shoulder preceded by twenty-three years the onset of paraparesis.

Symptomatology of acute traumatic protrusion.—Minor injuries in the cervical region may be followed by the instantaneous development of traumatic paraplegia. Such an injury may be inflicted by a fall down a few stairs, by an elderly patient falling on his face when walking along the pavement, and has followed sudden movement of the neck if a patient is pitched forward by the sudden arrest of a car. X-ray examination in such cases may reveal no evidence of cervical spinal fracture or dislocation. It has been suggested that in cases of this nature dislocation of the spine has occurred but the bones have rebounded into their normal position. Such a state of affairs is impossible owing to interlocking of the articular facets. Certain cases of this type are attributable to cervical cord contusion produced by hyperextension of the spine and rupture of the anterior common ligament, but others are clearly due to a sudden protrusion of a cervical disc, the effect of which will depend upon the degree of contusion inflicted on the cord at the moment of herniation. If the herniation produces a lesion in the anterior spinal artery at the site of impact the case will be irrecoverable; there is an immediate quadriplegia, the level of anæsthesia extends up to the arms, and gradually ascends to a still higher level, as the result of anterior spinal thrombosis which may even produce phrenic palsy within twenty-four hours.

Less serious cases are observed in which the cord escapes severe vascular injury; in these there is a substantial prospect of recovery. There may be an immediate quadriplegia, but the sensory loss extends only to the thorax and tends to pass off quickly. Within a matter

of days the sensory disturbance may be limited to paræsthesia in the feet. Signs of bilateral spasticity, however, persist in the lower limbs with incomplete recovery, retention of urine being often long-standing.

Symptomatology of root compression.—Disc protrusions at the fifth and sixth cervical interspaces produce compression of the sixth and seventh cervical nerve roots. The resulting pain characterized by exacerbations and remissions is experienced in the lower part of the neck, radiating to the shoulder tip, to the supraclavicular fossa, to the pectoral and precordial regions, and to the lateral aspect of the upper arm. Pain is seldom experienced in the forearm or hand. Painful and unpleasant paræsthesiæ are felt in the distal part of the affected dermatome.

The root syndromes are most sharply distinguished by the distribution of the paræsthesiæ. In compression of the sixth cervical nerve root paræsthesia will be felt at the radial side of the forearm and thumb, and in the first interosseous space; in compression of the seventh root paræsthesia will be experienced upon the back of the index, middle and ring fingers and the whole dorsum of the hand. The physical signs consist of local tenderness to palpation of the upper fibres of the trapezius and suprascapular region, and occasionally of the anterior pectoral areas. Usually, lateral flexion of the spine towards the side of the lesion increases pain, but flexion in the opposite direction may also do so, according to the relationship of the root to the protrusion. Long axis compression of the spine, as described by Spurling and Scoville, will not invariably lead to exacerbation of the pain.

Localizing signs in the nervous system are not observed until some time after the onset of pain and paræsthesia.

We observe three stages of root irritation, which I would term the phases of irritation, of compression, of paralysis. In the irritative phase a small protrusion makes light contact with a root, which is subjected to friction but is not so severely compressed that its conduction is seriously interfered with. In this stage pain will be extremely severe and widespread, and experienced throughout the whole course of the affected dermatome; but physical signs may be absent, or limited at most to a zone of sensory reduction in the peripheral skin areas, owing to the fact that the long sensory fibres are most easily affected. In the phase of compression the root is firmly fixed by the protrusion; there is less friction, and for this reason the pain is less severe. But the greater compression of the root results in a larger zone of impaired sensation, extending higher into the dermatome area, and in the appearance of physical signs of motor weakness and reduction of reflexes. Rarely, the compression of the root may be so severe as to fix it entirely. In such cases pain may be absent, sensory loss is widespread and a severe degree of motor weakness is encountered. Investigations by electromyography at all stages reveal abnormal spontaneous discharges from the muscles innervated by a single root.

Pseudo-angina in association with cervical disc protrusion.—In rare cases the pain resulting from cervical root irritation may radiate to the anterior pectoral region and be associated with tenderness of the pectoral muscles. This pain, being exacerbated by deep breathing and exercise and accounting for a certain degree of dyspnoea on exertion, may, rarely, be misdiagnosed as angina pectoris and lead to the patient being unwarrantably condemned to the life of a chronic cardiac invalid. This syndrome is especially observed in cases of irritation of the seventh cervical nerve root. The diagnosis should be established by the finding of a typical area of numbness and paræsthesiæ in the affected dermatome.

Symptomatology of half-cord compression.—Compression of the anterior aspect of one-half of the spinal cord can be produced by protrusions of small size. Pressure on the posterior columns is therefore not necessarily present and the signs may be limited to homolateral pyramidal involvement, with contralateral spinothalamic sensory loss. Paræsthesiæ are often conspicuous in the contralateral foot.

Symptomatology of bilateral cord compression.—Bilateral compression of the front face of the cord may constitute the presenting feature, or may develop gradually after a preceding period of root or half-cord compression in gradually increasing protrusions that extend mesially. In the majority of syndromes only the pyramidal and spinothalamic tracts will be affected, thus accounting for the frequent misdiagnosis of syringomyelia; but in those cases in which the posterior columns are also involved a diagnosis of subacute combined degeneration may be made.

It is important to emphasize how variable the clinical picture may be in the same patient on repeated examinations. Posterior column signs may come and go, and also signs from the spinothalamic tracts. This fluctuation is a most characteristic feature and can be most easily accounted for by variation in the effect that the protrusion produces upon the anterior spinal veins.

Treatment.—There can be no doubt that the majority of cases of cervical disc protrusion recover spontaneously as a result of conservative measures alone. Rest in the position of

greatest comfort should be tried first. Manipulation is dangerous owing to the risk of increasing a protrusion. Certain successes attributed to manipulation may be accounted for merely by the beneficial effects of the anæsthetic employed, which will relieve muscle spasm. There are no indications for any surgical intervention in the stage of irritation of a single nerve root, which should invariably recover as a result of conservative treatment. Surgical intervention will be needed occasionally in cases of established compression of a root in which conservative treatment has failed, and in all cases of half-cord compression. In syndromes of compression of the front face of the cord by mid-line protrusions there are points for and against operation which must be most carefully weighed. Attempts at removal have occasionally led to an increase rather than a decrease in the neurological signs. In high mid-line protrusions in which signs of defective movement of the diaphragm are already present, even a simple decompression may not be advisable.

In 37 cases under my care there were 29 examples of compression of a single root. 24 were relieved by conservative measures, which included the application of a plaster collar in 4 long-standing cases, after a preliminary period of skull caliper traction in 3 in whom the symptoms had been present for as long as seven years. (Laminectomy was required in 5.) 4 cases exhibiting compression of half the cord required laminectomy. In 4 cases of mid-line protrusion laminectomy with decompression was employed only in 2 owing to unfavourable features that were present in the other cases.

When operation is employed hemilaminectomy gives an adequate approach in cases exhibiting root symptoms only, removing the ligamentum flavum and the lower third of the upper lamina and the upper half of the next lamina below. This bone removal must be carried far laterally. The affected root will be found to be flattened and displaced posteriorly, and is usually extremely tense. It is best to draw the root up and remove the protrusion from its inner aspect, the portion of tissue removed being usually small in size.

A full laminectomy is required in those cases in which symptoms of cord compression are present. In cases of mid-line protrusion it is usually wiser to treat the patient by a simple decompression, with mobilization of the dentate ligaments, rather than risk the possibility of an anterior spinal artery thrombosis with its possible fatal consequences from phrenic palsy being precipitated by dissection and manipulation in contact with the front face of the cord.

Dr. J. W. D. Bull: In studying the question of protruded intervertebral discs it may be helpful to compare and contrast the anatomy of the lower cervical and lower lumbar vertebræ, for it is usually the lower vertebræ in each case which are involved. Taking the lumbar vertebræ first, for here we stand on firmer ground, as far as the ætiology of the disc syndrome is concerned, we find that these are the largest vertebræ in the body and the largest intervertebral discs. Their size, of course, is in keeping with the great pressures they are called upon to withstand. The volume of these discs is about 10 c.c. and if we allow the nucleus pulposus to be 15%—probably a generous estimate—of this volume, that is to say 1.5 c.c., then this is the volume which can potentially protrude. A spherical body of 1.5 c.c. has a diameter of a little over 1.4 cm., or half an inch, or the size of a small cherry. A body of such a size protruding into the lumbar canal will, and does, cause considerable obstruction and occasionally a complete block of the spinal canal. The canal in the lower lumbar region is traversed by the lower lumbar and the sacral nerves running longitudinally—the cauda equina.

In the lower cervical region there is a different anatomical picture. The vertebræ are very much smaller—the surfaces of their bodies have an area about four times less than the lumbar, and their intervertebral discs are correspondingly smaller. I have dissected out the intervertebral discs from the neck of a body whose vertebræ and discs were radiologically normal. The volumes of the discs were determined by placing the dissected fragments in a small test tube graduated in c.c. The measurements were:—C4 to C5 disc 1.0 c.c., C5 to C6 disc 1.2 c.c. and C6 to C7 disc 1.4 c.c.

This is a very much smaller volume, naturally, than the lower lumbar disc. Using the same arbitrary figure, 15%, for the volume of the nucleus pulposus, we find that if the nucleus between C6 and C7 protrudes entirely, a volume of 0.21 c.c. is extruded. Such a body, if spherical, will have a diameter of 0.7 cm., about half the diameter of the lumbar disc, whose volume is seven times greater. Such a protruded cervical disc would be about equivalent in size to a red currant and this, one must remember, is the maximum protrusion. Most protruded cervical and lumbar discs would be smaller than I have described as the extrusion of the nucleus pulposus is not normally complete.

In the lower cervical canal much of the space is occupied by the spinal cord. Here the nerves do not run parallel in the line of the canal as in the lumbar region, but instead leave the cord almost at right angles.

There is also the difference in form of cervical vertebræ compared with lumbar vertebræ.

of days the sensory disturbance may be limited to paræsthesia in the feet. Signs of bilateral spasticity, however, persist in the lower limbs with incomplete recovery, retention of urine being often long-standing.

Symptomatology of root compression.—Disc protrusions at the fifth and sixth cervical interspaces produce compression of the sixth and seventh cervical nerve roots. The resulting pain characterized by exacerbations and remissions is experienced in the lower part of the neck, radiating to the shoulder tip, to the supraclavicular fossa, to the pectoral and præcordial regions, and to the lateral aspect of the upper arm. Pain is seldom experienced in the forearm or hand. Painful and unpleasant paræsthesiæ are felt in the distal part of the affected dermatome.

The root syndromes are most sharply distinguished by the distribution of the paræsthesiæ. In compression of the sixth cervical nerve root paræsthesia will be felt at the radial side of the forearm and thumb, and in the first interosseous space; in compression of the seventh root paræsthesia will be experienced upon the back of the index, middle and ring fingers and the whole dorsum of the hand. The physical signs consist of local tenderness to palpation of the upper fibres of the trapezius and suprascapular region, and occasionally of increases pain, but flexion in the opposite direction may also do so, according to the relationship of the root to the protrusion. Long axis compression of the spine, as described by Spurling and Scoville, will not invariably lead to exacerbation of the pain.

Localizing signs in the nervous system are not observed until some time after the onset of pain and paræsthesia.

We observe three stages of root irritation, which I would term the phases of irritation, of compression, of paralysis. In the irritative phase a small protrusion makes light contact with a root, which is subjected to friction but is not so severely compressed that its conduction is seriously interfered with. In this stage pain will be extremely severe and widespread, and experienced throughout the whole course of the affected dermatome; but physical signs may be absent, or limited at most to a zone of sensory reduction in the peripheral skin areas, owing to the fact that the long sensory fibres are most easily affected. In the phase of compression the root is firmly fixed by the protrusion; there is less friction, and for this reason the pain is less severe. But the greater compression of the root results in a larger zone of impaired sensation, extending higher into the dermatome area, and in the appearance of physical signs of motor weakness and reduction of reflexes. Rarely, the compression of the root may be so severe as to fix it entirely. In such cases pain may be absent, sensory loss is widespread and a severe degree of motor weakness is encountered. Investigations by electromyography at all stages reveal abnormal spontaneous discharges from the muscles innervated by a single root.

Pseudo-angina in association with cervical disc protrusion.—In rare cases the pain resulting from cervical root irritation may radiate to the anterior pectoral region and be associated with tenderness of the pectoral muscles. This pain, being exacerbated by deep breathing and exercise and accounting for a certain degree of dyspnœa on exertion, may, rarely, be misdiagnosed as angina pectoris and lead to the patient being unwarrantably condemned to the life of a chronic cardiac invalid. This syndrome is especially observed in cases of irritation of the seventh cervical nerve root. The diagnosis should be established by the finding of a typical area of numbness and paræsthesiæ in the affected dermatome.

Symptomatology of half-cord compression.—Compression of the anterior aspect of one-half of the spinal cord can be produced by protrusions of small size. Pressure on the posterior columns is therefore not necessarily present and the signs may be limited to homolateral pyramidal involvement, with contralateral spinothalamic sensory loss. Paræsthesiæ are often conspicuous in the contralateral foot.

Symptomatology of bilateral cord compression.—Bilateral compression of the front face of the cord may constitute the presenting feature, or may develop gradually after a preceding period of root or half-cord compression in gradually increasing protrusions that extend mesially. In the majority of syndromes only the pyramidal and spinothalamic tracts will be affected, thus accounting for the frequent misdiagnosis of syringomyelia; but in those cases in which the posterior columns are also involved a diagnosis of subacute combined degeneration may be made.

It is important to emphasize how variable the clinical picture may be in the same patient on repeated examinations. Posterior column signs may come and go, and also signs from the spinothalamic tracts. This fluctuation is a most characteristic feature and can be most easily accounted for by variation in the effect that the protrusion produces upon the anterior spinal veins.

Treatment.—There can be no doubt that the majority of cases of cervical disc protrusion recover spontaneously as a result of conservative measures alone. Rest in the position of

Fig. 3 is a semi-diagrammatic illustration, intended to show the anatomical changes which occur when a disc degenerates. (A) shows the normal. Attention is drawn to the considerable space between the posterior wall of the disc and the cord. (B) shows a centrally protruding disc. This can and does occasionally occur. If large enough it behaves as an anteriorly situated extradural tumour, and was so regarded by the older surgeons before discs became the fashion.

I cannot believe that a disc *per se* can produce a complete block to the flow of cerebro-spinal fluid, as we sometimes see, but that some degenerative or neoplastic process is super-added: that, in fact, the older surgeons were less inaccurate in calling the lesion a chondroma. (C) illustrates the laterally protruding disc. This is the type generally regarded as producing the so-called cervical disc syndrome, a brachialgia, a pure lower motor neurone lesion.

FIG. 3.—Four types of "cervical disc". [Drawing by E. R. Alexander.]

Two things make one feel somewhat sceptical about this morbid anatomical picture. First it must be anatomically difficult for the disc to hit the nerve and miss the cord. Krogdahl and Torgersen (1940) showed how strong were the ligaments of the neuro-central joints. These ligaments must tend to deter the lateral wandering of protruded discs. Secondly, one is profoundly disappointed by the surgical findings. So often one reads an operative description where a laminectomy only was performed and the protruded disc was seen pressing on the nerve. But rarely, it seems, is the disc actually removed.

Lastly, let us consider the nerve as it issues between the two joints I have mentioned (fig. D). Here we must go back to the morbid anatomy for a moment and consider a case which shows narrowing of the C5 to C6 disc space and/or narrowing of the C6 to C7 space. As a result of this narrowing abnormal strain is placed on the joints of Lushka and the articular joints of the pedicles. It is fair to assume that arthritic changes supervene in these joints. The articular cartilages rub one another, a small effusion may collect in the joint, the periarticular tissues thicken and later osteophyte proliferation occurs—in fact all the well-known changes which occur in any joint in such circumstances. When these things occur the issuing nerve has every chance of being compressed, both from in front and from behind, as Krogdahl and Torgersen showed.

The pathological changes in Lushka's joints can be detected radiologically by taking oblique views of the cervical spine. This is a most important projection—far more important than the frontal views. Frequently one can detect the presence of osteophytes.

Radiological technique.—(1) *The straight X-rays:* Four projections should be taken,

Two pairs of joints abut on the issuing pairs of nerves. One joint lies in front, the other behind. In all other regions of the spine except the lowest five cervical vertebrae there is only one pair of joints. The joints of the atlas and axis lie in front of the nerves, and elsewhere—except in the lower cervical region—they lie only behind the nerves. The posteriorly situated joints are well known—those articulating the pedicles of adjacent vertebrae. The anterior joints are less well known and they receive very scant mention, in very small print, in the latest edition of Gray's "Anatomy". They are not even honoured with a name and receive no mention at all in the section on arthrology.

It was Luschka (1858) who first described these joints. He pointed out that the upper and lower surfaces of the bodies of the lower cervical vertebrae are curved at their posterolateral edges. Between each vertebra in this situation are small joints with synovial linings. His description seems not to have been improved upon and it is interesting to note that he regarded the joints as the homologues of the costovertebral joints in the thoracic region—a rather remarkable observation published one year before Darwin's "Origin of Species".

In modern times, Frazer in his "Anatomy of the Human Skeleton" makes certain observations, which I have summarized. "The first two cervical nerves", he said, "differ from all other spinal nerves in that they issue behind the articular masses. The explanation is that the articular masses concerned are morphologically different from those lower down. If the upper surfaces of the bodies of the middle and lower cervical vertebrae are inspected a prominent neurocentral lip is standing up outside the junction of the costal element and

FIG. 1.—N=Nerve.

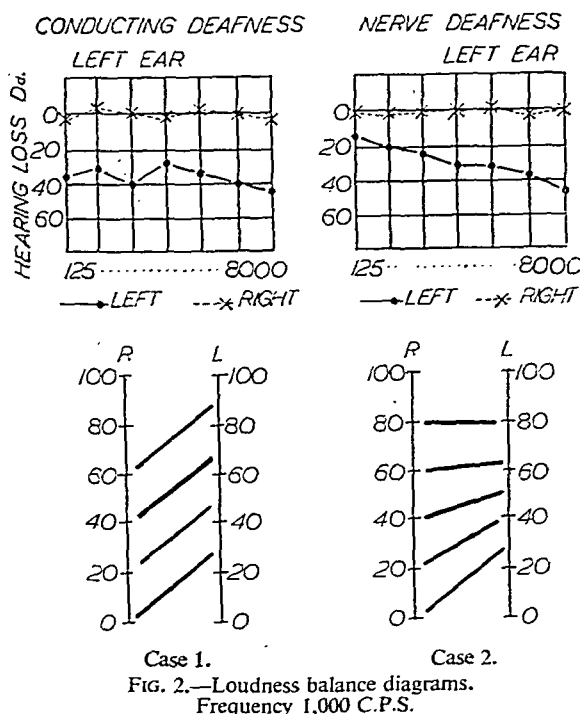

FIG. 2.—Typical cervical vertebra.

the neural arch, with the centrum; in the recent state a small synovial cavity lies between this lip and the bone above, outside and behind the intervertebral disc." Frazer goes on: "From its position this joint cavity is in front of the issuing nerve. These small joint cavities are probably in series with the costovertebral joints in the thoracic region." As I have said Lushka pointed this out nearly hundred years ago (fig. 1, after Frazer).

The lower pairs of cervical nerves are unique in being bounded both anteriorly and posteriorly by a joint as they issue from the spinal canal (fig. 2, after Frazer).

Pathological aspects.—When one X-rays the cervical spine one is struck by the frequency of narrowing of two intervertebral discs—those between C5 and C6 and C6 and C7. One is also struck by the normality of the upper cervical discs and, indeed, by the relative normality of all the other intervertebral discs except the lumbosacral, which is frequently narrow. I think that narrowing of the disc space indicates some degeneration and that the disc is no longer normal. I do not think that we are justified in assuming that it often means a protrusion backwards into the cervical canal, sufficient to cause symptoms.

Those cervical discs even when they protrude to the maximum are tumours no larger than red currants and frequently, of course, they would be much smaller.

intensity for the left ear will, of course, be 30 db. higher. Successive stimuli, rising in intensity in steps of 20 db., are then applied to the right ear and for each level the balancing intensity for the left ear is established by trial, the comparison being made by switching the stimulus backwards and forwards between the two ears. The result obtained in Case 1 indicates that the loss of sensitivity or deafness of the affected ear, 30 db. at threshold, remains constant at 30 db. throughout the entire intensity range.

This finding is an unvarying one in conducting deafness and is explicable on the straightforward assumption that the obstruction caused by the middle-ear disease to the sound waves on their way to the inner ear introduces an attenuation factor, in this case 30 db., which is constant at all intensities.

A very different result is obtained in Case 2. The audiogram is substantially the same as in Case 1, with a threshold shift at 1,000 cycles of 30 db. The balancing

points at threshold are identical with those of Case 1, with a 30 db. displacement upwards for the left ear. On ascending the intensity scale, however, it is found that the sensitivity loss or deafness of the left ear, 30 db. at threshold, becomes progressively less, until at 80 db. equal intensities at the two ears evoke equal loudness responses. In other words, the deafness of the affected ear present at threshold disappears at higher intensities, and this in its simplest terms constitutes the phenomenon of Loudness Recruitment.

A more conventional form for the graphic representation of these results is that given in fig. 3.

Sound intensities in decibels above the normal threshold are plotted on the vertical axis for the unaffected ear, and on the horizontal axis for the deaf ear. Equal loudness levels for the two ears are plotted on these charts as a series of points and the line AB passing through the origin connects the points which would be thus obtained in a normal individual.

CD is the corresponding line obtained in Case 1. Here the sensitivity loss at threshold of the deaf ear is represented by the displacement of the point C along the base line to the right of the origin. This sensitivity loss remains constant at higher intensities, and the line CD thus lies parallel to AB.

EF is the corresponding line obtained in Case 2. As in Case 1 the same sensitivity loss at threshold is represented by the same displacement of the point E to the right of the origin. At high intensities, however, this sensitivity loss is progressively eliminated, and the line EF approaches and finally coincides with the line AB.

There is general agreement by all who have since investigated the L.R. phenomenon that it is absent in deafness due to uncomplicated middle-ear disease, so-called conductive deafness.

On the other hand, it has frequently been demonstrated in a wide variety of disorders of the internal ear and cochlear nerve, including Menière's disease, which are collectively described as "nerve deafness", and it has come, therefore, to be regarded in a somewhat uncertain manner as a valuable indication of "nerve deafness" using the term in its widest sense.

anteroposterior, true lateral and right and left obliques. Each of these may be taken on 8½-in. by 6½-in. films. A Potter-Bucky or Lysholm fixed grid should be used for all projections, otherwise the pictures will not be of good quality. It is desirable to take all but the frontal picture with the patient standing or sitting, so that the shoulders may drop to the maximum.

The frontal picture should be taken last when one has examined the lateral view. One can then judge how much the central ray must be tilted in order that it passes along the plane of the intervertebral discs of the last three cervical vertebrae. These discs slope forwards and downwards quite considerably.

If the straight X-rays are normal, then a cervical disc is not present and there is no arthritis of the small joints.

If there is a diminution in the intervertebral disc spaces—and this is common from middle age onwards in the lowest three cervical vertebrae—the radiological conclusions are more difficult. The presence of arthritis of the small joints, even with considerable osteophyte proliferation invading the exit foramen, does not necessarily mean pressure on the nerve. Conversely, the absence of osteophytes does not rule out pressure on the nerve, for the periarticular tissues may be swollen and be pressing on the nerve but they may not cast a shadow on the X-ray film.

(2) *Myelography*. Owing to shortage of space this section of Dr. Bull's paper is omitted.

Observations Upon the Loudness Recruitment Phenomenon, with Especial Reference to the Differential Diagnosis of Disorders of the Internal Ear and VIII Nerve

By M. R. DIX, C. S. HALLPIKE and J. D. HOOD

(From the Otological Research Unit, Medical Research Council,
 The National Hospital, Queen Square, London)

Introduction.—The Loudness Recruitment (L.R.) phenomenon was first described in 1936 by E. P. Fowler of New York (1936), and its occurrence in certain varieties of nerve deafness has since been abundantly confirmed (Steinberg and Gardner, 1937; Huizing, 1942; de Bruine-Altes, 1946). The phenomenon can be demonstrated most readily when the deafness is limited to one ear, and the nature of the phenomenon itself can perhaps be best appreciated from the following brief description of the simple test procedure needed for its investigation in cases of this kind.

Fig. 1 shows the test procedure being applied:

FIG. 1.

mechanism of the left middle ear, and in Case 2 to Menière's disease affecting the left labyrinth.

The purpose of the test is to ascertain and mark upon the two ladder diagrams two series of intensity levels, one for the right ear and one for the left, each intensity level for the right ear being connected across the diagram with a level for the left ear, found by experiment to give a sensation of equal loudness. In each case the test frequency selected is 1,000 cycles, at which point the audiogram shows a threshold shift for the affected ear of 30 db. The test starts with a stimulus of threshold intensity at the right ear; the balancing

The subject wears a pair of telephone receivers, each supplied by a separate pure-tone audiometer, or preferably by a single audiometer with arrangements for independent adjustment of the intensity in the two receivers. The frequency of the sound stimulus is the same in each receiver, and the tester switches it alternately from right to left.

The audiograms of two typical cases of unilateral deafness are shown in fig. 2.

In Case 1 the deafness is due to a lesion of the conducting

FIG. 4A.— $\times 7.5$.FIG. 4B.— $\times 7.5$.

fairly well preserved, and presents a normal appearance. The cell outlines are well demarcated, and the cell nuclei are clearly differentiated.

It should be noted, however, that as usual in preparations of the human cochlea the technical difficulties of fixation make it impossible to discern any details of the hair cells.

In the affected ear, fig. 5B, marked changes are to be seen in Corti's organ. The cell mass is compressed, the cell outlines obscured and the staining differentiation between nuclei and cytoplasm virtually extinguished.

This type of pathological change in the cochlea was first described by Hallpike and

FIG. 5A.— $\times 200$.FIG. 5B.— $\times 200$.

Cairns (1938) in two clinically characteristic cases of Menière's disease. Since then, histological studies have been possible in three further cases, in one instance in collaboration with A. J. Wright (1940), and in a second with T. E. Cawthorne (1947).

The findings in a third case have not yet been published.

In addition to these, a number of other histological examinations have been carried out elsewhere (Rollin, 1940; Lindsay, 1942; Altmann and Fowler, 1943) in a number of subjects presenting the characteristic clinical features of Menière's disease.

Whilst in all of these the presence of an endolymphatic dilatation has been established, reports have varied on the condition of Corti's organ. In two of our own series it has appeared normal, and this has also been the finding in the majority of cases reported upon elsewhere. In no less than 3 of our 5 cases, however, Corti's organ has presented abnormalities of the type described. These abnormalities are so striking in character that it would appear inevitable that they should be regarded as being distinctive of Menière's disease in certain of its phases. That they are found sometimes and not always only means, as we see it, that they represent a transient and reversible reaction on the part of the hair cells to the chemico-physical disturbance which goes with the gross distension of the endolymph system. It seems quite reasonable that this disturbance should be phasic in character, so matching the clinical course of the disease, and it is natural, too, that the morphological changes in the hair cells should vary at the same time. It follows, that whether these changes are revealed in any given case or not must be largely a matter of chance, depending upon the phase of the disease at the time of death.

Although these morphological changes may be largely reversible, and may in fact appear to be absent at death, it does not follow that a corresponding reversal need be expected of the functional loss, and, indeed, the fact that the deafness in Menière's disease persists between its active phases can only be taken to mean that while the disorder of structure is apparently reversible, the disorder of function is *not*. The statement that the structural

The theoretical basis of the L.R. phenomenon has been discussed by Lorente de Nó and by Fowler (1939). Both adopt an explanation based upon certain general principles of neurophysiology and upon certain details of the finer structure of the cochlear neurones described earlier by the former. According to this explanation—a somewhat complex one—the occurrence of the phenomenon might be expected as a natural consequence of any pathological process involving a reduction in numbers of the neural elements, either of Corti's organ or of the cochlear nerve, and the matter is put by Lorente de Nó (1937) in the following terms:

"If a number of hair cells in the ear or a number of fibres in the cochlear nerve is missing, the tones will appear to be weaker in intensity when near threshold stimuli are used; but if the intensity of the tone is increased, the more strongly activated hair cells or cochlear fibres will be sufficient to saturate, i.e. to excite with the limiting intensity the cochlear fibre or the cells of the cochlear nuclei, so that the cerebral cortex will receive the same number of impulses per second from both ears and will perceive the tone delivered to the diseased ear as strongly as the tone delivered to the normal or less affected ear.

"Thus, it may be said that Fowler's phenomenon is an immediate consequence of the anatomy and physiology of the nervous system, and that, in fact, it must be pathognomonic of neural deafness".

The phenomenon of recruitment, or the variable type of deafness as they call it, is also discussed by Stevens and Davis (1938). These authors, too, accept the view that the phenomenon is attributable to "a deficiency in the total number of neural elements which normally contribute to give a tone loudness".

It must be said of the explanation that its implications are not devoid of obscurity. Moreover, in some of the cases in which the phenomenon has been found to occur, we seriously lack secure information on the nature of the pathological process. It has, therefore, been clear for some time that the confirmation of de Nó's explanation, and indeed any further developments of theory, must await a great deal of additional factual information. de Bruine-Altes (1946), in her recent monograph, has stressed very pertinently the particular need for further studies in which the results of L.R. phenomenon tests are more closely correlated with more exact information upon the underlying anatomical changes in the cochlea and cochlear neural pathways.

In the present study, therefore, we have endeavoured to throw more light upon the mechanism of the L.R. phenomenon by means of a detailed clinical study, including full investigation of the phenomenon in a number of patients referred to us by our colleagues at Queen Square and elsewhere suffering from two different and clearly defined varieties of hearing disorder, of which our knowledge both of the clinical features and morbid anatomy can now be regarded as considerable. The two disorders are Menière's disease and degeneration of the VIII nerve due to neurofibroma of the nerve and to other space-occupying lesions of the cerebello-pontine angle.

It was considered that the choice of these two disorders was likely to be particularly illuminating since in the one, Menière's disease, the primary lesion we now know to affect the endolymph system of the cochlea with its contained cochlear end-organs, while in the other, the primary lesion is of the cochlear nerve fibres within the internal auditory meatus. Some further details may be given at this point of these anatomical changes and their correlated symptomatology.

Menière's disease.—Fig. 4 shows the histological condition of the cochleæ in a case of Menière's disease.

The subject, a man of 46, had suffered for four years from paroxysmal attacks of vertigo with deafness and tinnitus of the right ear. Otological examination revealed a severe perceptive deafness on the right side, and a defect in the right caloric responses. The tympanic membranes were normal and there were no other abnormalities in the central nervous system. The patient died of acute lymphatic leukaemia.

Fig. 4A shows the cochlea of the unaffected ear (left) and fig. 4B the cochlea of the affected ear (right).

In fig. 4A, the normal position of Reissner's membrane will be noted (arrows). Corti's organ appears normal.

The apparent disappearance of Reissner's membrane in fig. 4B has been brought about by the maximal distension of the scala media, which has thrust the membrane back upon the bony wall of the scala vestibuli and caused its herniation through the helicotrema. Arrows indicate the new position of the membrane. It should be noted, however, that the cells of the spiral ganglion appear quite normal in number and structure. Further, there is no apparent reduction in number of the cochlear nerve fibres in the modiolus, or in the osseous spiral lamina.

Figs. 5A and B show the organ of Corti of the two ears. That of the left ear, fig. 5A, is

Cairns (1938) in two clinically characteristic cases of Menière's disease. Since then, histological studies have been possible in three further cases, in one instance in collaboration with A. J. Wright (1940), and in a second with T. E. Cawthorne (1947).

The findings in a third case have not yet been published.

In addition to these, a number of other histological examinations have been carried out elsewhere (Rollin, 1940; Lindsay, 1942; Altmann and Fowler, 1943) in a number of subjects presenting the characteristic clinical features of Menière's disease.

Whilst in all of these the presence of an endolymphatic dilatation has been established, reports have varied on the condition of Corti's organ. In two of our own series it has appeared normal, and this has also been the finding in the majority of cases reported upon elsewhere. In no less than 3 of our 5 cases, however, Corti's organ has presented abnormalities of the type described. These abnormalities are so striking in character that it would appear inevitable that they should be regarded as being distinctive of Menière's disease in certain of its phases. That they are found sometimes and not always only means, as we see it, that they represent a transient and reversible reaction on the part of the hair cells to the chemo-physical disturbance which goes with the gross distension of the endolymph system. It seems quite reasonable that this disturbance should be phasic in character, so matching the clinical course of the disease, and it is natural, too, that the morphological changes in the hair cells should vary at the same time. It follows, that whether these changes are revealed in any given case or not must be largely a matter of chance, depending upon the phase of the disease at the time of death.

Although these morphological changes may be largely reversible, and may in fact appear to be absent at death, it does not follow that a corresponding reversal need be expected of the functional loss, and, indeed, the fact that the deafness in Menière's disease persists between its active phases can only be taken to mean that while the disorder of structure is apparently reversible, the disorder of function is *not*. The statement that the structural

disorder in Menière's disease is *apparently* reversible requires some amplification in view of the well-known technical difficulties which beset the histological study of the human organ of Corti. Its post-mortem disintegration is rapid, and fixation difficult, and the resulting histological picture is, therefore, always an imperfect representation of the original.

This point will be made clearer from an examination of fig. 6 and its comparison with fig. 5A. Fig. 6 shows the organ of Corti in a cat, well fixed by an *intra-vitam* injection technique. Every detail of the hair cells and their associated membranes is well shown.

FIG. 6.— $\times 310$.

(Reproduced from Schafer's "Essentials of Histology" by permission of Messrs. Longmans, Green & Co.)

In human material, however, of which fig. 5A is a good representative sample, nothing like this degree of preservation is possible. The hair cells are seldom well defined, and such features as the nerve fibres crossing the tunnel of Corti are never to be seen. This means, inevitably, that changes in the human hair cells, morphologically slight but functionally vital, which are likely to be responsible for the deafness during the negative phases of Menière's disease, will never be demonstrable by histological means.

For this reason, although no definite abnormalities can be recognized in Corti's organ in some cases of Menière's disease, we feel it to be very likely that such changes *are* present and obscured only by the limitations of histological technique.

To sum up the structural changes found in Menière's disease, we can say that these are limited to Corti's organ, but the nerve fibres and cells of the spiral ganglion are normal.

Degeneration of the VIII nerve due to neurofibroma, &c.—Interruption of the cochlear nerve fibres central to the spiral ganglion, whether caused by pressure from a tumour or by surgical section, leads, in contravention of the Wallerian law, to degeneration of the nerve fibres and ganglion cells peripheral to the point of interruption (Witmaack, 1911; Kaida, 1931; Hallpike and Rawdon-Smith, 1934).

Fig. 7 shows a horizontal section through the cochlea of a patient with a high degree of

FIG. 7.— $\times 11$

FIG. 8.— $\times 9$.

deafness and a complete loss of the caloric responses resulting from a neurofibroma of the VIII nerve. The tumour is seen filling the meatus, and the fibres of the VIII nerve are lost to view. The main peripheral effect of this tumour is a gross reduction in the number of nerve fibres themselves and of the cells of the spiral ganglion.

Indeed, very few cells of the ganglion remain while the nerve canal of the osseous spiral lamina is virtually empty.

Corti's organ, however, is substantially normal and this is characteristically the case unless the tumour has involved the cochlear blood supply. These cochlear changes in VIII nerve tumours closely resemble in their essentials those which follow an operative section of any mammalian VIII nerve. Fig. 8 shows the cochlea of a cat twelve weeks after an intracranial section of the VIII nerve. It shows again the characteristic disturbance of the whole peripheral cochlear neurone with perfect preservation of the hair cells of Corti's organ. Figs. 9A and B show Corti's organ in these two conditions, namely: Fig. 9A, Neurofibroma of the human VIII nerve; fig. 9B, Degeneration following intracranial section of the VIII nerve of the cat.

FIG. 9A. $\times 200$.—Neurofibroma of the human VIII nerve.

FIG. 9B. $\times 50$.—Degeneration following intracranial section of the VIII nerve of the cat.

This evidence of animal pathology is particularly useful since it indicates that in the human subject there is no reason for supposing that an interruption in the course of the VIII nerve by a tumour would cause any structural changes in Corti's organ, even of a kind which would be obscured by defects of histological technique. The difference in the anatomical findings in the cochlea in these two conditions, Menière's disease and VIII nerve neurofibroma, may thus be summarized as follows:

	Organ of Corti	Nerve fibres and cells of spiral ganglion
<i>Menière's disease</i>	May show gross compression of cells and loss of staining reactions. These changes are not always found. Residual changes, however, are likely to be present and account for the deafness. They are obscured by limitations of histological technique	Normal in number and structure
<i>Degeneration of VIII nerve due to tumour pressure</i>	Normal, unless cochlear blood supply is interfered with	Much reduced in number and may be completely eliminated

The results of the Loudness Recruitment tests obtained in these two groups of cases will now be described.

RESULTS OF LOUDNESS RECRUITMENT TESTS IN MENIÈRE'S DISEASE AND VIII NERVE DEGENERATION

(1) *Menière's disease*.—The number of cases examined was 30. All gave a characteristic history of paroxysmal vertigo, deafness and tinnitus. In the great majority the deafness was substantially limited to one ear, and in all the pattern of the caloric reactions revealed one of the various characteristic abnormalities upon the side of the deaf ear (Cawthorne, Fitzgerald and Hallpike, 1942). None gave any history of head injury, and general neurological examination revealed no abnormalities apart from the octavus system.

In all of the 30 cases, Loudness Recruitment was marked.

Fig. 10 shows the Loudness Recruitment patterns of 3 representative cases with their audiograms. It will be seen that in every one the sensitivity loss at threshold of the affected ear is completely eliminated at higher intensities. In the third case, well-marked over-recruitment is seen; that is to say, at high intensities the loudness function of the affected ear exceeds that of the normal ear. Tests at other frequencies than 1,000 cycles yielded comparable results.

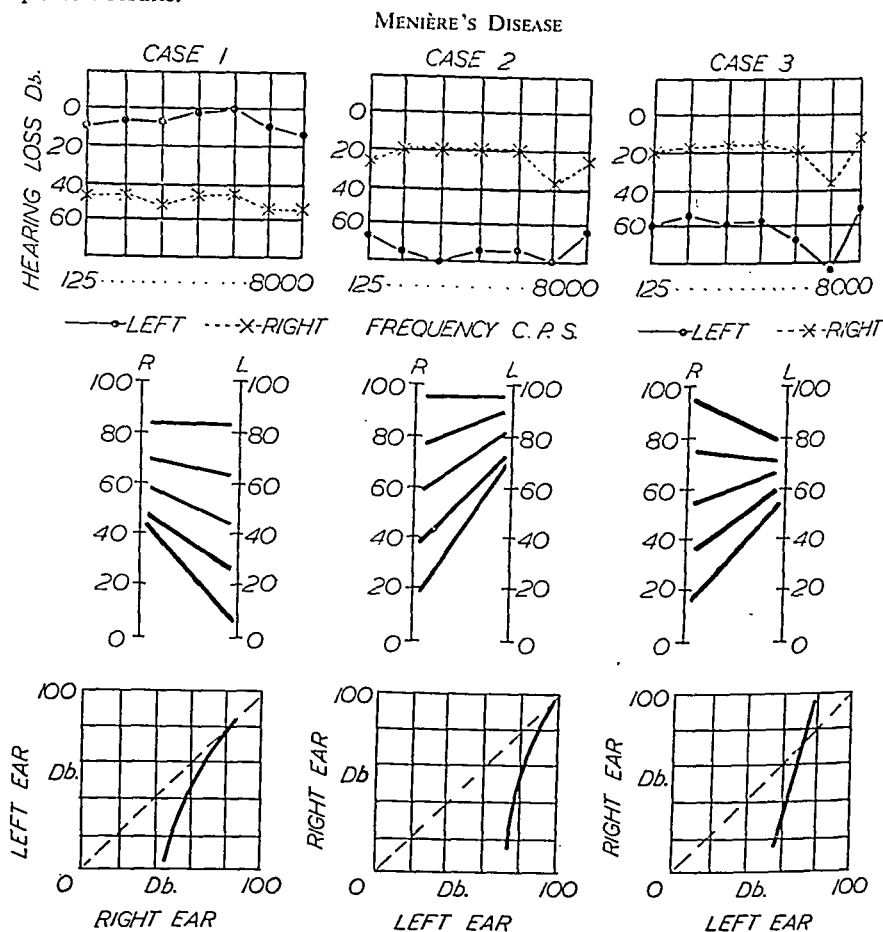

FIG. 10.—Loudness balance diagrams. Frequency 1,000 C.P.S.

(2) *VIII nerve degeneration.*—11 cases of neurofibroma of the VIII nerve were studied, in all of which the clinical diagnosis was confirmed by operative or post-mortem findings. In addition, 9 cases were examined of other varieties of cerebello-pontine angle lesion exhibiting well-marked involvement of VIII nerve function. In 6 of these cases the diagnosis was confirmed by operative or post-mortem findings. It is necessary to stress here that loudness balance tests for the Loudness Recruitment phenomenon can only be carried out satisfactorily when the deafness of the affected ear is of moderate degree. Very often, however, the deafness in cases of VIII nerve neurofibroma and cerebello-pontine angle tumour is severe and not infrequently complete. It has, therefore, been a matter of considerable difficulty to find cases in which the deafness of the affected ear was not too severe for the test. That we were able to find the cases, we owe to the good offices of a number of our colleagues both at Queen Square and elsewhere who have kindly referred their cases to us, and to whom we are greatly indebted.

In the majority of these 20 cases, tuning fork tests showed the typical findings of nerve deafness, reduced bone conduction with a positive Rinne. Bone conduction was, in fact, reduced in all, but in a few the Rinne test was definitely negative in spite of careful masking of the opposite ear.

The results of the loudness balance tests in 14 cases of this group were constant in showing a complete absence of recruitment.

Fig. 11 shows the test results in 3 characteristic cases, together with their audiograms.

VIII NERVE DEGENERATION

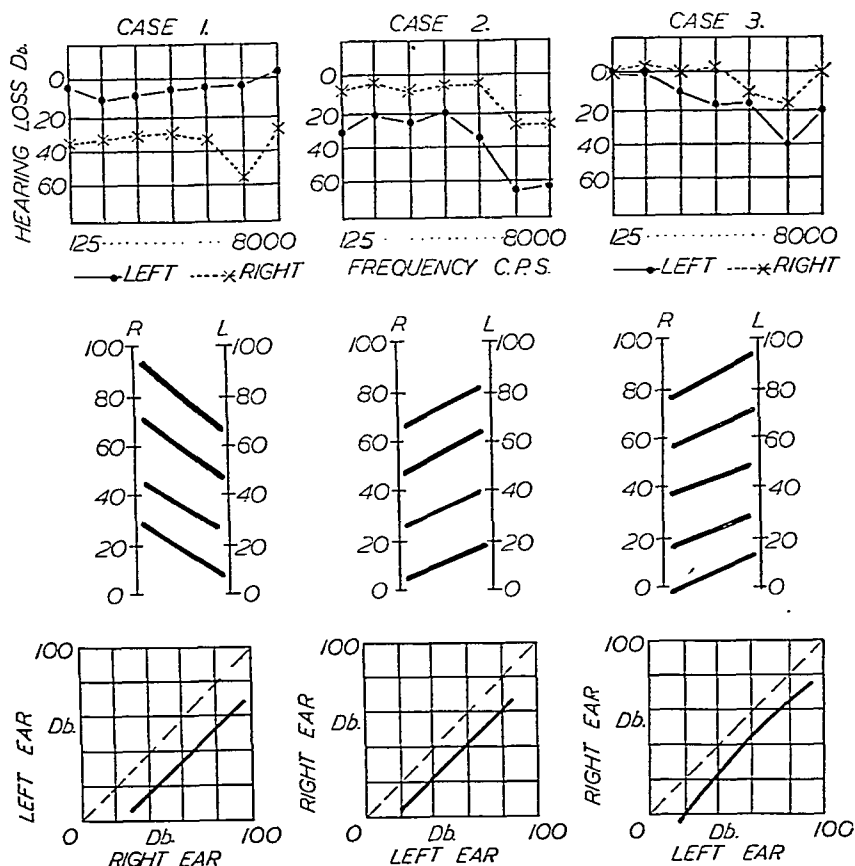

FIG. 11.—Loudness balance diagrams. Frequency 1,000 C.P.S.

It will be seen that in all 3 the sensitivity loss of the affected ear at threshold is maintained at all intensity levels. In the remaining 6 cases of this group a slight amount of recruitment was present. In some of these there was found a fixed upper loudness limit in the affected ear. That is to say, loudness appeared to increase in the affected ear up to a certain intensity level, and thereafter to increase no more. This phenomenon is shown in the second case of fig. 12. Tests at other frequencies than 1,000 cycles yielded comparable results.

SUMMARY OF EXPERIMENTAL FINDINGS

Loudness Recruitment was present and complete in all of 30 cases of Menière's disease, a primary affection of Corti's organ. In 20 cases of degeneration of the VIII nerve, due to pressure or infiltration by tumours, Loudness Recruitment was completely absent in 14. In the remaining 6 cases slight recruitment was present.

It would appear, therefore, that in this condition, an example par excellence of nerve deafness, Loudness Recruitment hitherto described as being uniquely distinctive of nerve deafness is characteristically not present at all. Instead, we have a type of response which is identical with that found in middle-ear deafness.

DISCUSSION

From the viewpoint of practical oto-neurology, the experimental results described make it clear that in the loudness balance test we have at our disposal a test procedure which should prove of great value in making clear the difficult and important distinction between end-organ deafness and nerve-fibre deafness. It seems likely, too, that the findings will prove to have a bearing upon a number of problems of auditory theory. The finding that the recruitment phenomenon is an unvarying occurrence in Menière's disease, a disorder

Fig. 10 shows the Loudness Recruitment patterns of 3 representative cases with their audiograms. It will be seen that in every one the sensitivity loss at threshold of the affected ear is completely eliminated at higher intensities. In the third case, well-marked over-recruitment is seen; that is to say, at high intensities the loudness function of the affected ear exceeds that of the normal ear. Tests at other frequencies than 1,000 cycles yielded comparable results.

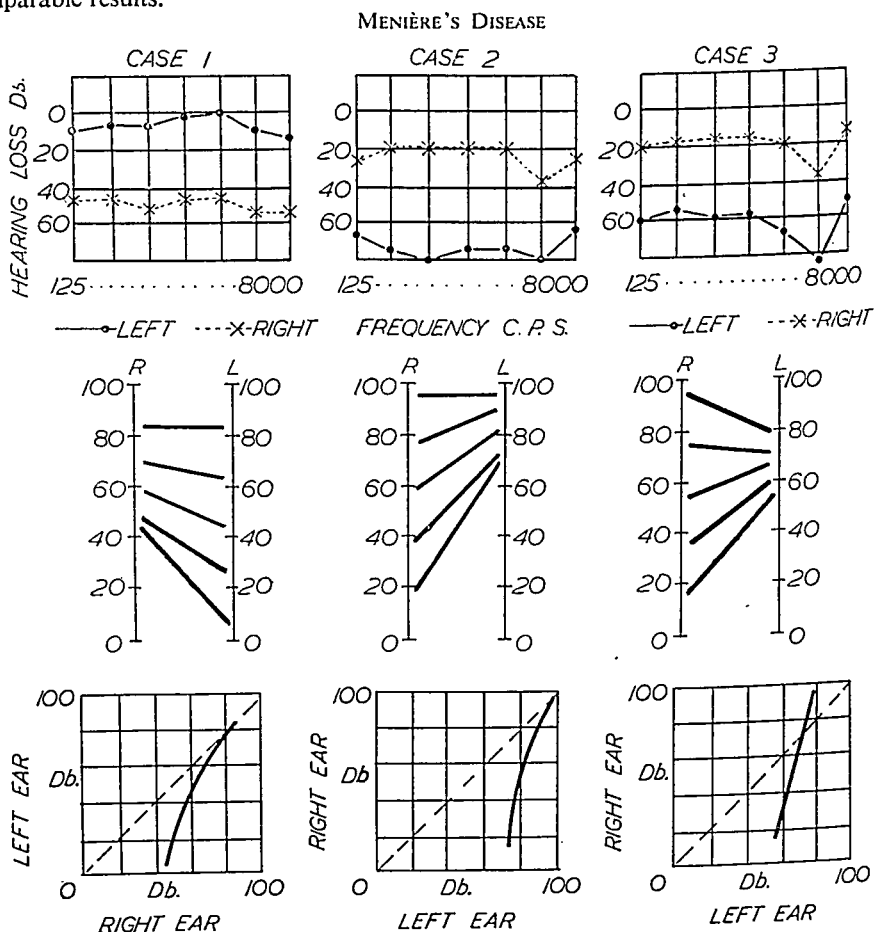

FIG. 10.—Loudness balance diagrams. Frequency 1,000 C.P.S.

(2) *VIII nerve degeneration*.—11 cases of neurofibroma of the VIII nerve were studied, in all of which the clinical diagnosis was confirmed by operative or post-mortem findings. In addition, 9 cases were examined of other varieties of cerebello-pontine angle lesion exhibiting well-marked involvement of VIII nerve function. In 6 of these cases the diagnosis was confirmed by operative or post-mortem findings. It is necessary to stress here that loudness balance tests for the Loudness Recruitment phenomenon can only be carried out satisfactorily when the deafness of the affected ear is of moderate degree. Very often, however, the deafness in cases of VIII nerve neurofibroma and cerebello-pontine angle tumour is severe and not infrequently complete. It has, therefore, been a matter of considerable difficulty to find cases in which the deafness of the affected ear was not too severe for the test. That we were able to find the cases, we owe to the good offices of a number of our colleagues both at Queen Square and elsewhere who have kindly referred their cases to us, and to whom we are greatly indebted.

In the majority of these 20 cases, tuning fork tests showed the typical findings of nerve deafness, reduced bone conduction with a positive Rinne. Bone conduction was, in fact, reduced in all, but in a few the Rinne test was definitely negative in spite of careful masking of the opposite ear.

The results of the loudness balance tests in 14 cases of this group were constant in showing a complete absence of recruitment.

Such a formula may be outlined as follows:

The intensity range on the scale shown in fig. 13 lies between four and five bels above the threshold of hearing for a tone of 1,000 cycles, that is to say, it covers the middle range of audible intensity for this frequency, and the total intensity change of 1 bel between the top and bottom of the scale is a tenfold one. Between these points there are twenty just distinguishable increments of loudness, each corresponding to an intensity increment of about 13%, this being the so-called Weber fraction, and according to the data of Shower and Biddulph (1931) the value of this fraction for frequencies between 1,000 and 4,000 cycles approximates very closely to the value given, i.e. 13% for a great part of the loudness scale.

Concerning the manner in which the steps on this loudness scale are related to the number of active nerve fibres, no precise quantitative details are known. We have, however, available a variety of well-known data derived from the electro-physiological recording of cochlear action potentials and from experiments on masking and auditory fatigue, which all indicate that as stimulus intensity is increased there occurs a spatial spread within the cochlea, with progressive activation of additional nerve fibres.

It is suggested that our present experimental finding, i.e. that Loudness Recruitment is absent in diffuse degeneration of the VIII nerve, would be adequately explained upon the following simple hypothesis: That each step on the loudness scale shown in fig. 13 corresponds to a definite fractional increase in the number of activated cochlear nerve fibres. The manner in which this hypothesis might be applied to the working of the normal and degenerate cochlear nerves is shown schematically in fig. 14.

FIG. 14.

This represents the fibres of two cochlear nerves arranged in linear fashion as they lie in the osseous spiral lamina of the cochlea.

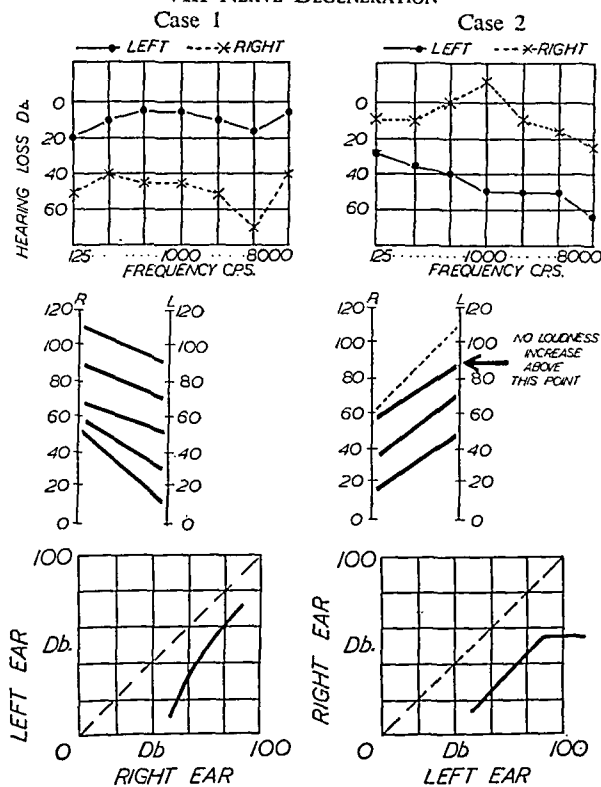

The lower set of fibres is that of a normal nerve, while the upper set is that of a degenerate nerve. The degeneration is diffuse, and the long strokes indicate the surviving fibres. The survival rate is one in ten. The small bracket "A" is taken to indicate the number of fibres stimulated by a sound stimulus of intensity 1 bel above threshold. The number of fibres is conveniently taken as ten. This stimulus exceeds by tenfold the threshold intensity. Correspondingly, stimulus intensities of two and three bels exceed it by one hundred- and one thousand-fold. Now, it is supposed that such changes of stimulus intensity involve corresponding changes in the number of active nerve fibres. This means, in the case of the normal nerve, that the 2 bel stimulus will activate 100 fibres and the 3 bel stimulus 1,000 fibres.

It will be noted that the loudness sensation elicited in the normal nerve by the 1 bel stimulus arises from 10 fibres, and to match this sensation in the degenerate nerve, 10 active fibres will also be required. It is clear that with a fibre survival rate of one in ten, a 2 bel stimulus will be required to bring these into action. In other words, a tenfold intensity increment, 1 bel, is required to compensate for this particular degree of nerve degeneration.

With a stimulus intensity of 2 bels, it will be seen that 100 fibres are activated in the normal nerve. To activate the same number in the degenerate nerve, we require again a tenfold increase of stimulus intensity, i.e. a 3 bel stimulus, and it follows that the same rule will apply as we go further up the intensity scale. In other words, given a constant fibre survival

of the end-organ of hearing, appears to be related in an interesting way to the recent experimental work of Pumphrey and Gold (1948). According to Gold's theory, based upon this work, the microphonic potentials of the cochlea arise somewhere in Corti's organ and play a vital part in determining both its sensitivity and frequency selectivity. We should, therefore, certainly expect that a disorder of this microphonic mechanism, i.e. Corti's organ, would lead to deafness and to certain disorders of pitch sense, i.e. paracusis dysharmonica, well known to be characteristic of Menière's disease. It is pertinent to recall that the very nature of the recruitment phenomenon corresponds very well with a type of derangement well known in certain microphones. Thus a carbon microphone in good order yields an electric response which is linear over a wide range of sound pressures. In a faulty microphone of this kind, however, the response at low sound pressures may be very defective, while approximating at high pressures to something nearer its normal value. It is clear that this variety of non-linearity in the response of a faulty microphone reproduces in essentials the characteristic of the Loudness Recruitment phenomenon, and it seems possible, therefore, that Gold's theory of the cochlear mechanism may provide us with a clearer explanation than any at present available of the occurrence of the Loudness Recruitment phenomenon in Menière's disease.

VIII NERVE DEGENERATION

Showing slight recruitment at frequency 1,000 C.P.S.

Showing loudness saturation at frequency 4,000 C.P.S.

FIG. 12.—Loudness balance diagrams.

FIG. 13.—Distinguishable loudness steps (each step corresponds to an intensity increase of about 13%).

The finding that recruitment is characteristically absent in cases of VIII nerve tumour has been a very surprising one. Clearly it controverts decisively the theory of its neurological mechanism advanced by Lorente de Nó and Fowler. It would seem quite possible, however, to explain this finding in a different and more simple way if the following assumptions be made: first, that the nerve degeneration engendered by tumour pressure or infiltration is an evenly diffused one with a definite fibre survival rate; secondly, that the relationship between stimulus intensity and loudness sensation depends upon a simple type of formula governing the numerical increase of active cochlear nerve fibres which accompanies each ascending step of the loudness scale.

Section of Dermatology

President—J. E. M. WIGLEY, F.R.C.P.

[March 18, 1948]

Polyarthrititis with Dermatitis. ? Keratoderma Blennorrhagica (Dr. PHILIP ELLMAN'S Case).—DAVID WEITZMAN, M.D., M.R.C.P. (for J. E. M. WIGLEY, F.R.C.P.).

Male, aged 42, complains of an eruption of the groins and feet since October 1947, and of painful swollen joints since November 1947. No urethral discharge.

Past history.—1943: Similar attack of arthritis with a rash in his groins, which subsided after a month's bed rest.

1928: Gonorrhœa, followed by corneal ulcer and transient polyarthrititis.

On examination.—Thin, toxic, febrile. Rheumatoid arthritis of knees, ankles and shoulders. Raised scaly erythematous area round pubes and groins; scattered smaller lesions, mostly regressing, on arms and trunk; ulcerated and crusted areas on toes; thin brittle nails.

Investigations.—Gonococcal complement-fixation test positive (on two occasions). Wassermann and Kahn negative. Skin scrapings; No fungus; culture grew staphylococci and *B. proteus*. Joint fluid: Many pus cells; sterile on culture. Urine: Pus cells; coliform bacilli on culture. Blood picture: Moderate anæmia; white count within normal limits.

Treatment.—Five million units of penicillin and 60 grammes of sulphamezathine.

Progress.—Improvement in the small patches on the arms and trunk, but the lesions in the pubic area and on the feet are unchanged.

Dr. Weitzman added: Dr. Ellman regards the joint picture as typical rheumatoid arthritis, and not gonococcal arthritis. He thinks that Reiter's disease might be considered. I understand from Dr. Wigley that cases of keratoderma have recently been reported to have cleared up after intensive penicillin therapy.

Professor Ö. N. Holsti: I believe this is a case of Reiter's disease. In our small country of Finland we have seen in a short time 300–400 cases of this disease, all in connexion with an epidemic of Flexner dysentery, affecting about 250,000 persons. The disease was definitely non-venereal, mainly localized to the joints, eyes and urethra, but also frequently accompanied by various skin lesions. I do not know whether Reiter's disease is a syndrome, which might accompany also other enteric infections, or whether it is a disease *sui generis*. Recently a case of Reiter's disease was seen at Hammersmith Hospital. The patient had no symptoms of dysentery, but the complement-fixation test was weakly positive.

Our cases of Reiter's disease developed during or after the dysentery, in mild as well as severe cases. The clinical course varies in duration and intensity. The joint lesions are nearly always multiple, and may be slight or severe enough to resemble rheumatoid or gonorrhœal arthritis. In our cases the knees and ankles were chiefly affected. Large effusions were often seen, as also noted in to-day's patient. The dermatitis was at times slight and greyish coloured; in other cases severe pustular eruptions occurred. The genital lesions were mostly confined to a slight urethritis

rate in the degenerate nerve, this would be compensated by a constant fractional increment of stimulus intensity at all points of the intensity scale.

This argument, therefore, leads us to expect that the sensitivity loss, or deafness of the affected ear in a case of diffuse degeneration of the VIII nerve, would be constant throughout the intensity range. In fact, the Loudness Recruitment phenomenon would be absent in accordance with our own experimental findings.

It is necessary to add two amendments to this general statement of theory.

It is unlikely to apply at low intensity levels near threshold, where the sensitivity of the ear to small intensity differences is changing rapidly. At high levels, too, it would seem inevitable that a saturation point would be reached very soon in the case of the degenerate nerve, above which no further increase of loudness perception would be obtainable.

This latter point is in good agreement with the finding in some of our cases of a fixed upper limit of loudness in the affected ear.

The highly schematic character of our hypothesis need not be stressed. It would indeed appear evident that loudness grading depends upon a grading not only of fibre numbers but of discharge frequency in the fibres themselves, the resultant being a grading of the total number of nerve impulses reaching the cochlear centres per unit time. While this may be the case, it is doubtful whether it would seriously affect the general validity of our hypothesis.

Thus, while a certain degree of nerve degeneration may lead to a definite fractional decrease in the number of cochlear fibres activated by a sound stimulus of given intensity, it is likely, also, to lead to a definite fractional decrease in the discharge frequency of these surviving fibres, and the combination of these two effects will result in a fixed fractional decrease in the total number of action potentials reaching the cochlear centres per unit time.

This decrease will be compensated and loudness loss restored in the manner of our experimental findings by a fixed fractional increase of stimulus intensity over a wide range of the intensity scale.

SUMMARY

Loudness balance tests were carried out in

(a) 30 cases of unilateral deafness due to Menière's disease.

(b) 20 cases of degeneration of the VIII nerve, due to neurofibroma of the VIII nerve and other varieties of space-occupying lesions of the cerebello-pontine angle.

Results.—Loudness Recruitment was found to be present and complete in all 30 cases of Menière's disease.

Loudness Recruitment was found to be absent in 14 of the 20 cases of VIII nerve degeneration. In the remaining 6 cases it was present but incomplete.

Loudness Recruitment was thus shown to be characteristically present in a disorder of the end-organ of hearing and to be characteristically absent in a disorder of the cochlear nerve fibres.

This latter finding sharply controverts existing views upon the neurological mechanism of recruitment. The practical and theoretical significance of the experimental results is discussed. New hypotheses are advanced in explanation of these results and are based upon recent experimental work on the physiology of hearing and upon the known pathology of the cochlea and VIII nerve.

The following took part in the subsequent discussion:

Mr. T. Gold; Mr. E. D. D. Davis; Mr. D. W. C. Northfield; Dr. C. Worster-Drought; Dr. C. H. Edwards; Dr. N. G. Hulbert; Dr. G. D. Dawson.

Dr. Overton's case we have decided hypercholesterolaemia, and surely one of the aims of treatment ought to be to diminish the cholesterol in the blood and keep it down fairly to normal. Not only that, but the patient is fat, with a history of diabetes in the family. She surely ought to keep her weight down and keep herself in as good general condition as she possibly can.

The cardiovascular system in these cases should be specially considered; the patients may die of cardiovascular xanthomatosis or atheroma. A man with xanthomatosis very like that of Dr. Overton's patient recently told me that his brother had had the same xanthomatosis as he had, but had got better without any treatment. However, the brother had had to have amputation for ischaemic gangrene (probably due to atheromatous obstruction) of one foot. One of our colleagues had similar cutaneous xanthomata at the elbows and got better for a time, but then suffered from intermittent claudication of the legs, which was found to be due to atheroma (atherosclerosis) at the lower end of the aorta.

The dietetic treatment should be such as, if possible, to avoid hypercholesterolaemia, and there is no reason why, if a patient is being treated in that kind of way, small minimal doses of thyroid should not also be given a trial.

Purpura with Capillary Fragility.—H. W. BARBER, F.R.C.P., and J. D. EVERALL, M.R.C.S., L.R.C.P. (Case-history by Dr. Barber.)

N. J. R., aged 23. Formerly Able Seaman.

30.11.45 : His eruption, which still persists, had been present for three months and had appeared first on the arms. In childhood he had been subject to tonsillitis, and his tonsils had been removed seven years previously. He had been given a course of penicillin injections (one injection daily) after which the eruption cleared almost entirely from the chest and partly from the back. Investigations: Hb 100%; R.B.C. normal; W.B.C. 15,400; Platelets 200,000; Bleeding time 3 mins.; Clotting time 6 mins.

At that time, therefore, there was a considerable leucocytosis, the platelet count was at the lower limit of normality, the bleeding-time was about normal, and the clotting-time was slightly prolonged.

The eruption, which was widespread, involving the trunk and limbs, bore a striking resemblance to Schamberg's disease and to that provoked uniquely by adalin. It was, however, much more purpuric than these eruptions. I suggested that it might be due to a latent haemolytic streptococcal infection, and that a course of penicillin injections in full doses should be given.

In my absence, the patient was seen by Dr. Allan Yorke, 21.6.46. Investigations for a haemolytic streptococcal infection proved negative. A second course of penicillin (30,000 units five times daily for five days) again cleared the eruption on the chest, abdomen and back, but the arms were unaffected. Dr. Yorke noted the resemblance to Schamberg's disease, but compared the case with those seen in the Army in which a purpuric eruption, associated with marked capillary fragility, was apparently provoked by contact with the uniform. Patch-testing with his uniform, pyjamas and blankets, however, proved negative.

I saw him again myself on 3.10.46 and concluded that the eruption resembled Schamberg's disease more than anything else. As regards alternative diagnoses: Hutchinson's "infective angioma" or angioma serpiginosum, of which I showed a beautiful example in a child some years ago, is clearly, I think, a naevoid condition; Majocchi's disease begins on and is usually confined to the legs, and some atrophy is often a sequel to it; Gougerot and Blum's "Pigmented purpuric lichenoid dermatitis" is a diagnosis I have never made, but in our patient there are no lichenoid papules.

The most remarkable feature is the capillary fragility so that purpuric spots may be readily produced on the forearm by compressing the upper arm at a pressure of 100 mm.Hg or by pinching the skin. I have not personally investigated undoubted cases of Schamberg's disease from this point of view.

and penile erythema. In some cases prostatitis, cystitis and hydronephrosis occurred. Conjunctivitis was usually mild, but sometimes severe keratoconjunctivitis and iritis were seen. The duration varied from four weeks to two years. The joint lesions persisted longer until Reiter's disease finally developed into a simple arthritis.

Early in the epidemic the symptoms were often mistaken for gonorrhœa. In a patient with urethritis, eye lesions, joint lesions and skin lesions resembling keratoderma blennorrhagica, one should not feel too sure about gonorrhœa, when the smears are negative and the complement-fixation test is also negative. Most of these patients are young soldiers. If they have conjunctivitis, a joint lesion or dermatitis they are not much concerned, but if they also have urethritis they become "venereal-minded", think about their last exposure and believe they have gonorrhœa. The doctors are often willing to accept this diagnosis. Many of our cases were treated as gonorrhœal and appeared to improve with sulphonamides and penicillin, but they got worse after a while. Our experience is similar to that of Bauer in Los Angeles, who described increased hypersensitivity with peculiar skin lesions resembling those in to-day's case during treatment with sulphonamides. Finally I think the crops of blisters on the soles of both feet in to-day's patient are characteristic of Reiter's disease.

In Finland the disease showed a decided tendency to spontaneous healing in most cases. In severe cases various forms of treatment were tried, generally without any clear-cut effect. We became convinced that the only treatment of any value was fever treatment, such as was used in the treatment of gonococcal arthritis before the discovery of sulphonamides and penicillin. The patient at Hammersmith Hospital had his first attack five years ago and his second attack three years ago. In the second attack, having been ill for fourteen weeks and treated with sulphonamides and penicillin without benefit, fever treatment was applied with the Kettering's hypertherm. Within forty-eight hours there was a dramatic improvement.

Familiarity with Reiter's disease makes one realize that one is not dealing with the first attack; the patient recalls similar attacks before, even as long ago as twenty years. As a rule these attacks were associated with venereal stigmata, in spite of repeated negative smears and fixation tests.

Dr. H. W. Barber: Personally I regard this case as one of arthropathic psoriasis. I think the eruption in the groins is the type of psoriasis that is so apt to be diagnosed as seborrhœic dermatitis.

Xanthoma Tuberosum Multiplex.—JAMES OVERTON, M.D.

Mrs. B. E. G., aged 56. In July 1947 a number of pinkish nodules appeared on the elbows, knees and big toes. She felt "off-colour", with loss of energy and mild dizzy attacks. She also noticed that the skin of her face, antecubital fossæ and flexor aspects of wrists was assuming a dirty brown tinge. For the last few years, and especially in recent months, her weight has been steadily increasing. No loss of hair or dryness of skin. Appetite good; ? increase in thirst. Nocturia $\times 2$; bowels normal.

Family history.—Patient's mother suffered from diabetes mellitus. No knowledge of members with xanthomata.

Personal history.—Menopause three years ago.

On examination.—An obese, lively, jovial woman. Scalp hair and eyebrows normal. Yellow coloration of soft palate. Diffuse, dirty brown pigmentation of face, neck, antecubital fossæ and all aspects wrists. Xanthoma papules and nodules on both elbows, umbilicus, buttocks and patellæ, with linear xanthomata in creases and webs of palms and soles.

B.P. 190/105. General medical, urine and X-ray examination of skeleton and gall-bladder revealed nothing else abnormal.

Fasting blood sugar, blood sugar curve, blood urea, blood sodium and chlorides, and liver function tests were all within normal limits.

Blood cholesterol on 11.11.47 was 520 mg. % and on 12.3.48 it was 920 mg. %.

W.R. negative.

Dr. F. Parkes Weber: I agree with Dr. Overton that this is an absolutely typical case illustrating the commonest kind of Thannhauser and Magendantz's (1938) hypercholesterolemia group of primary or essential xanthomatoses.

I believe that in hypercholesterolemic cases treatment is of the greatest importance. It may be very disheartening, but, on the other hand, it may do good and very likely prolong life. In

entity. They had previously described their first case in 1925 as "purpura angio-scléreux prurigineux avec éléments lichénoïdes". The essential features of the condition may be briefly summarized. The eruption, which runs a very chronic course but with a tendency to eventual cure, consists primarily of small, slightly raised, smooth, shiny lichenoid papules which are initially pink, but become orange

[Photograph by Dr. W. G. Millar

FIG. 1.—Medial aspect of left lower leg.

and then purpuric and later pigmented. The individual papules do not enlarge and may remain discrete, but often become confluent in irregular plaques. The legs are the commonest site, and the eruption may, as in our patient, remain localized to one leg, but in some cases small discrete papules are widely distributed over arms, legs and trunk. Pruritus is usually absent.

We have found reports of 9 cases in the literature since 1929. In some of these cases the diagnosis seems questionable as venous hypostasis was present. Of the recorded cases, 8 were males and 5 females, and the majority were adults between 30 and 50 years of age, but Senebar and Caro's patient was a girl of 14.

Where the histological appearances have been examined they have been similar to those described above.

The differentiation of this condition from Schamberg's disease is sometimes difficult. Schamberg himself considered that it was an allied condition, but that it was not the same as his pigmentary disease, in which papules are absent.

Primary Focus of Tuberculous Infection in the Skin.—R. M. B. MACKENNA, M.D.

V. F., female, aged 11, complaining of a swelling in the neck near the left angle of her jaw.

Family history.—An aunt was said to have tuberculosis.

Patient's previous history.—Nothing relevant.

History of present condition.—In December 1947 a small spot appeared on the left cheek just in front of the ear. Four weeks later the swelling appeared in her neck. She was admitted to Oster Hills Hospital under the care of Dr. A. W. Franklin (to whom I am indebted for permission to show the case), and it was clinically

Dr. Allan Yorke: About a year ago I saw two similar cases.

The first was a young man who developed this eruption on the legs after the removal of teeth for apical abscesses. Further extractions were followed by an exacerbation involving the extremities and trunk. Culture from the sockets yielded hæmolytic streptococci. He was treated with penicillin intramuscularly and the condition cleared.

The second patient was a young girl with a clear history of recurrent sore throats and malaise. A culture from the tonsils revealed hæmolytic streptococci. She was successfully treated by tonsillectomy, and then by penicillin (lozenges and intramuscularly). We took further cultures from the excised tonsils and they too yielded hæmolytic streptococci.

Thus in two cases hæmolytic streptococci were demonstrated. I believe that some of these cases may be allied to subacute bacterial endocarditis. Franks doubts whether the flea-bitten kidney found in this condition is due to emboli. He implies that the capillaries become unduly permeable under the influence of an infecting agent, and suggests that it is a capillary toxicosis; possibly the cutaneous capillaries also may become permeable under the influence of an infecting agent.

Dr. F. Parkes Weber: I believe that this is an example of a condition which I was one of the first to describe—*telangiectasia macularis eruptiva perstans*. But the present case is one of the rare examples in males of early middle age. Such a case was described by Sir William Osler under the heading "*Telangiectasis Circumscripta Universalis*" in a man who had epistaxis (see F. Parkes Weber, "*Osler's Telangiectasis Circumscripta Universalis*", *Internat. Clinics*, 1931, series 41, 2, 131).

Pigmented Purpuric Lichenoid Dermatitis of Gougerot and Blum.—E. W. PROSSER THOMAS, M.D., and ARTHUR ROOK, M.R.C.P.

Ronald S., schoolboy, aged 13. The youngest of 5 children all of whom are healthy. Apart from measles, chickenpox and whooping cough he has always been fit.

About six months ago he first noticed a group of "small dry pimples" just above and anterior to the left internal malleolus. There was some irritation in the area at first but there has been none since then. The original papules gradually coalesced to form a plaque. New papules have continued to appear in irregular groups both in the neighbourhood of the original plaque on the anterior aspect of the leg, and in a new area on the medial aspect of the leg. The papules everywhere tend to coalesce into plaques, which by the confluence of papules at their periphery, extend to fuse with other plaques.

On examination.—The skin lesions are in two groups on the anterior and medial aspects of the left leg, just above the level of the malleoli. They consist of slightly raised shiny lichenified plaques of irregular outline. The largest plaque measures $2\frac{1}{2}$ in. at its greatest length and has an average width of 1 in. All plaques show a brownish-red pigmentation and are purpuric on diascopy. Their original papular components can no longer be distinguished. In the neighbourhood of the plaques there are several irregular groups of small brownish-red lichenoid papules and some small pigmented macules (see fig. 1).

No other lesions of the skin or mucous membranes are present.

General medical examination reveals nothing of significance.

Histological report (Dr. Ian Whimster).—**Epidermis:** Slight hyperkeratosis throughout the section and several small patches of parakeratosis which are separated from the granular layer by normal horn. The granular layer is present throughout the section and appears normal. Slight acanthosis with prolongation of rete pegs. **Dermis:** Infiltration by lymphocytes and histiocytes, fairly generalized in the upper third of the dermis but only round vessels, glands and follicles in the lower layers. Many small hæmorrhages and some free pigment in the upper third of the dermis. Prussian blue stain confirms the presence of free blood pigment.

Comment.—Gougerot and Blum in 1929 published an account of 4 cases of a pigmented and purpuric lichenoid dermatitis which they regarded as a clinical

[April 13, 1948]

Experimental Investigations in the Endocrinology of Schizophrenia

By R. E. HEMPHILL, M.D., and M. REISS, M.D.

It is not our intention to propose—as the title might suggest—that schizophrenia is an endocrine disorder, but from our work and that of others, there is sufficient evidence to encourage search for endocrinological relationships. It is, however, difficult to find case material that is clinically homogeneous. At first we endeavoured to select our cases because of psychiatric similarity, but, as we have found evidence that cases with an apparently identical clinical picture may have dissimilar physiological patterns, we are endeavouring to classify cases according to physiological patterns, and thereby to specify categories of schizophrenia. The paranoid form of schizophrenia has been excluded from this study.

There must be general dissatisfaction in grouping under the clinical label of schizophrenia cases of unknown aetiology, similar in prognosis and perhaps psychopathology, but with little else in common and many points of individual variation. Although it is far from certain that the schizophrenic illnesses of adolescence have the same origin as those of early adult life or following the puerperium, the only accepted treatment for all types is either the production of extreme physiological stress (as in the shock therapies) or creation of a new neural integration (as in leucotomy). Therefore the indications for and results of treatment should be susceptible to expression in physiological and biological terms.

From the enormous literature on the subject, containing so many facts and so few conclusions, it would seem that this hope is not likely ever to be fulfilled. By and large, all workers have reported physiological abnormalities in a proportion of all cases investigated, but there has been no success in correlating these abnormalities with the clinical appearances.

Unless the pathophysiological phenomena are unrelated to the disorder (which is unlikely), this lack of success is either because the polymorphism of the disease group defeats study, or because in the disease group are different entities treated as one illness, the psychiatric diagnosis acting as a mask, or because the physiological behaviour of individuals is subject to unpredictable variation.

In published research in schizophrenia, unlike research in chronic physical disorders, such as rheumatism or cancer, little account seems to have been taken of

obvious that the swelling in the neck was due to tuberculous adenitis. The glands were aspirated on four occasions and brown sterile pus was obtained on each occasion.

Histological report on the skin lesion (Dr. J. W. Whittick).—Within the dermis of both fragments there is a tuberculous reaction consisting mainly of epithelioid cells, occasional multinucleate giant cells and a few peripheral lymphocytes. There is a small amount of necrosis at the centre.

Mantoux test: Six weeks ago 1 : 10,000 negative. One week ago 1 : 10,000 negative.

X-ray (Chest): No evidence of tuberculosis past or present.

Treatment.—Calciferol 50,000 units twice daily has been administered; the cutaneous lesion has retrogressed and the condition of the neck is very satisfactory.

The following cases were also shown:

Lentigo Malignum.—Dr. J. E. M. WIGLEY.

Multiple Superficial Basal-cell Carcinomata.—Dr. P. J. FEENY.

(1) **Keratotic Nævus**. (2) **Large Pigmented Nævus of the Scalp**.—Dr. R. E. BOWERS.

Darier's Disease.—Dr. STEPHEN GOLD.

Granuloma Annulare in a Boy of 11 Years Treated with Vitamin E.—Dr. CLARA M. WARREN.

[These cases may be published later in the *British Journal of Dermatology*.]

schizophrenia with constant clinical characteristics, patiently elucidated biochemical correlates. To establish other clinical categories by psychiatric examination alone is probably impossible, but we believe that physiological patterns will emerge from widespread research, by which groups of corresponding cases can be identified without the necessity of relying on the clinical appraisalment.

Published reports show that if various biochemical tests, for example, insulin sensitivity and sugar tolerance, are repeated frequently in schizophrenic patients, there is much day-to-day variation in results, and from clinical experience we know how unpredictable is the response to insulin treatment. If tests are carried out on a large series of patients, significant deviations occur in a greater proportion than in normal controls.

To express these facts in a different way, it is clear that there exist many cases of schizophrenia whose physiological equilibrium is inconstant and a proportion in whom it is constant, irrespective of whether the results of tests are themselves within or without the normal range. It is the factor of inconstancy that operates so strongly against biochemical research. However, we think these schizophrenic patients could be grouped profitably into those with constant and those with inconstant biochemical patterns. Inconstancy might be significant of active, and constancy of arrested disease, or the opposite; or a biochemical pattern might be established at a certain stage of the disease, or it might be characteristic of a certain type. Therefore, much variation in research results is to be expected unless the patient material is in the same stage of the disease or suffering from the same type—conditions clinically unascertainable. If tests could be devised which, repeated frequently, would reveal constancy and inconstancy, it should be possible to spot patients with similar physiological patterns who could then be subjected to extensive and detailed investigations.

The amount of 17-ketosteroids excreted in twenty-four hours bears some relation to the activity of the adrenal cortex and the testis. Its estimation was chosen in preliminary investigations as the master test for the study of constancy and inconstancy as well as to give information about endocrine activity. In previous investigations (Hemphill, Macleod and Reiss, 1942) it had been observed that the output of 17-ketosteroids increased after electro-shock treatment, leucotomy, and occasionally even testis biopsy.

This increase is not, as we thought at first, a regular result of successful electro-shock treatment. We have seen increases even up to three times the normal. This suggested that the daily level of 17-ketosteroid output might vary in schizophrenic patients in whom the biochemical pattern was inconstant.

In a large series of patients of different types many daily analyses of the 17-ketosteroid excretion were made. There was in some of them a day-to-day variation, some showed a rather constant behaviour. It is not yet possible to isolate from these results any particular pattern of variation. Fractionation of the different 17-ketosteroid excreted appears to be more promising at present. The figure gained for the total 17-ketosteroid excretion in twenty-four hours is a resultant only of the different fractions, some of them produced in the testicles, some of them in the adrenal cortex, and some being inactive intermediary products of the steroid metabolism not yet formed to a specific hormone by a ductless gland.

A recently published method of Dingemans and co-workers (1946) was applied for fractionation. In this method a chromatographic separation of over 20 different ketosteroids is possible, including the separation of androsterone and dehydroandrosterone, the former produced mainly by the testicles, the latter by the adrenal cortex. Our fractionation experiments showed that even if different individuals excrete exactly the same amount of total 17-ketosteroids, this total figure might

the duration and stage of the disease; nor do many papers show that the end-result was of consequence to the investigators after the research programme had been carried out, and investigations do not seem to have been conducted on many patients in apparently total remission. There has been much study of phenomena such as circulation, oxygen consumption, and liver function, considered in isolation. Merely to add to the multitude of such investigations could contribute little, and, although we have applied methods of research to isolated phenomena, we have tried to direct our research by biological or endocrine indications.

In recent years we have studied pathological changes in the testis in schizophrenia (Hemphill, 1944; Hemphill, Reiss, Taylor, 1944). Biopsy specimens consistently showed an abnormal histological picture in schizophrenia of early life. The pathological changes were not found in other mental disorders, nor were they marked in paranoid schizophrenia. They were maximum in younger patients and where the prognosis was bad or the disease process far advanced.

The advantage of the biopsy method, in that fresh material can be procured from patients selected at any stage of the disease and in any state of health, is somewhat offset by the small portion of tissue available, for biopsy specimens are too small to enable one to express an opinion about the interstitial elements and Leydig cells. The striking abnormalities were: gross disorder of spermatogenetic elements, with destruction of many tubules, hyalinization of basement membrane, and infertility. The only parallel picture in humans is found in senile testes, but there were points of histological similarity between the schizophrenic testis and that of the animal after partial hypophysectomy. It therefore appeared likely that the testis atrophy was due to abnormal anterior pituitary activity, the normal hormonal control of spermatogenesis and testis development being disturbed.

Attempts to repair this testicular disorder by hormone treatment were not entirely successful. Follicular stimulating hormone (Gestyl) influenced the cells, causing many to increase in size and stimulated spermatogenesis, but complete maturation was not re-established.

The testis structure remained pathological as was to be expected, for the disturbance occurring in adolescence was likely to be complex involving different gonadotrophic, adrenotrophic and other hormones. Simultaneous estimation of anterior pituitary hormone excretion could only be carried out on a selected number of cases; such a programme is in fact nearly impracticable, as the consumption of animals and time appears quite prohibitive. Reference will be made later to some attempts to develop newer and more sensitive methods of assaying anterior pituitary hormones.

A very extensive battery of tests, thorough biochemical investigation of the blood and urine calculated to mirror the physiology of the patients and indirectly to throw some light on anterior pituitary functions combined with the estimation of the excretion of 17-ketosteroids and of cortin-like substances, was employed. No definitely conclusive information was gained by these procedures about pituitary disorder. They did reveal, however, the importance of constancy and inconstancy in physiological patterns and a possible correlation between steroid hormone metabolism and some forms of schizophrenia.

Up to the present the only biochemically-controlled clinical type of schizophrenia yet described is that of Gjessing. He selected cases suffering from the rare periodic catatonic illness and, after repeated physiological investigations, showed that a disturbance of nitrogen balance was associated with psychotic phases. Administration of thyroid to discharge nitrogen retention was accompanied by remission of mental symptoms. Gjessing, therefore, having succeeded in isolating a type of

schizophrenia with constant clinical characteristics, patiently elucidated biochemical correlates. To establish other clinical categories by psychiatric examination alone is probably impossible, but we believe that physiological patterns will emerge from widespread research, by which groups of corresponding cases can be identified without the necessity of relying on the clinical appraisalment.

Published reports show that if various biochemical tests, for example, insulin sensitivity and sugar tolerance, are repeated frequently in schizophrenic patients, there is much day-to-day variation in results, and from clinical experience we know how unpredictable is the response to insulin treatment. If tests are carried out on a large series of patients, significant deviations occur in a greater proportion than in normal controls.

To express these facts in a different way, it is clear that there exist many cases of schizophrenia whose physiological equilibrium is inconstant and a proportion in whom it is constant, irrespective of whether the results of tests are themselves within or without the normal range. It is the factor of inconstancy that operates so strongly against biochemical research. However, we think these schizophrenic patients could be grouped profitably into those with constant and those with inconstant biochemical patterns. Inconstancy might be significant of active, and constancy of arrested disease, or the opposite; or a biochemical pattern might be established at a certain stage of the disease, or it might be characteristic of a certain type. Therefore, much variation in research results is to be expected unless the patient material is in the same stage of the disease or suffering from the same type—conditions clinically unascertainable. If tests could be devised which, repeated frequently, would reveal constancy and inconstancy, it should be possible to spot patients with similar physiological patterns who could then be subjected to extensive and detailed investigations.

The amount of 17-ketosteroids excreted in twenty-four hours bears some relation to the activity of the adrenal cortex and the testis. Its estimation was chosen in preliminary investigations as the master test for the study of constancy and inconstancy as well as to give information about endocrine activity. In previous investigations (Hemphill, Macleod and Reiss, 1942) it had been observed that the output of 17-ketosteroids increased after electro-shock treatment, leucotomy, and occasionally even testis biopsy.

This increase is not, as we thought at first, a regular result of successful electro-shock treatment. We have seen increases even up to three times the normal. This suggested that the daily level of 17-ketosteroid output might vary in schizophrenic patients in whom the biochemical pattern was inconstant.

In a large series of patients of different types many daily analyses of the 17-ketosteroid excretion were made. There was in some of them a day-to-day variation, some showed a rather constant behaviour. It is not yet possible to isolate from these results any particular pattern of variation. Fractionation of the different 17-ketosteroid excreted appears to be more promising at present. The figure gained for the total 17-ketosteroid excretion in twenty-four hours is a resultant only of the different fractions, some of them produced in the testicles, some of them in the adrenal cortex, and some being inactive intermediary products of the steroid metabolism not yet formed to a specific hormone by a ductless gland.

A recently published method of Dingemans and co-workers (1946) was applied for fractionation. In this method a chromatographic separation of over 20 different ketosteroids is possible, including the separation of androsterone and dehydroandrosterone, the former produced mainly by the testicles, the latter by the adrenal cortex. Our fractionation experiments showed that even if different individuals excrete exactly the same amount of total 17-ketosteroids, this total figure might

the duration and stage of the disease; nor do many papers show that the end-result was of consequence to the investigators after the research programme had been carried out, and investigations do not seem to have been conducted on many patients in apparently total remission. There has been much study of phenomena such as circulation, oxygen consumption, and liver function, considered in isolation. Merely to add to the multitude of such investigations could contribute little, and, although we have applied methods of research to isolated phenomena, we have tried to direct our research by biological or endocrine indications.

In recent years we have studied pathological changes in the testis in schizophrenia (Hemphill, 1944; Hemphill, Reiss, Taylor, 1944). Biopsy specimens consistently showed an abnormal histological picture in schizophrenia of early life. The pathological changes were not found in other mental disorders, nor were they marked in paranoid schizophrenia. They were maximum in younger patients and where the prognosis was bad or the disease process far advanced.

The advantage of the biopsy method, in that fresh material can be procured from patients selected at any stage of the disease and in any state of health, is somewhat offset by the small portion of tissue available, for biopsy specimens are too small to enable one to express an opinion about the interstitial elements and Leydig cells. The striking abnormalities were: gross disorder of spermatogenetic elements, with destruction of many tubules, hyalinization of basement membrane, and infertility. The only parallel picture in humans is found in senile testes, but there were points of histological similarity between the schizophrenic testis and that of the animal after partial hypophysectomy. It therefore appeared likely that the testis atrophy was due to abnormal anterior pituitary activity, the normal hormonal control of spermatogenesis and testis development being disturbed.

Attempts to repair this testicular disorder by hormone treatment were not entirely successful. Follicular stimulating hormone (Gestyl) influenced the cells, causing many to increase in size and stimulated spermatogenesis, but complete maturation was not re-established.

The testis structure remained pathological as was to be expected, for the disturbance occurring in adolescence was likely to be complex involving different gonadotrophic, adrenotrophic and other hormones. Simultaneous estimation of anterior pituitary hormone excretion could only be carried out on a selected number of cases; such a programme is in fact nearly impracticable, as the consumption of animals and time appears quite prohibitive. Reference will be made later to some attempts to develop newer and more sensitive methods of assaying anterior pituitary hormones.

A very extensive battery of tests, thorough biochemical investigation of the blood and urine calculated to mirror the physiology of the patients and indirectly to throw some light on anterior pituitary functions combined with the estimation of the excretion of 17-ketosteroids and of cortin-like substances, was employed. No definitely conclusive information was gained by these procedures about pituitary disorder. They did reveal, however, the importance of constancy and inconstancy in physiological patterns and a possible correlation between steroid hormone metabolism and some forms of schizophrenia.

Up to the present the only biochemically-controlled clinical type of schizophrenia yet described is that of Gjessing. He selected cases suffering from the rare periodic catatonic illness and, after repeated physiological investigations, showed that a disturbance of nitrogen balance was associated with psychotic phases. Administration of thyroid to discharge nitrogen retention was accompanied by remission of mental symptoms. Gjessing, therefore, having succeeded in isolating a type of

significant individual variation, as well as daily or weekly variations in the same patient, in schizophrenics as a whole, and work is being done to show how these changes are related to the fractionated 17-ketosteroid output.

In the case described above, there was a sharp rise in blood cortin after treatment with testosterone. This in its turn might account for the increased muscle activity, although it should be noted that in the other patients the normal level of blood cortin was not associated with the same result.

The catatonic state.—The catatonic state might be the result of a central neurophysiological process or influenced by hormone dysbalance. It might, however, be caused by inhibitory substances in the blood, giving a picture that masks the true illness. Experiments were devised to test the last possibility. Special cages were constructed to contain a rat comfortably. The base of the cages was a large rubber tambour, connected with a kymograph. The slightest movement in any direction agitated the tambour and was recorded on the kymograph. Simultaneous records were made of the activity of six rats, each time under standard conditions of complete quiet. By adjusting the speed of the kymograph, the amounts that the rats moved in twenty-four hours could be assessed from the kymograph record, and therefore the total activity estimated and expressed by % activity. The rats were then injected with blood from catatonic patients, and from normal controls. This experiment is still proceeding, but so far there has been no evidence of inhibitory substance, and in some cases the activity of the rats has been significantly increased by catatonic blood.

Thyroid function in schizophrenia.—Estimation of B.M.R. in schizophrenia is practically valueless, and until recently it has seemed impossible to get a true index of thyroid activity. It is important to do so, for, as we know, a proportion of schizophrenic patients respond to thyroid treatment for a time and in many a tolerance of thyroid develops after treatment for a few weeks. It is not clear whether this anomaly is due to a failure of reactivity or some special property of the schizophrenic thyroid itself. Clinical hyperthyroidism is rare in schizophrenia, and in the few cases we have seen and reported there was eventual recovery. We have felt justified in regarding hyperthyroidism with schizophrenia as a separate clinical entity (Hemphill, 1942).

Reliable methods for the determination of the thyroid function should be the determination of the protein-bound blood iodine, determination of the iodine uptake of the thyroid and determination of the iodine excretion. As a result of more than a year's work a modification of the method used by Taurog and Chaikoff (1946) was finally adopted as the routine method for the investigation of the patients. The iodine uptake and iodine excretion are being investigated with the radio-active tracer technique. A combination of all three methods should give reliable evaluation of the thyroid function. The methods were unfortunately not available at the time when the bulk of the early work on the fractionation of ketosteroids was being done.

Enzyme systems.—In recent years enzyme activity has received much attention. Some workers have speculated that many of the somatic deviations in schizophrenia originate in enzyme abnormality. Richter and Lee (1942), having studied cholesterinase levels in blood, showed that cholesterinase could be an indicator of autonomic activity, as well as of muscular activity. Contrary to the findings of previous workers, notably Stedman and Stedman (1935), we have demonstrated true cholesterinase in C.S.F. (Reiss and Hemphill, 1948).

We have investigated the levels of true and pseudo cholesterinase in blood and in C.S.F. in more than a hundred patients, suffering from different mental disorders,

be arrived at by the excretion of entirely different components. There might be, for instance, a complete lack of dehydro-androsterone excretion, the total sum being made up of an unspecific or not yet completely identified ketosteroid.

The fractionation method of Dingemans was carried out on a great number of patients' urine extracts, but it has not been established as a routine method for research in our laboratories, owing to the unreliability of the various absorption materials obtainable to-day. The method as it is now being carried out consists of separation into ketonic, non-ketonic, alpha and beta fractions; a procedure much better suited to routine work and which gives valuable differentiations.

A group of six chronic catatonic patients, mute and cataleptic for years, who had failed to respond to recognized treatments, were chosen for special examination. They were as nearly similar in state of health, nutrition, and clinical picture as possible, and they were investigated under standard conditions. They were kept under control for several months, during which time fractionated ketosteroids were investigated frequently, and a battery of biochemical tests was applied. Urinary cortin excretion and other hormones were also studied. Although clinically these patients were identical, their fractionated ketosteroid patterns were not so, and in one patient no dehydro-androsterone was excreted.

K. B., aged 33. He had not spoken for eight years, he was practically immobile, and could only just feed himself. Testis biopsy had shown gross atrophy and infertility, with marked sclerosis of small vessels. Total ketosteroids remained within normal limits, but fractionation consistently showed no dehydro-androsterone, the total ketosteroids therefore having little physiological value. The question was, did he produce no dehydro-androsterone, or was it broken down in the body and not excreted? He was treated with 25 mg. daily of testosterone. His ketosteroid pattern altered, and he started to excrete dehydro-androsterone. This more normal pattern is maintained as long as he is under treatment. The change was accompanied by a remarkable clinical improvement. He became active, walked easily, talked and worked. He discussed literature, and asked for chocolates and cigarettes. He put on weight, his circulation improved, and his beard began to grow. He has not recovered, but this partial remission has remained now for about a year. He tends to relapse if not treated with testosterone. His testes are firm; biopsy shows a very abnormal but remarkable picture, unlike anything we have seen before. The testis has been influenced but not repaired.

Administration of testosterone to the other patients in the group, in whom the picture was clinically the same, and who already excreted dehydro-androsterone, failed to produce any clinical response beyond a tendency to auto-erotic behaviour.

It is reasonable to assume that in this single case there is a close relationship between the abnormal endocrine state and the clinical condition. Partial correction of the former produced a maintained improvement in the latter.

Without biochemical control, empirical treatment of these patients with testosterone would have produced the same result, but we would not have been able to suggest why treatment succeeded in one case and not in the others. We see in this an explanation for the occasional successes of haphazard hormone treatment in schizophrenia, observed by Hoskins and most other workers.

One can optimistically speculate that if our methods of analysis were sufficiently accurate we could find definite indications for treatment in many cases. Probably the endocrine disturbance is not simple, and might have to be corrected with the administration of more than one hormone; nor do we know whether a successful result is due to the direct action of the hormone administered, or to its effect in altering the hormone balance.

Cortin in blood and urine.—Heard, Sobel and Venning (1946), and Talbot *et al.* (1945) have described methods for determining cortin in urine by chemical means depending upon the reducing properties of the side chain. Hemphill and Reiss (1947) have made use of the same principles to determine cortin in blood. We have found

constitution is usually good, as evidenced by the fact of marriage, and in the clinical histories there is seldom evidence of a bad or schizoid constitution; the physique is frequently normal; it is the one form of schizophrenia that comes under treatment regularly within a few days or weeks of the appearance of psychotic symptoms; the prognosis should therefore be most favourable. In point of fact, the prognosis is probably worst of all schizophrenic illnesses, and in our survey in Bristol few cases of clear puerperal schizophrenia appear ever to have recovered.

Of 117 cases of puerperal mental illness of various kinds treated at Bristol Mental Hospital in recent years, 21 suffered from schizophrenia; 2 of these made doubtful remissions, and the remainder became chronic and degenerated in spite of insulin and shock treatment. Of the remaining 96 non-schizophrenic reactions, 92 made complete recoveries; 2 died of pneumonia; and 2 improved but were lost sight of after leaving hospital.

Puerperal schizophrenia follows an acute physiological event; we would suggest that this event is not childbirth, but sudden loss of placenta. That the illness responds so badly to insulin and other treatments indicates that the physiological abnormality has some special quality. This special feature might be related to the placental loss. Most animals eat the placenta. Man does not do so, because presumably in the human the acute loss of placental hormone is bridged temporarily from other sources while endocrine equilibrium is being established. It is interesting to speculate that if the schizophrenic constitution represents a more archaic type of functioning, there is a greater demand than normal for the placenta to readjust endocrine balance.

Puerperal schizophrenia logically should be an entity in the disease group and, as there is a minimum of uncontrollable extraneous factors, most suitable for hormone investigation. These patients are so unco-operative and difficult to nurse that collection of urine is not easy and research may be impracticable. However, in some cases we have found evidence of marked deficiencies; in some cases absolutely no oestrone or pregnandiol has been recovered from successive urinary specimens. There are reports of at least two cases in the literature who recovered after immediate treatment with progesterone (Blomberg and Billig, 1942, Schmidt, 1943). There is, therefore, some clinical and biological evidence to support the theory that puerperal schizophrenia is an entity with a particular endocrine basis, in which replacement therapy may be practicable.

It is still worth considering what actually happens in the brain after an endocrine disturbance that could be responsible for the development of mental changes. Attention in this direction is centred around the brain circulation and the brain metabolism. Model experiments carried out in our laboratories on the brains of rats (Reiss and Rees, 1947) have shown disturbance of the economy of the metabolism. Hexokinase activity and glycolytic activity are increased after hypophysectomy. The brain uses more of its carbohydrate reserves, a state which consequently may lead to a breakdown of certain brain functions.

Summary.—In this rather scattered survey, we have endeavoured to show some of the lines along which our research is being planned, and to mention what we have found productive.

We have avoided any mention of the obvious question as to the location of a disease process that operates sometimes through endocrine channels. However, it is not difficult to offer a physiological explanation for some of the psychological phenomena.

A reduced awareness and responsiveness to environment allows the appearance of dream-like states, so similar to schizophrenic thought content. Reduced awareness

including schizophrenia, and during and after experiences such as electro-shock treatment.

In the schizophrenic group, deviations are still being studied. If it is true that cholesterinase levels reflect autonomic activity, we have now another instrument for studying this important aspect of neurophysiology in schizophrenia, and examining the assumptions of autonomic dysbalance in this disorder.

To summarize this section of the work, we feel that with methods for fractionation of 17-ketosteroids and estimating blood and urine cortin, protein-bound blood iodine, cholesterinase in blood, and in C.S.F., and tracer technique with radio-active iodine, we have methods with which to approach the physiological problem in a more definite and refined way than ever possible before.

Investigation of isolated phenomena is not likely to be helpful, and these methods will have to be used in combination. They should be exhaustively applied in the course of and after treatment, and it will be necessary carefully to investigate patients in full remission and at intervals after discharge from hospital.

Relationship of growth and physical constitution to schizophrenia.—In the many studies of physical constitution in schizophrenia allowance does not seem to have been made for the possibility that as the result of the disease process the physical constitution might have changed. Body measurements in psychotic patients, irrespective of the duration of illness or the age, are usually classified together under the respective clinical headings. It is our impression that some patients change shape during the illness and become more leptosomatic.

If the atrophy of the testis is due to faulty anterior pituitary regulation, it may well be that the regulation of growth hormone is upset as well. It is quite plausible that a schizophrenic patient becomes leptosomatic if the disease process begins before growth is complete and not because he is primarily of leptosomatic constitution.

In planned research, cases of schizophrenia should be measured and photographed according to standard scales, with an X-ray control, the procedures to be repeated every six months up to say five years. Analysis of anterior pituitary hormones and growth substances should be made on cases showing an abnormal physical development. This work could be conducted on a large scale in collaboration with other mental hospitals, and it is an item in our research programme in Bristol. The tremendous difficulty in planning a reliable scheme of measurement is evident. Non-psychotic siblings should be included in family controls.

Continuous efforts have been made to improve the methods for the assay of pituitary anterior lobe hormones in the body fluids. One is faced in this work with the difficulty that large volumes of urine or blood are necessary for tracing small amounts of hormone and many animals are required. It was important to find test objects sensitive to small amount of hormones and therefore requiring smaller amounts of body fluids. At present in our laboratories the total hormones are absorbed on permutit. After passing several litres of urine through such a permutit column the concentrated total amount of growth hormone, gonadotrophic hormone and corticotrophic hormone can be gained in a few ml. of the eluate. The method has already been worked out for corticotrophic hormone assay (Cooke, Graetzer and Reiss, 1948).

Puerperal schizophrenia.—Puerperal schizophrenia strikes one immediately as being an important clinical entity, and for various reasons eminently suitable as a research problem. It occurs rarely before delivery and, although commoner in primipara, it is sometimes seen in multipara. It constitutes about one-fifth of all the pregnancy reactions. Its unique characteristics are as follows: the patients are fertile, unlike the majority of comparable males with atrophic testes; the prepsychotic

Nutritional Œdema

By H. M. SINCLAIR, D.M.

(Wellcome Laboratory of Human Nutrition, University of Oxford)

(1) INTRODUCTION

THE following observations were made in Holland and Germany in the course of work conducted for public health purposes by the Oxford Nutrition Survey. The nature of the work unfortunately precluded the experimental method and the detailed study of a few persons. In the observations in Holland, made mainly in May and June 1945, 3,184 persons were clinically examined of whom 359 (11·3%) had nutritional œdema, 30 (0·9%) had non-nutritional œdema, and 2,795 (87·8%) had no œdema; the German results relate to September 1945 to July 1946 and include an analysis of 10,225 persons of whom 4·1% had nutritional œdema, 4·8% had œdema probably not nutritional, and 91·1% had no œdema. Some results on these persons were communicated to the VII Congress of Biological Chemistry in Liège in October 1946 (Sinclair, 1947).

Three types of nutritional œdema may be distinguished. First, wet beriberi is caused by a diet relatively high in carbohydrate and low in thiamine. Clinically the cases are distinct from the other two types. Secondly, hypoproteinæmic œdema is caused by a low level of protein, particularly albumin, in plasma with a consequent fall in the colloidal osmotic pressure. Low plasma protein, however, does not necessarily cause œdema. The third type may be an early form of the second and is reasonably called famine œdema; the subjects have usually subsisted on diets low in calories and in protein, but they are not necessarily grossly emaciated and the plasma protein values are usually within the normal range. It is this third type that I wish to discuss. But, if famine œdema is defined as pitting œdema that is apparently caused by nutritional deficiency other than deficiency of thiamine and that cannot be ascribed to any non-nutritional cause (such as orthostasis, varicose veins, cardiovascular disease or albuminuria), then the second type as well as the third will be included.

The extensive literature concerning the ætiology of famine œdema cannot be discussed here. The hypotheses include the following: low plasma protein, low colloidal osmotic pressure with normal levels of plasma protein, circulatory failure, increased capillary permeability, renal failure, deficiency of thiamine, pituitary deficiency, thyroid deficiency, and adrenal cortical deficiency.

(2) CLINICAL

History.—The subjects have usually, although not always, lost a considerable amount of weight before œdema appears. They have had nycturia, in which the output of urine is increased. The œdema, which may come on rapidly following cold or exertion, is most commonly noticed as swelling of the ankles in the evening.

Dietary history.—It seems that famine œdema may arise in adults on a dietary intake of between 600 and 1,800 calories a day, with total protein of up to 50 grammes and animal protein of up to 15 grammes. In undernourished persons œdema may be produced, or if present increased, more easily than in normal persons, by administration of sodium chloride—a common observation in Holland and Germany.

Clinical examination.—Famine œdema is very rarely seen in children. Its

is common in fatigue, and in conditions such as the male climacteric, where poor adrenal cortex function or inadequate male sex hormone is causative.

The conception that schizophrenia represents a failure of responsiveness to the environment cannot easily be proved, but test situations such as response to heat and cold can be created. Where there is faulty adaptation, with poor thermal regulation, there should be, on the basis of animal experience, a poor response in the output of cortin, cortin levels being used as an index of physiological adaptability.

Some such experimental planning might serve the dual purpose of extracting from the great mass of schizophrenics those with poor responsiveness and those with good, and thereby act as a guide to prognosis.

Nutritional Œdema

By H. M. SINCLAIR, D.M.

(Wellcome Laboratory of Human Nutrition, University of Oxford)

(1) INTRODUCTION

THE following observations were made in Holland and Germany in the course of work conducted for public health purposes by the Oxford Nutrition Survey. The nature of the work unfortunately precluded the experimental method and the detailed study of a few persons. In the observations in Holland, made mainly in May and June 1945, 3,184 persons were clinically examined of whom 359 (11.3%) had nutritional œdema, 30 (0.9%) had non-nutritional œdema, and 2,795 (87.8%) had no œdema; the German results relate to September 1945 to July 1946 and include an analysis of 10,225 persons of whom 4.1% had nutritional œdema, 4.8% had œdema probably not nutritional, and 91.1% had no œdema. Some results on these persons were communicated to the VII Congress of Biological Chemistry in Liège in October 1946 (Sinclair, 1947).

Three types of nutritional œdema may be distinguished. First, wet beriberi is caused by a diet relatively high in carbohydrate and low in thiamine. Clinically the cases are distinct from the other two types. Secondly, hypoproteinæmic œdema is caused by a low level of protein, particularly albumin, in plasma with a consequent fall in the colloidal osmotic pressure. Low plasma protein, however, does not necessarily cause œdema. The third type may be an early form of the second and is reasonably called famine œdema; the subjects have usually subsisted on diets low in calories and in protein, but they are not necessarily grossly emaciated and the plasma protein values are usually within the normal range. It is this third type that I wish to discuss. But, if famine œdema is defined as pitting œdema that is apparently caused by nutritional deficiency other than deficiency of thiamine and that cannot be ascribed to any non-nutritional cause (such as orthostasis, varicose veins, cardiovascular disease or albuminuria), then the second type as well as the third will be included.

The extensive literature concerning the ætiology of famine œdema cannot be discussed here. The hypotheses include the following: low plasma protein, low colloidal osmotic pressure with normal levels of plasma protein, circulatory failure, increased capillary permeability, renal failure, deficiency of thiamine, pituitary deficiency, thyroid deficiency, and adrenal cortical deficiency.

(2) CLINICAL

History.—The subjects have usually, although not always, lost a considerable amount of weight before œdema appears. They have had nycturia, in which the output of urine is increased. The œdema, which may come on rapidly following cold or exertion, is most commonly noticed as swelling of the ankles in the evening.

Dietary history.—It seems that famine œdema may arise in adults on a dietary intake of between 600 and 1,800 calories a day, with total protein of up to 50 grammes and animal protein of up to 15 grammes. In undernourished persons œdema may be produced, or if present increased, more easily than in normal persons, by administration of sodium chloride—a common observation in Holland and Germany.

Clinical examination.—Famine œdema is very rarely seen in children. Its

incidence increases with age; and it is of course much commoner in males than in females if their dietary intake is equal in amount. Table I shows the incidence of œdema as found in the examination of random samples of the population in particular areas of Leiden and The Hague.

TABLE I.—AGE AND SEX INCIDENCE OF FAMINE (ŒDEMA) (%) (HOLLAND)

Degree of œdema		Age-group	Males			Females		
			20–	45–	60–	20–	45–	60–
Leiden	Mild	..	3	11	32	7	21	31
	Marked	..	0	3	10	0	1	7
Hague	Mild	..	5	18	49	5	23	41
	Marked	..	0.6	3	7	0.3	1	5

Number examined:

		Total all ages						
Leiden	..	1,050	147	69	41	190	89	42
Hague	..	1,488	171	95	84	308	154	120

The common clinical manifestations of undernourishment are usually present, and acrocyanosis of the hands is particularly prominent. We have found no correlation between incidence of famine œdema and the following: thickness of skin and subcutaneous tissue, systolic or diastolic blood-pressure, pulse rate (measured on persons in the same population with no œdema or with non-nutritional œdema).

(3) BIOCHEMICAL OBSERVATIONS

To our surprise we found in Holland that there was no significant difference between the mean values for serum protein and for albumin of subjects with nutritional œdema and those for subjects without; and the mean values fell within the statistically normal range (Table II). The same result was subsequently obtained in Germany.

TABLE II.—MEAN VALUES FOR SERUM PROTEIN AND SERUM ALBUMIN (IN G./100 ML.) OF ADULTS WITH AND WITHOUT (ŒDEMA) (NUMBER OF PERSONS IN BRACKETS)

				Males			Females		
				Famine œdema	Other œdema	No œdema	Famine œdema	Other œdema	No œdema

We intended in Holland to rely for total protein upon the rapid densitometric method of Jacobsen and Linderstrøm-Lang (1940) which we had used for nearly four years and had investigated carefully (*see* Lloyd *et al.*, 1945). Because our values in Holland were unexpected we checked them by estimating protein by four methods: densitometric, gravimetric, micro-Kjeldahl and biuret (*see* Sinclair, 1947); the agreement was excellent. But the density-protein relation for serum or plasma calculated from the first two methods was different from that given by others: Protein = 355 (G - 1.0069) where G is the density expressed in terms of d_{20}^{20} . The comparison between the gravimetric and micro-Kjeldahl methods for blood samples from persons with or without famine œdema showed that the serum protein from the former contained significantly less nitrogen: protein from 11 non-œdematous persons gave an average conversion factor (\pm s.e.) of 6.252 ± 0.067 , whereas for 17 œdematous persons the factor was 6.435 ± 0.046 if two outlying values were omitted and

6.582+0.122 if these were included; in either case the difference is significant. A qualitative change in the serum protein of persons with nutritional œdema has also been proved by Florkin and Duchâteau (1944).

We found in cases of famine œdema that there was a correlation between colloidal osmotic pressure of serum and total serum protein ($r = 0.78$), and we confirmed the observation of Govaerts and Grégoire (1941) that the pressures were lower than those calculated from Govaerts's equation relating them to concentration of albumin and globulin. We found the protein content of œdema fluid was about 0.8 g./100 ml., but it was probably raised because our cases in Holland were not of recent origin. Since Luckner (1938) showed that œdema could be produced in rats on a diet low in protein and prevented or cured by cystine, we estimated this amino-acid in the serum of 64 persons without œdema and 27 persons with famine œdema, but found no significant difference in the levels.

Estimation of various inorganic ions, hæmoglobin, hæmatocrit, certain vitamins, &c., showed no marked differences between mean values for persons with and without famine œdema (Sinclair, 1947), and there was no evidence from the values that hæmoconcentration was causing high values for serum protein in persons with famine œdema.

Simonart (1947) and Heilmeyer (1946) have attributed famine œdema to deficiency of thiamine. In the cases we studied this was not a factor for five reasons: the ratio of thiamine to non-fat calories in the diet was not low; the clinical picture was different; there was no difference in blood pyruvate levels between persons with and without famine œdema; urinary excretion of thiamine gave no evidence of deficiency; therapeutic tests were negative.

(4) NYCTURIA

Persons with famine œdema tend rapidly to lose their œdema through urinary excretion when they are recumbent, and undernourished persons even without pitting œdema complain of nycturia and excrete unusually large amounts of urine at night. Normal individuals concentrate urine more when upright than when recumbent (Erlanger and Hooker, 1904); and this effect of posture is intensified in undernourishment. Govaerts (1947) has shown that persons with famine œdema when erect give a diminished response to Volhard's water test, and there is also a diminished renal excretion of orally administered salt. It was found in Germany that when recumbent they give an increased response to the water test, and Dr. Cunningham will show in the discussion that in these persons the urinary excretion of water and of solids is increased significantly. According to Brun *et al.* (1945), the diminished water diuresis in the passive erect posture is brought about by increased reabsorption of water in the renal tubules through increased secretion of the antidiuretic hormone of the posterior lobe of the pituitary. If this is so, the effect on the pituitary of the upright posture might be intensified in undernourishment. Trueta *et al.* (1947) have suggested that posture or the antidiuretic hormone causes increased tubular reabsorption of water through arteriolar constriction shunting the renal blood-flow from the cortical glomeruli to the juxtamedullary glomeruli which are part of nephrons with long thin loops of Henle and vasa recta that are well adapted for reabsorption of water. In undernourished persons this arteriolar constriction in the upright posture may be intensified. It should be noted that arteriolar constriction is responsible for the acrocyanosis of the hands.

(5) ADRENALS

The changes in the adrenals that occur in undernourishment and in deficiency of thiamine do not seem to have been studied much in recent years. The extensive early literature indicates that in children inanition produces a considerable diminution in size of the adrenals (Jackson, 1922). In adults, simple fasting (in which famine

œdema is not usually found) is accompanied by loss of weight of the adrenals, but deficiency of protein or of salts or of thiamine causes enlargement. With one exception (Enright, 1920), a number of authors have reported enlargement of the adrenals in famine œdema, and the same has been reported for human beriberi; the cortex is mainly affected. McCarrison (1919), as a result of his work on pigeons, concluded "that disorder of the adrenal glands and malnutrition of the tissues are the main factors concerned in the production of œdema in both inanition and beriberi". He likened the adrenal enlargement to that found in the thyroid in iodine deficiency but thought there was an increased production of adrenaline. In pigeons fed autoclaved rice he found the adrenals weighed about 23 mg. in controls, 36 mg. in birds with "dry beriberi", and 68 mg. in those with "wet beriberi". This association with nutritional œdema is striking, and should be further investigated especially as oral administration of salt enormously increases water retention in famine œdema in man and in pigeons deficient in thiamine.

(6) SUMMARY

The rapid examination for public health purposes of a large number of persons during the famine in Holland and subsequently in Germany has shown that in famine œdema the levels of serum protein, of serum albumin and of serum cystine are within the statistically normal range. Protein was estimated by four different methods. Although the colloidal osmotic pressure of serum is slightly lowered, this cannot account for the œdema; the lowering may be caused by a qualitative change in serum protein, the mean nitrogen content of which is significantly decreased in cases of famine œdema.

In two of the types of nutritional œdema, namely famine œdema and wet beriberi, there is enlargement of the adrenals. The nycturia of undernourishment appears to be caused by an intensification of the effect of posture on the kidneys of normal persons: there is increased reabsorption of water in the renal tubules in the passive erect posture. In famine œdema this reabsorption appears to be greater, and when recumbent there is a large excretion of urine. The postural effect might be brought about by a greater secretion than normal of antidiuretic hormone of the posterior lobe of the pituitary or by the renal shunt of Trueta (through the juxtamedullary glomeruli). Further work is needed to settle this.

[The work described here was done by members of the Oxford Nutrition Survey: in Holland, mainly of Mr. B. B. Lloyd, Dr. van der Kamer, Dr. Emmerie and Dr. Engel; in Germany, mainly of Mr. B. B. Lloyd, Dr. D. J. C. Cunningham, Dr. J. C. Thompson and Dr. Widmann. Full particulars will be published in due course by those who did the work.]

Nutritional Anæmia

By MARTIN HYNES, M.D.

NUTRITIONAL anæmia may be defined as an anæmia due to deficiency of the elementary materials of red-cell formation or of the accessory vitamin-like factors necessary for hæmatopoiesis. It is difficult, however, to translate this definition into quantitative terms, for deficiency depends upon the individual's demands as well as upon the available supplies. A diet which is hæmatologically adequate for a healthy man is often insufficient for a pregnant woman or a victim of hookworm infestation or malaria. Moreover, infections of all kinds are more common when the diet is ill-balanced or insufficient, and even quite trivial infections rapidly cause anæmia, which may therefore be common in the undernourished even when no strictly hæmatological deficiency is present.

Only two of the raw materials of red-cell formation seem to be essential—iron, and protein from which the pyrrol ring and globin fraction of the hæmoglobin molecule can be synthesized. Little is known of the nature of the accessory hæmatopoietic principles, but two classes are clearly recognized—Castle's extrinsic factor, and Wills's factor which is concerned in nutritional macrocytic anæmia. Other members of the vitamin-B complex are necessary for erythropoiesis in some animals, and lack of vitamin C causes anæmia in man.

It is possible to find cases of anæmia due to each of these deficiencies, but a combination of deficiencies is much more common than a single one, and it is often impossible, as well as undesirable, to cure the patient's anæmia without correcting his whole diet.

Iron deficiency.—Iron-deficiency anæmia arises when the loss of iron from the body exceeds the intake. In the individual case abnormal loss is usually a more important factor than deficient intake, but the incidence of iron-deficiency anæmia in a community depends in large measure upon the iron available in the diet, and is in that sense a problem of nutrition. In this country before the war, for example, this form of anæmia was much commoner in women of the poorer social classes, for the cheapest foods—fish and chips and white bread—had a low iron content (Davidson *et al.*, 1944).

The total iron content of a diet is not, however, a reliable estimate of the amount which is physiologically available for hæmatopoiesis. Only ionic iron can be absorbed, so that if a high proportion of the iron of a foodstuff is supplied by organic, porphyrin compounds, only the small fraction broken down into ionic iron by digestion or, more probably, by bacterial action, can be absorbed. The direct estimation of "available" or ionic iron by the α -dipyridyl reaction does not, however, give a reliable indication of the value of a diet as an iron source. A more important factor is the dietary content of substances such as phosphates, certain protein derivatives, and phytic acid, which form insoluble compounds with iron in the intestine.

It is possible to lay down general rules, such as that a diet containing a total of 15 to 20 mg. of iron is adequate for women in this country, but it is important to remember that the nature of the diet is implicit in this statement. The ratio of physiologically available iron to total iron is reasonably constant in a given community, but if the nature and proportion of the foodstuffs eaten are very different the amount of iron potentially available for hæmatopoiesis may be lower even though the total iron content is higher. Hynes *et al.* (1945), for example, found that 64% of 1,400 North-West Indian soldiers suffered from hypochromic anæmia which could be corrected by iron therapy. The total iron content of their diet was about 65 mg. daily, but the composition of the diet was very different from that of Europeans; foods made from *ata* (coarse wheat flour) predominated, and only 1 oz. of meat was eaten daily.

The importance of increased iron loss as a cause of iron-deficiency anaemia is well exemplified in this country by the fact that hypochromic anaemia is rare in men, but is common in women, who suffer the iron losses of menstruation and child-bearing. In the tropics hookworm infestation is a nearly universal cause of blood loss but the infestation, unless exceptionally heavy, only produces anaemia when malnutrition is present. The anaemia can be cured, without worming, by large doses of iron, but it also recovers spontaneously when the patient is given an adequate, balanced diet (Hynes *et al.*, 1946). It seems probable that factors other than a simple increase in dietary iron are involved in this recovery.

A relatively slight decrease in iron absorption may also precipitate deficiency, and we are very familiar in this country with the association between gastric achlorhydria and hypochromic anaemia.

Protein deficiency.—Anaemia can be produced experimentally by protein deficiency, but the anaemia does not arise until the protein reserves are completely depleted and even the plasma protein level is substantially reduced. Such anaemia is due in part to the general lack of protein, and in part to deficiency of lysine, phenylalanine, and, especially, of methionine, which play some essential but ill-understood part in erythropoiesis (Glynn *et al.*, 1945). In practice, however, it is probable that the infections associated with severe malnutrition are a more potent cause of anaemia than protein deficiency itself. Vaughan (1948) has suggested that the anaemia of infection is itself a result of a general disturbance of protein metabolism affecting the synthesis of the globin element of haemoglobin.

Protein deficiency is probably more important as an obstacle to the cure of anaemia than as a cause of it. A patient during recovery from severe anaemia may build some 400 grammes of globin into haemoglobin, an amount of protein equivalent to 4 lb. of steak.

The lack of haematopoietic factors associated with meat may cause the nutritional macrocytic anaemia described below, but meat has other, less defined, roles in blood formation. The addition of extra meat to the diet of Indian recruits, for example, hastened the spontaneous cure of their anaemia, whereas an equal addition of protein as milk was without effect (Hynes *et al.*, 1946).

Nutritional macrocytic anaemia.—A severe and often fatal macrocytic anaemia is common amongst people who live on a restricted and largely carbohydrate diet. It differs in many important clinical and haematological respects from pernicious anaemia, but especially, as Lucy Wills showed, in the fact that it can be cured by large doses of marmite by mouth.

The nature of the haematopoietic principle—Wills's factor—which cures nutritional macrocytic anaemia is still unknown. It is certainly not any known member of the vitamin-B complex, and it is not, as was once thought, identical with Castle's extrinsic factor.

The blood and marrow pictures of nutritional macrocytic anaemia differ clearly from those of pernicious anaemia, and the response of nutritional macrocytic anaemia to highly purified liver extracts such as anahæmin is uncertain and demands at least five times the dose which will cure pernicious anaemia.

In the tropics nutritional macrocytic anaemia is nearly always associated with malnutrition, although it is usually possible to name pregnancy, malaria, or dysentery as the precipitating cause. The fundamental lack seems to be that of some factor associated with animal protein, for in the Indian Army during the last war the disease was much commoner in vegetarians than in meat eaters. When the incidence was highest, as in the earlier Burma campaigns, the lack of fresh meat and milk and the religious prejudice of the Indian against tinned meat had forced most Indian soldiers to live on a purely vegetable diet. The disease was practically unknown.

amongst Europeans in the same army, who willingly ate tinned "bully" and bacon. There is some evidence that milk will prevent nutritional macrocytic anæmia even when no meat is eaten.

Deficiency of Wills's factor alone, however, will rarely, if ever, give rise to nutritional macrocytic anæmia unless the demand for the factor is increased. Napier (1939) has suggested that in chronic malaria the need for blood formation is increased by phagocytosis of red cells by the hypertrophic reticulo-endothelial system. The utilization of Wills's factor consequently increases, and if the amount in the diet is insufficient to meet the higher demand, malformed red cells are produced and still more readily phagocytosed, so that a vicious circle is set up.

Pregnancy may similarly cause nutritional macrocytic anæmia because the mother's diet has to meet the additional demands of the fœtus for Wills's factor. It was the importance of anæmia as a cause of puerperal mortality in India which first drew the attention of hæmatologists to nutritional, or as it was then called, tropical macrocytic anæmia. The rather rare macrocytic anæmia of pregnancy seen in this country may be of the same fundamental nature.

Nutritional macrocytic anæmia may be precipitated by dysentery, which presumably diminishes absorption of Wills's factor. It is not yet clear whether the macrocytic anæmia of sprue is due to deficiency of Wills's or of Castle's factor, and so far as I am aware no study of the bone-marrow has been made by anyone who has grasped the distinction between the megaloblasts of nutritional macrocytic anæmia and of pernicious anæmia.

The treatment of nutritional macrocytic anæmia during the last war was still very unsatisfactory. Moderately severe cases, with a hæmoglobin of 5 grammes per 100 ml. or higher, would often recover spontaneously without any specific hæmatinic treatment when they were given the generous hospital diet and concomitant disease was cured. When, however, the hæmoglobin was 3 grammes per 100 ml. or less the marrow function was not restored by any amount of liver injections, and only repeated transfusions would keep the patient alive. Later reports have suggested that proteolysed liver is as effective in this tropical macrocytic anæmia as it is in the allied macrocytic anæmia of pregnancy seen in this country, and still more recently folic acid has been claimed to be effective. The response of the less severe cases to dietary treatment alone, however, makes the assessment of any new therapy difficult.

Dimorphic anæmia.—Nutritional deficiencies rarely occur singly, and it is not surprising that iron deficiency is often added to nutritional macrocytic anæmia. Trowell has used the name "dimorphic anæmia" for the combined deficiency, to emphasize that the peripheral blood picture combines the features of a megaloblastic and an iron-deficiency anæmia. In practice it is important to recognize that macrocytic anæmia will often not respond adequately to therapy until iron as well as liver is given and that severe iron deficiency may completely mask Wills's factor deficiency unless sternal puncture is used as an aid to diagnosis.

Vitamin deficiency.—Of the vitamins only C is essential to hæmatopoiesis, and the anæmia of scurvy will not respond to hæmatinics until ascorbic acid is given. The infections associated with deficiencies of other vitamins are, however, a very potent cause of anæmia.

Dr. R. B. Hawes: Dr. Sinclair has definitely demonstrated that famine œdema has no relation to beriberi with which it had so often been confused. It would be a great contribution to progress if the term beriberi were defined so that every ailment that recovered after receiving B₁ should not be labelled as such. True beriberi is a very definite syndrome and should not be used to connote any dietetic deficiency with œdema and neuritis. My experience agrees with that of Dr. Sinclair in that œdema in starving people is often related to the salt intake.

Regarding macrocytic anæmia, when I was treating many cases long before folic acid was discovered, it appeared to me that the condition was related to a deficiency of phospholipoids in the diet and by using one to two dozen egg yolks at a dose I obtained a very rapid regeneration of the blood commencing within forty-eight hours.

Dr. D. J. C. Cunningham (Oxford): The following studies of nycturia were made during the course of nutrition surveys carried out in Germany in 1946 for the Control Commission by Nutrition Survey Group. As Dr. Sinclair has already remarked, a very common feature of inanition is the appearance of nocturnal polyuria, or nycturia. It seemed to the writer to be important to establish its nature and its relationship, if any, to famine œdema. The investigation was carried out by German doctors interned in a Civilian Internment Camp in the summer of 1946. The apparatus used was of the simplest; there were no facilities for any chemical work.

For the night of June 12-13, 1946, every sample of urine passed by the occupants of one barrack room was collected and its volume and specific gravity recorded. The following day blood samples were taken for the estimation of plasma protein and hæmoglobin by the densitometric method of Linderström-Lang; blood-pressures were recorded, and the subjects examined for œdema. Altogether 89 subjects contributed of whom 13 had clinical œdema.

At the time of the investigation the subjects had been for nine months to a year on a diet supplying daily between 1,500 and 2,000 calories and containing 35 to 45 grammes of protein, 4 to 10 grammes of which were of animal origin.

For statistical analysis of the results, the subjects have been divided into three groups: those with clinical œdema (13), those with no œdema but with polyuria (66), and those with neither (10). Polyuria has been arbitrarily taken as 600 ml. or more passed during the night. It is thought that the psychological effect on the "normals" of seeing their companions on the move all night (the total number of micturations in the barrack-room was about 360!) would make them micturate more frequently than they would otherwise have done. The results are as follows:

The majority (79 out of 89) passed more than 600 ml. during the night.

Those in the œdema group passed on the average a significantly greater volume of urine during the night than those in the polyuria group. (Averages, 1,650 and 1,227 ml. respectively.)

The average of the specific gravities of the last samples passed was significantly lower than that of the first sample. This was not the case with the few subjects in the normal group, and seems to be a feature of those with polyuria. There was an indication that the specific gravity was maintained or even raised during the first few samples and only fell with the later ones.

The "total solids" passed during the night was calculated as the sum of the volumes multiplied by the S.G.—1.000. On this rather crude basis, it was apparent that those with œdema excreted more total solids than those with simple polyuria, who in turn excreted more than the normal group. This appeared to be an active excretion of solids as the specific gravity seldom reached very low levels, and the lowest average recorded for any comparable group of specimens was 1.010.

None of these findings applies to individual cases: the largest volume and the greatest amount of solids was excreted by a non-œdematous individual.

From this it is suggested that the majority of the individuals had a disorder of water metabolism in which water and solids were presumably retained during the day and were eliminated during the night. This retention was sometimes sufficient to produce clinical œdema.

Dr. S. E. Dicker: On the assumption that the cell membranes are impermeable to chloride, it is possible to calculate the extracellular fluid phase of muscles. Series of rats were fed for seven, fourteen and forty-two days on a protein-deficient vegetable diet and compared with controls fed on a standard diet. After seven days on the protein-deficient vegetable diet no significant changes could be found in the plasma nitrogen content, the albumin/globulin ratio, the colloid osmotic pressure of the plasma and the total water content of plasma and muscle, but there was a significant increase in the extracellular fluid phase of the muscle, indicating that tissue œdema was present already. After fourteen days on the protein-deficient diet, there was a fall in the plasma nitrogen and in the albumin/globulin ratio, accompanied by a fall in the colloid osmotic pressure, and a further increase in the extracellular fluid phase. It can thus be concluded that the onset of œdema formation in malnutrition is independent of changes either in the albumin/globulin ratio or in the colloid osmotic pressure of plasma. At a later stage further increases of the extracellular fluid phase were concurrent with a progressive fall in the colloid osmotic pressure of the plasma. However, even after forty-two days on the protein-deficient diet, when the plasma protein concentration had fallen by nearly 30% as compared with controls, no clear correlation could be found between the

degree of hypoproteinæmia, the fall of the colloid osmotic pressure of the plasma and the magnitude of the extracellular fluid phase of tissues.

The President: The data presented at this Meeting were in accord with the growing opinion that famine œdema could not be explained entirely on the basis of the classical hypothesis of Starling, that the quantity of fluid accumulating in the tissues depended on the interplay between the colloidal osmotic pressure of the plasma and the blood-pressure within the capillaries, the level of interplay being influenced by the degree of capillary permeability. Some additional factor was indicated and the identity of this was suggested by the observation that ingestion of salt conspicuously increased the degree of famine œdema. This might arise in one of two ways. The transient retention of water normally induced by taking salt tends also to dilute the plasma proteins and, if through under-nutrition these cannot be rapidly restored to normal levels, the consequent lowering of plasma osmotic pressure would allow fluid to accumulate in the tissues. Such an hypothesis could easily be put to test. Alternatively there might be an impaired ability to excrete salt and/or water in undernourished people. Ralli, Robson, Clarke and Hoagland (1945) have demonstrated this in cases of hepatic cirrhosis and further that this impairment was accompanied by an increased excretion of an antidiuretic factor in the urine. This was attributed to failure of the damaged liver to destroy a pitressin-like factor. Following this clue Leslie and Ralli (1947) have shown that rats given a low-protein high-fat diet for two or three weeks began to excrete in the urine increasing quantities of the antidiuretic factor. This occurred long before such diets had produced hepatic cirrhosis and was ascribed to impairment of liver function by fatty infiltration. In view of the results reported by Dr. Dicker of the effects of low-protein diets the impairment might well be due to protein deficiency, and applicable to human cases of starvation.

With regard to nutritional macrocytic anæmia Dr. Hynes had mentioned that a similar anæmia could be produced experimentally by lack of an essential amino-acid such as methionine. The clinical clues indicated a correlation between protein deficiency and nutritional macrocytic anæmia in man. Gajdos (1946) had reported a similar anæmia during the famines in Europe and had observed that it responded to methionine.

Lieut.-Colonel J. A. Manifold, R.A.M.C.: During the war I was for some time connected with the administrative side of Dr. Martin Hynes' survey work in India. My colleagues and I, while there, were able to make some investigations into severe cases of anæmia affecting Indian troops in a hospital of 7,500 beds. We not only did the hæmatological work but through the kindness of the Officer Commanding the hospital we were also able to control the treatment.

These men were selected base troops not having been exposed to the hæmatological risks of the campaign in Assam and Burma and were on a diet of some 4,000 calories containing 109 grammes of protein (animal 24 grammes). The mean Hb level on reporting sick was 7.22 grammes per 100 ml. and the peak incidence in the second and third year of service. Non-meat eaters were very significantly more susceptible than were meat eaters. At a low Hb level there was a strong association between hookworm infestation, microcytosis and hypochromia and chronic malaria with macrocytosis. Dr. Hynes has indicated the mechanism by which the latter may take place. The former is really a simple iron-deficiency microcytic hypochromic anæmia of the "pile"-bleeding, iron-deficient type. This association did not hold good at high Hb levels.

The suggested ætiology may be expressed in the form of an equation, in which "Precipitating Factors" added to a hypothetical "Unknown Factor" acting in a substrate (probably a poor intake of protein of high biological value and/or a high phytic acid content of the diet) give rise to anæmia. The precipitating factors are chronic malaria and/or hookworm infestation and/or dysentery and diarrhoea and/or pregnancy. These factors are, of course, very common in the agricultural classes in India, and are far more common than are severe cases of anæmia.

The substrate is more or less universal in the tropics and therefore it becomes necessary to postulate an unknown factor which is really a peculiar susceptibility to hæmatological stress, possibly conditioned by protein starvation. Within broad limits the extent of the precipitating factors do not affect the issue.

Various graphs and charts were shown illustrating hæmatological details from cases of this type and attention was drawn to the fact that, within about three months, 62 persons out of 66 suffering from severe anæmia attained an almost completely normal blood picture without any supplementary aids such as blood transfusion. Orthodox hæmatological treatment achieved this end, disproving

Dr. R. B. Hawes: Dr. Sinclair has definitely demonstrated that famine œdema has no relation to beriberi with which it had so often been confused. It would be a great contribution to progress if the term beriberi were defined so that every ailment that recovered after receiving B₁ should not be labelled as such. True beriberi is a very definite syndrome and should not be used to connote any dietetic deficiency with œdema and neuritis. My experience agrees with that of Dr. Sinclair in that œdema in starving people is often related to the salt intake.

Regarding macrocytic anæmia, when I was treating many cases long before folic acid was discovered, it appeared to me that the condition was related to a deficiency of phospholipoids in the diet and by using one to two dozen egg yolks at a dose I obtained a very rapid regeneration of the blood commencing within forty-eight hours.

Dr. D. J. C. Cunningham (Oxford): The following studies of nycturia were made during the course of nutrition surveys carried out in Germany in 1946 for the Control Commission by Nutrition Survey Group. As Dr. Sinclair has already remarked, a very common feature of inanition is the appearance of nocturnal polyuria, or nycturia. It seemed to the writer to be important to establish its nature and its relationship, if any, to famine œdema. The investigation was carried out by German doctors interned in a Civilian Internment Camp in the summer of 1946. The apparatus used was of the simplest; there were no facilities for any chemical work.

For the night of June 12-13, 1946, every sample of urine passed by the occupants of one barrack room was collected and its volume and specific gravity recorded. The following day blood samples were taken for the estimation of plasma protein and hæmoglobin by the densitometric method of Linderström-Lang; blood-pressures were recorded, and the subjects examined for œdema. Altogether 89 subjects contributed of whom 13 had clinical œdema.

At the time of the investigation the subjects had been for nine months to a year on a diet supplying daily between 1,500 and 2,000 calories and containing 35 to 45 grammes of protein, 4 to 10 grammes of which were of animal origin.

For statistical analysis of the results, the subjects have been divided into three groups: those with clinical œdema (13), those with no œdema but with polyuria (66), and those with neither (10). Polyuria has been arbitrarily taken as 600 ml. or more passed during the night. It is thought that the psychological effect on the "normals" of seeing their companions on the move all night (the total number of micturations in the barrack-room was about 360!) would make them micturate more frequently than they would otherwise have done. The results are as follows:

The majority (79 out of 89) passed more than 600 ml. during the night.

Those in the œdema group passed on the average a significantly greater volume of urine during the night than those in the polyuria group. (Averages, 1,650 and 1,227 ml. respectively.)

The average of the specific gravities of the last samples passed was significantly lower than that of the first sample. This was not the case with the few subjects in the normal group, and seems to be a feature of those with polyuria. There was an indication that the specific gravity was maintained or even raised during the first few samples and only fell with the later ones.

The "total solids" passed during the night was calculated as the sum of the volumes multiplied by the S.G. — 1·000. On this rather crude basis, it was apparent that those with œdema excreted more total solids than those with simple polyuria, who in turn excreted more than the normal group. This appeared to be an active excretion of solids as the specific gravity seldom reached very low levels, and the lowest average recorded for any comparable group of specimens was 1·010.

None of these findings applies to individual cases: the largest volume and the greatest amount of solids was excreted by a non-œdematous individual.

From this it is suggested that the majority of the individuals had a disorder of water metabolism in which water and solids were presumably retained during the day and were eliminated during the night. This retention was sometimes sufficient to produce clinical œdema.

Dr. S. E. Dicker: On the assumption that the cell membranes are impermeable to chloride, it is possible to calculate the extracellular fluid phase of muscles. Series of rats were fed for seven, fourteen and forty-two days on a protein-deficient vegetable diet and compared with controls fed on a standard diet. After seven days on the protein-deficient vegetable diet no significant changes could be found in the plasma nitrogen content, the albumin/globulin ratio, the colloid osmotic pressure of the plasma and the total water content of plasma and muscle, but there was a significant increase in the extracellular fluid phase of the muscle, indicating that tissue œdema was present already. After fourteen days on the protein-deficient diet, there was a fall in the plasma nitrogen and in the albumin/globulin ratio, accompanied by a fall in the colloid osmotic pressure, and a further increase in the extracellular fluid phase. It can thus be concluded that the onset of œdema formation in malnutrition is independent of changes either in the albumin/globulin ratio or in the colloid osmotic pressure of plasma. At a later stage further increases of the extracellular fluid phase were concurrent with a progressive fall in the colloid osmotic pressure of the plasma. However, even after forty-two days on the protein-deficient diet, when the plasma protein concentration had fallen by nearly 30% as compared with controls, no clear correlation could be found between the

COMBINED MEETING WITH THE

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE

DISCUSSION: THE EPIDEMIOLOGY OF TRYPANOSOMIASIS IN MAN AND ANIMALS

Dr. J. Carmichael: The trypanosomes which cause disease in mammals can be divided into two large groups, those which are normally transmitted by species of *Glossina* or tsetse fly, and those which are not so transmitted. The epidemiology of trypanosomiasis varies, of course, with each group. From the human point of view Chagas' disease caused by *T. cruzi* and transmitted by the Reduviid bugs is the most important. In South America also there are two important diseases of animals caused by trypanosomes—mal de caderas, a trypanosomiasis of horses caused by *T. equinum*, and a disease of cattle caused by a parasite similar in morphology to *T. vivax* and often referred to as *T. venezuelense*.

The epidemiology of these diseases is obviously closely related to the seasonal distribution of the Tabanidæ. Another important disease of animals is that caused by *T. evansi*, and often referred to as surra. Here again the disease is transmitted by flies belonging to the family Tabanidæ and certain species of *Tabanus*.

The tsetse fly is confined almost entirely to Africa. The most important *Glossinæ* which are responsible for the disease in man and animals are the riverine species *G. palpalis* and *G. tachinoides*. In the open savanna and bush country *G. morsitans* and the closely related species *G. swynnertoni* are responsible for the vast amount of human and animal trypanosomiasis. Recently, however, *G. pallidipes* has become more important and has been incriminated with the animal and the human disease. Other species of *Glossina* such as *G. brevipalpis* and *G. longipennis* are not so widespread but they are important where they exist. In Zanzibar up till quite recently tsetse fly were said to be absent, although many outbreaks of *T. congolense* in cattle kept occurring. Diligent search, however, revealed that *G. austeni* existed in appreciable numbers and was no doubt responsible for the losses from trypanosomiasis. There is no doubt that the starting point of trypanosomiasis both in man and animals is the tsetse fly. Generally speaking, contact with the fly is incompatible with the existence of domestic animals, with the possible exception of the dwarf cattle of West Africa. These animals possess a tolerance to trypanosomiasis but only when they are well cared for. There are, however, large numbers of human beings living in contact with tsetse fly, both the riverine species and the savanna bush types of *Glossina*.

Since the classical epidemic in the Lake Victoria region of Uganda about 1900, thousands of people were moved away from their homes out of contact with the fly, *G. palpalis*, and they were not allowed to return for some twelve to fifteen years, during which time the fly had no human beings to feed on, but confined itself to the fauna which existed on the Sesse Islands and the lake shore. The swamp antelope or sitatunga, in the absence of its human enemies, left the swamps and assumed the habits of its near relative, the bush buck, and provided the fly with food. *G. palpalis* also had crocodiles, varanus lizards, birds, monkeys and small mammals to feed on. It is now well over twenty years since the population returned to quite a number of the islands, and no epidemic has occurred, and it has been suggested that during the intervening period in the absence of man *T. gambiense* has lost its pathogenicity for the human being. It seems to me that even in the presence of the parasite, whether it be *T. gambiense* or *T. rhodesiense*, there must occur in many parts of Africa a balance between host and parasite, and until some adverse

the oft-repeated statement that these types of anæmia do not respond to established physiological principles of treatment, i.e. crude liver extract of the "Campolon type" to the macrocytic cases, and ferrous iron to those iron-deficient and microcytic, aided by a diet rich in protein of a high biological value given to all cases.

Dr. Nicholas H. Martin: With reference to Dr. Sinclair's paper, it appears to me that what is important in considering the circulation of proteins in starvation is not so much the *percentage* of circulating protein or the *percentage* of circulating albumin and globulin as the absolute amounts of the circulating protein. The need for such an estimate was brought home to me strikingly in the study of protein metabolism in infective hepatitis and serum-transmitted hepatitis (Martin, 1948). I wonder if Dr. Sinclair has any available data of absolute figures of the circulating proteins in his patients?

While it is true that with the more modern and refined techniques no gross quantitative disturbances of protein pattern have been demonstrated in extreme starvation, nevertheless, as Bourdillon predicted and Luetscher demonstrated, there are qualitative differences in the individual "protein" in other diseases. It might be informative to examine the individual proteins in nutritional oedema by the same techniques in the hope of disclosing similar or parallel qualitative differences.

Major A. R. T. Lundie: I was very interested, in view of personal experience, in the remarks of Dr. Sinclair and other speakers on the ill-effects of the administration of sodium chloride to cases of nutritional oedema.

I should like to know if any explanation can be given for the craving for salt which I have noticed in such cases; and which sometimes proved too strong even for those who suspected that the taking of large quantities of sodium chloride would be unwise.

Dr. Sinclair (in reply): I agree with Dr. Martin about the desirability of estimating plasma volume so that the absolute amount of protein could be calculated. In Holland this was not practical, and from a large number of different determinations of various substances in blood and plasma we concluded that the volume was not greatly altered. In view of the qualitative change in protein that we found in Holland, we tried in Germany to obtain data on the electrophoretic constitution of the protein but with great difficulty. A few samples of serum from cases of famine oedema in Germany were flown to Oxford and examined in the ultra-centrifuge by Dr. Ogston without any abnormality being discovered.

Professor Himsworth's suggestion that there may be a failure of destruction of antidiuretic hormone is very interesting, but I think it is unlikely as there is usually no evidence of liver damage and it is unlikely that such damage occurred within seven days in Dr. Dicker's rats. But an increase in the amount of antidiuretic hormone in the circulation is the most probable hypothesis to explain the increased reabsorption of water and salt in the renal tubules.

during dry weather. Thus during a few months they often come in contact with fly and the disease becomes noticeable after their return to their normal grazing grounds many miles away from tsetse. Here the disease is transmitted from animal to animal by *Stomoxys* and other biting flies. It is in these cases where a prophylactic drug which would protect the animals during their dry-weather grazing and contact with the fly would be most valuable. Such a drug is within the bounds of possibility, but when a chemical is required which will protect animals indefinitely in these tsetse areas the realms of practicability are exceeded at any rate for the present.

Other methods by which cattle become infected are contact with fly during travel from one part of the country to another on ordinary trade routes. Providing the fly belt through which they pass is not too extensive, an injection of Phenanthridinium 1553 or some other drug which will protect for a few days should prove a practical proposition and confer protection for the short period of risk from tsetse. On many occasions cattle are trekked through a fly belt at night, but this is often a hazardous undertaking and in any case is not effective as several species of *Glossina* feed at dusk.

Leaving the tsetse fly aside, a vast amount of trypanosomiasis in cattle is represented by *T. congolense* infections in herds far removed from known tsetse infestation. This is usually a chronic infection, causing unthriftiness and gradual emaciation, with exacerbations of virulence at certain times of the year. Sometimes these occur during drought when the animals are in poor condition owing to lack of grazing. At other times they occur during the rainy season when the biting flies such as *S. hematopota* and *Tabanus* occur in large numbers and the animals' resistance is reduced by fly worry, and mechanical transmission takes place more easily. Normally the disease in these non-tsetse areas spreads through a herd fairly slowly, which is in very marked contra-distinction to what happens if the herd is exposed to tsetse. In these non-tsetse areas there is no doubt that special conditions are involved and these occur in nature but are extremely difficult to reproduce under artificial conditions. In spite of numerous attempts to transmit *T. congolense* mechanically by *Stomoxys* and the *Tabanidæ* over a period of many years at Entebbe veterinary laboratory in Uganda I have always failed to set up infection, and under laboratory conditions where cattle are kept housed even if fairly large numbers of biting flies are present, cross-infection rarely if ever takes place. Over a period of sixteen years with trypanosome infections constantly being maintained in cattle I have yet to see an accidental infection taking place, and I cannot imagine that cross-infection by mechanical means could ever happen in this country under laboratory conditions, or even in ordinary farm buildings.

Mechanical transmission in human beings rarely occurs, but in the outbreak of sleeping sickness in Mwanza, Tanganyika, about twenty years ago, Duke was under the impression that mechanical transmission by tsetse actually took place in the villages where the fly concentration was extremely heavy.

I have not touched upon the epidemiology in other animals than cattle. Trypanosomiasis in dogs, sheep, goats and horses is almost invariably by the bite of a tsetse, and mechanical transmission does not appear to be an important factor. Dogs are especially susceptible to trypanosomiasis, and *T. brucei* and *T. congolense* are the important parasites. The disease set up by *T. brucei* and *T. rhodesiense* is indistinguishable on clinical grounds and is invariably a severe infection. Dogs are a very sensitive index of the presence of tsetse in a particular area.

Dr. Cecil A. Hoare (Wellcome Laboratories of Tropical Medicine, London): *Reservoir hosts of human trypanosomiasis*.—The trypanosomiasis affecting man and domestic animals afford one of the best examples of a field where the medical and veterinary sciences meet on common ground. The contact is particularly close in the sphere of epidemiology, especially in Africa where the tsetse flies and wild game represent a common pool for the pathogenic mammalian trypanosomes.

environmental factor such as famine intervenes, no epidemic occurs. If my memory serves me aright it was a famine which precipitated the devastating epidemic in Uganda early in this century.

I have already pointed out that domestic animals and tsetse fly are incompatible and in areas infested with *G. morsitans*, *G. pallidipes* and most of the other non-riverine species of tsetse flies, domestic animals cannot survive. In areas infested with *G. palpalis*, such as river banks and the Lake shore, cattle can exist and even thrive, at any rate in Uganda. This is mainly due to the fact that *G. palpalis* does not transmit *T. congolense*, which is the most pathogenic trypanosome as far as domestic animals are concerned. It does, however, transmit *T. vivax* and *T. brucei* but neither of these parasites causes severe disease, at any rate when transmitted by *G. palpalis*, in animals kept in good environmental conditions. Under adverse conditions such as drought, long journeys, work as draft oxen, &c., this tolerance to *T. vivax* and *T. brucei* breaks down, and a severe disease supervenes. An interesting epidemiological point arises in connexion with *T. brucei* for it has been seen that this organism can on occasion set up a severe disease in cattle when transmitted by *G. morsitans* or *G. pallidipes*.

Treatment of cattle which are in constant contact with tsetse fly is of little value owing to the fact that reinfection is taking place. When herds treated by the modern drugs for *T. congolense* repeatedly break down after treatment this indicates almost invariably that reinfection is taking place through tsetse. On more than one occasion this fact has led to a sustained search and the tsetse hitherto considered to be absent have been discovered. Parts of Uganda and Zanzibar are cases in point.

One of the most important factors in the epidemiology of trypanosomiasis whether it be of man or animals, is the shifting fly population. The "fly" areas, apart from those infested by *G. palpalis* near lakes and rivers, are never static and in recent years *G. pallidipes* and to a certain extent *G. morsitans*, have spread alarmingly. In Uganda where I have had first-hand experience over many years, the extension of the fly areas during the past three or four years has been most serious and in large areas the cattle population has been exterminated. It has been suggested that the fly *G. pallidipes* existed in these areas all the time and has only now been discovered. I can say categorically that as far as Uganda is concerned this is not so, because for many years large herds of cattle occupied these regions and healthy cattle are the best indicator that tsetse does not exist. In one particular area in Buruli in the province of Buganda there were famous grazing grounds early in this century, but *G. morsitans* and probably *G. pallidipes* invaded the area and existed in large numbers prior to the rinderpest epidemic about 1918 which killed off the big game, especially the buffalo. The fly disappeared and the cattle returned and thrived, and I myself carried out a careful survey using bait animals in 1928. No tsetse were to be found. Within the last three years this same country has become reinfested, probably by traffic across a narrow strip of water, from a recognized "fly" area and the cattle have again been wiped out—that is twice within forty-odd years, due to shifting fly population.

There is no doubt that tsetse flies feed on game and that game, especially buffalo and antelopes, carry trypanosomes which are pathogenic to domestic animals. There is also no doubt that buffalo and to a certain extent elephants, can and do carry tsetse, especially *G. morsitans* and *G. pallidipes*, many miles into fresh country which if suitable may become permanently infested and the cattle population infected with trypanosomiasis. The question of game destruction is outside the scope of this discussion but from the epidemiological point of view it has been observed that with the disappearance of game the fly has gone and trypanosomiasis of cattle does not occur. Several examples of this can be given from various parts of Africa.

The vast majority of chronic trypanosomiasis in cattle occurs outside tsetse areas and infection comes about in a variety of ways. In some parts of Africa, especially in Nigeria, the nomadic tribesmen move their cattle in search of grazing and water

would gradually adapt itself to the new host, at first behaving like *T. rhodesiense* and subsequently like *T. gambiense*. Conversely, it is thought that after passages through lower mammals the human trypanosomes may revert to *T. brucei*.

However, these views cannot be accepted unreservedly. First, because in enzootic areas of *T. brucei* no cases of human infection have ever been recorded. Secondly, because practically all attempts to infect human volunteers with *T. brucei* have failed. Finally, it has been demonstrated that after cyclical transmission through ruminants for many years *T. rhodesiense* does not lose its power to infect man again, i.e. it does not revert to *T. brucei*.

From these conflicting data it can be concluded that *T. brucei* does not readily adapt itself to man and that its transformation into *T. rhodesiense* does not take place under normal conditions, but presumably this evolution has actually happened in the past and might recur under exceptionally favourable conditions, the nature of which is not yet clear.

We now turn to the question regarding the reservoir hosts of American human trypanosomiasis, or Chagas' disease. Here the role of lower mammals as sources of human infection is much clearer, for in various countries of the New World numerous wild and domestic mammals are naturally infected with *T. cruzi*. This fact is of considerable importance in the epidemiology of human trypanosomiasis. The occurrence of natural infections in wild animals is closely correlated with the incidence of *T. cruzi* among Reduviid vectors. Infected bugs are encountered throughout the Americas, not only in localities where the human disease is endemic, but also outside these areas, where they inhabit the burrows of wild mammals and transmit the infection to these animals.

Since Chagas' disease has a restricted geographical distribution and its incidence in man is very low as compared with the incidence of infection among wild mammals and Reduviid bugs, there can be no doubt that *T. cruzi* is a natural parasite of these animals and Chagas' disease is a typical zoonosis, i.e. primarily an infection of wild animals which act as reservoir hosts from which the disease is occasionally spread to man by bugs introduced into human dwellings. This connexion has been clearly established in South America, where armadillos represent the source of human infection outside human habitations, but once established in a community the infection is transmitted from man to man by the domesticated bugs. Under these conditions domestic animals, like dogs and cats, also acquire the infection and constitute important reservoirs of the disease. The position in the southern parts of the United States is peculiar, for human trypanosomiasis has not hitherto been recorded there, in spite of the fact that local wood rats and Reduviid bugs harbour *T. cruzi* which is capable of infecting man under experimental conditions.

In conclusion, it may be noted that, in addition to trypanosomes which are common to man and lower mammals, there are a number of cases on record showing that purely animal parasites, e.g. *T. vivax* and *T. lewisi*, can occasionally break the barrier of host-restriction and establish themselves temporarily in man.

Dr. J. T. Edwards stressed the important difference between the human and veterinary aspects in so far as, in the former, two closely related species only, namely *T. gambiense* and *T. rhodesiense* were in question, at any rate in Africa (with *T. cruzi*, of minor importance, in South America), whereas, in the latter, the field was far more extensive and comprised trypanosomes belonging to the three very different groups, namely (a) the *brucei-pecaudi*, (b) *congolense-dimorphon*, and (c) *cazalboui-vivax*. Each of these three groups represented trypanosomes with marked morphological, developmental, and antigenic differences, as well as of response to chemotherapeutic agents, so that in devising methods of control of infection the veterinarian, over a large part of Africa, was presented with a far more complicated problem than the medical worker. If the recent work of Fiennes was confirmed, which pointed to a dermal pathogenesis in *congolense* infection in cattle, with remote disorganization

I propose to restrict myself to the animal reservoirs of human trypanosomiasis. In the case of sleeping sickness we have to deal with two forms of the disease, the chronic and the acute; however, there is no doubt that the causative organisms are very closely related and probably identical, *T. rhodesiense* representing merely a virulent strain or race of *T. gambiense*. Indeed there are indications that the two trypanosomes are convertible into each other.

The question regarding the reservoir hosts of sleeping sickness is highly controversial. In endemic areas of this disease natural infections with trypanosomes of the *brucei* group are common in tsetse flies and among wild and domestic mammals. In view of the absence of morphological distinctions between the three members of this group their identity in natural infections can be established with certainty only by observing their effect in susceptible animals, by inoculating these with the blood of the natural host, by allowing wild tsetse flies to feed on them, or by experimental infection of human volunteers. However, in most cases the nature of the trypanosomes detected in natural infections is determined from evidence provided by the epidemiological data. Thus, trypanosomes found in animals from localities where the human disease is unknown most probably are *T. brucei*, while those occurring in endemic areas of the Rhodesian disease may be either *T. rhodesiense* or *T. brucei*. Since both these species are highly virulent for laboratory animals they can only be differentiated by inoculating human volunteers. In endemic areas of the Gambian disease the differential diagnosis of *T. brucei* and *T. gambiense* is based on the relative virulence of the trypanosome for laboratory rodents.

The occurrence of natural infections with human trypanosomes among wild and domestic mammals has an important bearing on their role as reservoir hosts of sleeping sickness. Significant results, throwing light on this problem, have been obtained from experimental infections of various animals. These have shown that *T. rhodesiense* and *T. gambiense* can be maintained by cyclical transmission through wild and domestic mammals for several years, without losing their transmissibility to man.

From these observations it is concluded that in sleeping sickness, in addition to man, various other mammals constitute a source of infection. The relative importance of the human and animal reservoirs differs according to the type and distribution of the disease. The Rhodesian disease, which is usually encountered on the fringes of thinly populated bush-country abounding in big game, is transmitted by tsetse flies from man to antelopes and from these back to man, antelopes representing important reservoir hosts even in localities which have been depopulated for some years. In the Gambian disease, which occurs in relatively well-populated localities with a sparse mammalian fauna, man appears to be the essential host, but in view of the prolonged survival of the trypanosome in antelopes and domestic animals, without loss of cyclical transmissibility to man, some of these animals should be regarded as potential reservoir hosts.

The question of reservoir hosts of *T. gambiense* and *T. rhodesiense* is closely linked with that of their relationship to *T. brucei*, which has both a theoretical and practical interest, for there are reasons to believe that the human trypanosomes have originated from *T. brucei*. This question has also an important bearing on the epidemiology of sleeping sickness, for if it could be proved that *T. brucei* is capable of establishing itself in man, both wild and domestic animals harbouring this trypanosome would have to be reckoned with as dangerous sources of human infection. However, there is considerable controversy on this matter. The chief factor which prevents *T. brucei* from gaining a footing in man is the trypanocidal action upon it of normal human serum, to which the human trypanosomes are resistant. But it is conceivable that persons suffering from pathological conditions which destroy the trypanocidal power of their serum might become susceptible to infection with *T. brucei*. Furthermore, exceptionally virulent strains of this trypanosome might overcome the trypanocidal action of normal human serum. Having thus established itself in man *T. brucei*

fixation test. This proved the very close antigenic affinity existing between the several members of the *brucei-pecaudi* group. However, although ordinarily it is not possible to transmit *T. equiperdum* to rats, yet, very rarely indeed, a strain from a natural case can be discovered to infect an animal of this species, and when once that has been achieved then serial transfer in the species takes place readily, and the disease-picture is indistinguishable from that seen after *T. brucei* or *evansi* infection in them.

To the veterinarian, the principles of epidemiological control in tropical or sub-tropical territories as applicable to a grave disease, like, for example, cattle plague, differ enormously from those applicable to the trypanosomiasis. For, whereas, in the former, resort must be had to vaccination (and research undertaken continuously to perfect methods of vaccination), in the latter resort must be had to chemotherapy (also with the steady pursuit of improving methods of both preventive and therapeutic treatment). In the case of the former, methods of segregation and quarantine are usually out of the question. In the case of the latter, however, the recent discovery of excellent insecticides, such as D.D.T., will supplement, if not eventually supplant, chemotherapy.

Brigadier J. S. K. Boyd said he thought Dr. Carmichael was taking an unduly pessimistic outlook on the subject of drug prophylaxis in animal trypanosomiasis. In the Belgian Congo, van Hoof and his colleagues had reported that a single dose of pentamidine protected man against infection with *T. gambiense* for a period of six months. It seemed reasonable to hope that a drug conferring a similar or even a greater degree of protection against *congolense* infection might some day be discovered. Recent reports on certain phenanthridinium compounds were encouraging and it was possible that sooner or later a drug, possibly less toxic than those already known, and conferring a longer period of protection, might be discovered.

Dr. E. M. Lourie (Director of the Warrington Yorke Department of Chemotherapy, Liverpool School of Tropical Medicine) supported Brigadier Boyd's optimism in regard to the possibility of eventually finding an effective prophylactic agent for *T. congolense* infections of cattle. All that would be needed, after all, would be to find a substance which is not only lethal to the trypanosome but which is also capable of being retained in the host, in adequate amount, for a long period of time. There should be no insuperable difficulty in finding a compound in which these two properties are combined, and there is every reason to expect that substances of such a nature will become available before very long.

Dr. Lourie remarked that many of the problems of trypanosomiasis have been made more puzzling because of a tendency to regard the characters of *T. gambiense*, *T. rhodesiense*, *T. brucei*, &c., as of a fixed nature. One must constantly bear in mind, however, that the characteristics of any particular strain of trypanosome can undergo radical changes, which may be retained for very long periods. For example, after passage through suckling rats, *T. gambiense* no longer produces the chronic benign infections ordinarily characteristic of *T. gambiense* in laboratory animals; it acquires the virulent properties, together with other features, of *T. brucei* (Sandground, *Ann. Trop. Med. Parasitol.*, 1947, **41**, 293). Is it not possible that the reverse change, that is from virulence to benignancy, may account for the situation in Uganda, referred to by Dr. Hoare? After the devastating epidemics on the shores and islands of Lake Victoria at the beginning of this century the populations were shifted from the affected areas. On their return, many years later, there was no recurrence of epidemic conditions, although Fairbairn and Burt (*Ann. Trop. Med. Parasitol.*, 1946, **40**, 270) have shown that trypanosomes may retain their infectivity after many years of passage through game animals, which are, of course, abundant on the shores and the islands of Lake Victoria. However, a highly significant point is that although infectivity for man is retained after many years of passage through other animals, it is not unlikely that virulence for man may be considerably reduced. Indeed, Fairbairn and Burt produced evidence for such a change in a strain of *T. rhodesiense*

of the internal tissues, especially the thyroids, resulting from the products of the superficial infection, then the whole conception underlying chemotherapeutic treatment would need to be revised. So far, in trypanosome control, with the extreme difficulty of dealing effectively with vectors and carriers, main reliance had had to be placed on diagnostic methods coupled with chemotherapeutic procedures. Dr. Edwards himself, after experiences in India and Egypt (and the same applied to North African territories generally) had been concerned only with trypanosomiasis caused by that monomorphic, mechanically-transmitted trypanosome of the *brucei-pecaudi* group known as *T. evansi*. What was striking in connexion with it was the difference in response of the different species of domestic animal to chemotherapeutic treatment. Since the introduction of Naganol (Bayer 205) towards 1923 the prospects of recovery after proper treatment had changed greatly for the better. Moreover, preventive treatment was hopeful, for after injection of a prophylactic dose the drug remained in trypanocidal concentration in the system for over a month. In therapeutic treatment, the response was paralleled by the susceptibility of the species. In horses, which were very highly susceptible, nothing was effective save Naganol, administered intravenously in adequately large doses, repeated at monthly intervals, on two or three occasions, preferably concurrently with intrathecal administration to ward off possibility of a trypanosomal cerebrospinal meningitis (as Naganol did not traverse the "blood-brain barrier"). Whereas in ordinary cattle and buffaloes, among which outbreaks occasionally arose caused by strains of the trypanosome particularly highly adapted to these relatively resistant species, much less drastic treatment, using simpler remedies, was usually fully effective, the tissues of these animals being able to fend, as it were, for themselves after a little help. In these more resistant species, however, the trypanosomes could be shown to persist, without causing obvious harm to the hosts, after incomplete treatment—a status which could not be established in the far more highly susceptible equine. That Indian Zebu cattle could constitute dangerous reservoirs of infection was exemplified in the classic outbreak in Mauritius over half a century ago, when the local cattle were decimated after the importation of some Indian cattle. Between horses and cattle, in susceptibility and response to chemotherapy, came dogs and camels, among which *T. evansi* infection constituted a grave menace in the extensive territories with which the speaker was familiar. In dogs, intravenous Naganol therapy had promptly suppressed local outbreaks, as in foxhounds, while in camels, improved methods of diagnosis, such as the mercuric-chloride gel test, for those chronic infections in which the trypanosome was not readily detectable, coupled with Naganol therapy had proved wholly satisfactory.

Whether *T. gambiense* and *T. rhodesiense* of man and *T. brucei* of animals were so nearly related that human infection could arise through adaptation of the animal trypanosome, by some process not yet discovered, to human beings was a point of very grave epidemiological importance. The experiments of Kleine and others on human volunteers failed to support the assumption that adaptation took place. However, veterinary experience suggested it was not improbable that in natural circumstances such a phenomenon might arise. Thus, for example, effective control of dourine in horses, caused by a trypanosome of the *brucei-pecaudi* group (*T. equiperdum*), transmitted by coitus, had been achieved by wholesale slaughter of carriers detected by the application of the complement-fixation test on the blood serum. The antigen used in the test consisted of a fresh suspension of trypanosomes separated from the blood of small laboratory rodents (rats or mice) suffering from a rapidly progressive hyperacute septicæmia following inoculation with highly adapted strains of *T. brucei* or *T. evansi*. These trypanosomes, and not *T. equiperdum*, were employed because it was extremely difficult to discover a strain of *T. equiperdum* from natural cases that was infective for these rodents, but experience proved that antigen prepared from *brucei* or *evansi* strains was fully satisfactory in the complement-

d-Tubocurarine Chloride

By T. CECIL GRAY, M.D., D.A.

Two years ago we (Gray and Halton, 1946) expressed the opinion that *d*-tubocurarine chloride was the curare preparation of choice and were surprised that anæsthesiologists of the United States had preferred a comparatively crude substance. It is gratifying to find that the pure alkaloid is now used almost exclusively in this country and tends to replace intocostin in the New World. It is unfortunate, however, that the States continue to assay their preparations against an arbitrary standard rather than compute the dosage in mg. of the pure alkaloid. It is even more regrettable and to be deprecated that one firm has introduced a preparation of tubocurarine of different strength to that usual in this country. Such deviations from accepted local custom can only cause confusion and may be dangerous.

The history, pharmacology and story of the clinical use of *d*-tubocurarine chloride have been amply discussed during the last years. This paper, therefore, will be a critical appraisal of the status of this substance in the light of three years' experience of its use in anæsthesia.

I circulated a questionnaire to all the anæsthetists in the Liverpool district who were using *d*-tubocurarine chloride for their major abdominal and thoracic surgery. From the replies it would appear that in Liverpool alone close on 8,500 cases had been anæsthetized with the aid of this substance up to the end of 1947. Much information accrued from this survey, and, most important, it was evident not one of these other anæsthetists had had a single death which they attributed in any way to *d*-tubocurarine chloride. Nor had they seen any evidence of an unexpected side-effect.

From my own observations on the human electrocardiogram and from animal experimentation (Gray and Gregory, 1948) it seems quite certain that there is no significant effect produced by *d*-tubocurarine chloride on the heart. In animals large amounts injected quickly may produce a sudden fall in blood-pressure. In human subjects, although Harroun and her colleagues (1947) have described a slight fall in blood-pressure, I have never been able to observe this and in two cases it did not follow the very rapid injection of doses of the order of 45 mg. Nor did Smith (1947), in the experiment in which he received 500 units of intocostin, exhibit any alteration in the blood-pressure.

There has not been any evidence of kidney or liver dysfunction following the use of tubocurarine nor, in my experience, has there been any hyperglycæmia. I have used this substance in diabetic patients without any disturbance of their carbohydrate balance.

¹ The March Meeting will appear in the next issue of the *Proceedings*.

maintained for many years in sheep, although it is true they found no such evidence after passage of the same strain through antelope. However, these workers are precluded from making complete studies of virulence in man, because of the necessity of curing their volunteers at a very early stage of infection. Is it, then, not possible that the strains which produced the serious Uganda epidemics at the turn of the century may have subsequently become benign and relatively unimportant during their sojourn in game animals, before human resettlement was allowed in the affected areas?

No doubt many of the epidemiological problems of trypanosomiasis require that we should disabuse ourselves of the notion that *T. gambiense* always behaves in such and such a way, *T. rhodesiense* in another way, and *T. brucei* in still another way.

Dr. F. Hawking pointed out that most of the trypanosomes which infected cattle in Africa were derived from wild game, and so were some of those which infected man. Control of game was necessary for the control of trypanosomiasis; but this did not mean destruction of the game, since ample game reserves could be set aside for their preservation.

Dr. P. L. LeRoux: No mention has been made of the possible influence which temperature may have on the epidemiology of trypanosomiasis. In the case of human trypanosomiasis in Northern and Southern Rhodesia and in the Bechuanaland Protectorate, it is significant that the disease seems to remain confined to certain well-defined areas—Lake Tanganyika and the Luangwa Valley in Northern Rhodesia, certain parts of the Zambesi Valley in Southern Rhodesia, and the endemic area in Northern Bechuanaland—which are probably the hottest areas in these territories. It has been reported from Tanganyika that the incubation of the pupæ of *Glossina* has resulted in more flies becoming infected, on exposure to an infected meal, than is otherwise the case.

It would appear that temperature, in the case of human trypanosomiasis, must have a direct influence on the development of the trypanosome in the tsetse fly and this may explain why cases do not occur in the rest of the *Glossina*-infected areas.

The destruction of game for the eradication of the tsetse fly seems necessary and the complete disappearance of the "fly" from the Northern Transvaal after the outbreak of rinderpest, is often cited in support of game destruction. In the case of the Transvaal the "fly" was actually on the decrease before the rinderpest invaded the country and the rinderpest did not kill off all the species of antelopes. The zebra is not susceptible to rinderpest.

It would appear, also, that other tropical diseases of man and stock are directly influenced by temperature in that the development of their parasites or viruses in the invertebrate hosts is more dependent on temperature than is generally realized or accepted.

Dr. C. A. Hoare (in reply): While the finding of *T. congolense* in India is an isolated case, in *T. vivax* we have an example of a tsetse-borne infection which had spread outside its natural boundaries to Mauritius, the West Indies and South America, where the disease is transmitted to cattle mechanically by horse-flies. As regards surra, the disease occurs all along the Mediterranean coast of North Africa, from Egypt to and including Morocco, where it is represented by races affecting camels and equines. The existence of common antigens in trypanosomes of the *brucei* group has been demonstrated recently by van Hoof, who has shown that immune serum of one of these trypanosomes, when added to the culture medium, inhibits the growth of the others. Recent work by Brand and Johnson indicates that the metabolic processes of trypanosomes belonging to various groups show marked differences which may be correlated with differences in their response to chemotherapeutic agents. With regard to the relationship between *T. gambiense* and *T. rhodesiense*, the clinical manifestations attributed to these parasites are not clearly demarcated, for cases showing symptoms of one type of sleeping sickness may occur in a minority within the area of distribution of the other type.

that provided by laparotomy, tightening of the diaphragm and intercostal muscles in association with bronchospasm is likely to occur. I am convinced that this accounts for most of the difficulties which have been experienced. The whole picture in such a case is changed by increasing the depth of anæsthesia or by further curarization. I feel justified in saying that the possibility of this complication need be no deterrent in the use of d-tubocurarine chloride.

As to the effects on other smooth muscles, Cole (1946) has shown in dogs that tubocurarine abolishes the normal intestinal movements and that they are restored by morphine. Massey Dawkins (1947) reported a series of cases in which the incidence of post-operative ileus caused some inconvenience.

In man the intestinal movements are still very evident after tubocurarine. It is a feature of these anæsthetics that the colon and even the ureters exhibit active peristalsis and neither I nor any of those answering my questionnaire have seen any increased incidence of ileus following its use. If tubocurarine itself really caused ileus we might expect to see this complication a little more often in thoracic work where large doses are often employed. We have not had a single case.

Idiosyncrasy.—The factors determining the dosage of d-tubocurarine chloride are the patient's age, physique, general condition, and in children, body-weight. To some extent possibly the anæsthetic agent with which it is going to be used should be considered. A factor of some interest, but less well recognized, is that if patients have a high natural or acquired tolerance to sedative drugs, notably morphine, they are likely to require more d-tubocurarine chloride to produce the desired response. Even, however, when we take all these factors into consideration there seems to be a variability in patients' reactions. Out of the 15 observers who answered my questionnaire this variation was mentioned specifically by 12. In the vast majority of the cases it is so slight as to be of little or no clinical importance, but on occasion it has been extreme. Halton and I (1948) have recently described two cases of apparent idiosyncrasy and we had ample opportunity of confirming the hypersensitivity of the second case as she underwent a three-stage operation and her reactions to the drug were identical on the three occasions.

Now there are those who would say there is no such thing as idiosyncrasy to a drug. All I wish to relate here is that some patients show an exaggerated and a dangerous response to injections of d-tubocurarine chloride which, if not anticipated, may place the anæsthetist in an embarrassing and difficult position. For these reasons we advocate very strongly that to be safe, all who use this substance should administer a preliminary small dose as a test. It does not matter whether the patient is anæsthetized or not when this test dose is given. The effects on the respiration will be apparent in either case.

In a final attempt to evaluate the dangers of this agent, I investigated the cases which had been reported to the coroner in the Liverpool area from April 1945 to December 1947, the period during which d-tubocurarine chloride has been most widely used. There have been 18 fatalities following the use of this drug within forty-eight hours of operation. The details of these deaths are analysed in the table. Within the same period 60 patients died following the use of other anæsthetics and 28 of these fatalities were due to mismanagement of the anæsthesia. Owing to the difficulty of obtaining any accurate estimate of the total number of non-curare anæsthetics given in this large area it is impossible to express these latter figures in percentages. However it should be noted that the majority of the major general surgery and all the major thoracic procedures have been performed using d-tubocurarine chloride. Furthermore those deaths which were due to mismanagement of the anæsthesia in the non-curare cases were often extremely disturbing. In only one case which had died following d-tubocurarine chloride was there a really grave

Therefore, it is in a sense true to say that this is one of the least toxic drugs used in anaesthesia. Those stumbling-blocks, the heart, the liver and the kidneys, are unaffected by it. Nevertheless, it is potentially one of the most dangerous drugs we are called upon to exhibit.

d-Tubocurarine chloride produces paralysis of striated muscle by interfering with the conduction of the motor impulse across the myoneural junction. The muscles of respiration, the intercostals and diaphragm, being striated, are affected. Although some muscles are affected more and therefore earlier than others there is really no constant serial progression in the paralytic effects. There is a marked overlap and any dose likely to be of service to anaesthetists will affect to some extent the respiratory muscles. At the outset, therefore, it might be said that any substance which is likely to impair the respiratory function so drastically cannot be safe. That is a matter of opinion, for it is now recognized that the anaesthetist is able to compensate for such effects and restore to normal the impaired tidal exchange. That is now an everyday procedure but complete competence in assisting respiration and in dealing if necessary with an apnoeic patient is an essential pre-requisite for the anaesthetist who intends to use this substance.

Ever since the important work of Ranyard West in 1938 there has been reason to fear that bronchospasm might prove to be a serious if not a prohibitive factor in the employment of preparations of curare in clinical practice. West examined the exposed lungs of guinea-pigs and observed that an intense bronchiolar-constriction followed the intravenous injection of crude extracts. His clinical experiences also seemed to confirm this action.

There appeared to be a certain similarity of this action to the effects of injections of histamine, a similarity which was made more striking by the report of Comroe and Dripps (1946) that the intradermal injection of tubocurarine produced a wheal similar to that produced by histamine. Landmesser (1947) in an important communication last year showed that bronchiolar-constriction occurred in seven out of ten dogs after an injection of 0.3 mg. of *d*-tubocurarine chloride. The spasm did not occur if the animal was "protected" by the previous administration of the anti-histamine preparation, benadryl. The work of Gregory and Schild (1947) has shown quite conclusively that histamine is liberated when solutions containing *d*-tubocurarine chloride are perfused through mammalian skeletal muscle.

In April 1947 when this Society discussed this subject (*Proc. R. Soc. Med.*, 1947, 40, 593) more than one reputable authority reported bronchospasm in patients anaesthetized with *d*-tubocurarine chloride and in one or two cases this was thought to have produced a fatal result. We should review the position in regard to this possibility, remembering, however, not to give undue importance to the results of animal experiments when, as is in fact the case, the clinical evidence contradicts them. Halton and I have given *d*-tubocurarine chloride to 2,500 cases; out of these broncho-constriction has occurred only once and that was in a very bad asthmatic who was bronchoscoped when thiopentone was the anaesthetic agent used. The only other report of bronchospasm in Liverpool also followed a bronchoscopy when difficulty was experienced in inflating the lungs after withdrawal of the bronchoscope. Bronchospasm is not uncommon when bronchoscopy is performed under thiopentone, and in this latter case anoxia was present before the spasm developed and was an aggravating feature. Therefore, there have been two cases in over 8,000, and they both might have been expected to develop this complication. When there is a resistance to manual inflation of the lungs by pressure on the rebreathing bag, quite apart from occasions when there has been frank obstruction due, for example, to a kinked tube, there is a tendency for anaesthetists to say, "Ah! bronchospasm". The condition has been described by Morton (1945) as characteristic of light anaesthesia and this I believe it to be. If the anaesthesia is too light, whenever there is an intense stimulus such as

curarine is given intravenously and our custom is to give $\frac{1}{2}$ of the estimated induction dose as a test. Usually for adults this is 5 mg., and the effect of this on the conscious patient is watched for two minutes. In the very great majority the result is purely subjective. They feel a little drowsy and heavy in the eyelids, which they will frequently close. On request they are able to open their eyes and there should be no real ptosis. Any patient who exhibits more than this, e.g. complete ptosis, difficulty with speech or any difficulty with respiration is considered as being hypersensitive. This gives us a nice indication of the likely requirements of patients, particularly aged patients, in regard to d-tubocurarine chloride.

In the absence of any unforeseen reaction another 10 mg. is given followed immediately by 0.5 gramme of thiopentone. An endotracheal tube or a pharyngeal airway, depending upon the exigencies of the case, is introduced and the cheeks packed to ensure a close fit of the mask which is now applied and connected to a closed circuit anaesthetic machine. Anaesthesia for abdominal cases is usually maintained with thiopentone or kemithal, 50% nitrous oxide and a little ether if required, the tubocurarine being given in doses of 5 mg. as necessary. I consider that the best attitude to the question of ether-d-tubocurarine chloride potentiation is to use the same amount of tubocurarine which we know to be non-toxic and to reduce considerably the amount of toxic ether. For some cases cyclopropane is preferred particularly in those who are aged, shocked or have a poor myocardial reserve.

In thoracic work anaesthesia is maintained with kemithal and 30%-50% nitrous oxide and oxygen. The average order of dosage in, for example, an adult undergoing pneumonectomy would be thiopentone 0.5 gramme, kemithal 0.5 gramme or less and 30-35 mg. of d-tubocurarine chloride.

There are some further points about this technique: First and most important is the necessity to aid or assist the respiration when d-tubocurarine chloride has been given. Any dose which produces abdominal relaxation depresses the respiration to some extent. It is easy to show that even an injection of 15 mg. of d-tubocurarine chloride materially reduces the tidal volume and causes a collapse of the chest wall.

Now unless the anaesthetist compensates for these effects during the operation he must be prepared to have not only the troubles attendant upon under-ventilation at the time of the operation, but also a high incidence of post-operative pulmonary collapse. I have repeatedly seen experienced anaesthetists returning patients to the ward after operation still partially curarized. They often appear to be breathing fairly adequately and to be of a reasonably good colour; but a little closer observation would show that their respirations are depressed and inadequate. It is my opinion that nothing will so predispose to chest complications as returning patients to the ward in this condition. Harroun *et al.* (1947) have shown that in dogs post-operative atelectasis always follows the administration of tubocurarine if the animal is returned to his cage before his intercostals have fully recovered. The dog appears fit and has a fair respiratory exchange but the collapse is inevitable. It is so easy to give a dose of prostigmine and atropine, and in order to be quite certain it is now almost my invariable custom to do so. This injection of prostigmine should have the same sedative effect on anaesthetists as do the "hypnotic sutures" of Moynihan on surgeons. From the tracing in fig. 1 it will be seen that prostigmine will increase the tidal exchange even twenty-three minutes after an injection of thiopentone 0.5 gramme and tubocurarine 15 mg.

It will be noticed that in the technique I have described the d-tubocurarine chloride is administered before the induction of anaesthesia. There is a clear rationale for this. The intravenous injection of thiopentone is effective within seconds, that of d-tubocurarine chloride takes about two minutes to reach its maximum effect. Synchronizing the maximum effects of both these drugs by giving the tubocurarine first facili-

TABLE I.—DEATHS REPORTED TO THE CORONER FOLLOWING D-TUBOCURARINE CHLORIDE 1945-47

Specialists .. 6,646

8,333

Number of deaths reported to Coroner—18, i.e. 0.22%.

fault in technique and whilst the others in the light of subsequent experience with the drug might have been avoided they were bad risks and were due to misjudgment rather than to mismanagement.

The case in which death was attributed to tubocurarine was that of idiosyncrasy which has already been reported (Gray and Halton, 1948). If steps had been taken to avoid the regurgitation of stomach contents even this case might not have ended fatally.

How safe then is this substance? Dr. John Talbot of the University of Buffalo School of Medicine stated recently: "That it is only human to minimize the untoward reactions of a new therapeutic substance in the enthusiasm of discovering and subjecting it to clinical trial" (Talbot, 1948). This mistake I hope I have not made. I have reviewed the facts as we know them and it is for each of us to form our own judgment.

The use of tubocurarine confers two blessings upon the anaesthetists and the surgeons and one, perhaps the greatest, upon the patient. It ensures complete abdominal relaxation, and, if necessary, perfect control of the respiration. Both of these are possible quickly and at once, with a certainty which is most comforting for the anaesthetist and surgeon. The great blessing for the patient is that the anaesthetist can achieve these desiderata without resorting to deep anaesthesia.

We have in the past considered that it served a further function. The small amounts of narcotic drugs necessary to maintain anaesthesia led us to believe that the narcotic effectiveness of anaesthetic agents was increased by d-tubocurarine chloride, i.e. there was a potentiation effect; however, this is not the case. I have carried out a controlled series of experiments in which volunteers have been subjected to repeated doses of thiopentone and d-tubocurarine chloride and have tested their pain sensitivity and the time of their return to consciousness. It has become clear in the course of these experiments that our impression, as may so often be the case with clinical impressions, led us to an unjustifiable assumption. The experiments are still progressing but we have gone far enough to be able to say that there does not appear to be any decrease in sensitivity to painful stimuli or prolongation of the narcosis when d-tubocurarine chloride is used with thiopentone.

TECHNIQUE

Each anaesthetist will adopt the technique which suits him best, but I would again appeal for the universal adoption of a test dose for I fear that otherwise difficulty and embarrassment, if not indeed tragedy, will sooner or later attend the administration of effective doses of this substance. The following technique has given us the most consistent and best results: Very light premedication is still the rule. For adults we use morphine grain 1/6 (11 mg.) and atropine grain 1/100 (0.65 mg.). The tubo-

A further comforting feature is that with this type of anæsthesia the condition of the patient at the end of the operation does not deteriorate when the mask is removed as is so often the case with other methods of anæsthesia, particularly if cyclopropane is used. You see the patient in his worst condition at the end of the operation and not half an hour later in bed in the ward (figs. 2 and 3).

(1) Induction. (2) Chest opened. (3) Mesenteric traction. (Anæsthesia too light.) (4) — (5) Rest. (6) Close wound. (7) Return to bed. (8) In bed.

FIG. 3.—B.P. and pulse record of a patient undergoing transthoracic oesophago-gastrectomy. Note the steady blood-pressure after removal of the anæsthetic mask. (A) Induction. (B) Operation started. (C) Pleura opened. (D) Closing up. (E) Anæsthetic completed.

Good post-operative condition of the patients despite bigger and more extensive operations and working with poorer risks is definitely a feature of this type of anæsthesia. We are seeing less shock than ever before. I attribute this to early replacement therapy, replacing the lost blood almost drop for drop, and to light anæsthesia.

(2) *Vomiting*: The actual incidence of vomiting in my own series of abdominal cases has not been significantly altered, but the length of time and severity of this vomiting is very considerably modified. Patients may still return the first drink, especially, as is so often the case, when this is given too early post-operatively, but the prolonged nausea, malaise and vomiting, which used to be seen have practically disappeared from our post-operative wards.

(3) *Pulmonary complications*: With regard to pulmonary complications it is extremely difficult if not impossible to come to any clear and definite conclusion. I have a slide showing figures for pulmonary complications in a series of upper and

FIG. 1.—Spirometer recording of the respiration of a human subject twenty-three minutes after an intravenous injection of thiopentone 0.5 grammes and tubocurarine 15 mg. At ↑ prostigmine 2.5 mg. and atropine gr. 1/100 was administered intravenously. The increase in tidal volume was evident one minute later.

tates either intubation or the insertion of a pharyngeal airway. Some have reported a difficulty in intubation after thiopentone and tubocurarine; others have had to use more than 15 mg. for this purpose. I feel that if they gave the tubocurarine first they would appreciate the difference and have little difficulty. The objection to this procedure is that the needle may come out of the vein and the patient be left conscious and partially curarized. On the single occasion when this did happen and I felt that I might have difficulty in finding another vein I induced the patient quickly and smoothly with cyclopropane and on inquiry later she reported no unpleasant effects.

Intubation.—I now intubate rather more frequently. I am impressed with the danger of regurgitation of stomach and intestinal contents. The relaxation of the oesophagus and the light anaesthesia conduce to this and it is an accident which will obviously be more likely if there is an element of gastric or intestinal obstruction. Furthermore, in upper abdominal operations when an endotracheal tube has not been passed, manual inflation of the stomach has occasionally been coincidental with inflation of the lungs. This can be very trying for the surgeon and amusing to the onlookers but a little humiliating to the anaesthetist.

RESULTS

In conclusion what are the results likely to follow on the use of this substance? I have employed it in all ages varying from a 4-year old for lobectomy to an old gentleman of 87 who successfully underwent a nephrectomy and ureterectomy. The results have undoubtedly maintained their early promise. This is well exemplified by the fact that out of 145 consecutive lobectomies performed in the Liverpool Chest Surgical Centre there has not been one death. I want to emphasize, however, that the good results are due not to any inherently wonderful properties of d-tubocurarine chloride, but to the use of only light anaesthesia. I would like to examine some aspects of these results in a little detail.

(1) *Shock.*—It is a clinical impression among many that patients who have been anaesthetized with the help of d-tubocurarine chloride suffer less from shock than those who were subjected to deep or moderately deep anaesthesia. Ralph Knight, in America, goes so far as to say that deep anaesthesia is a more potent cause of peripheral circulatory failure than is surgical trauma. There is no doubt that these patients, provided that they have been handled carefully, are on the whole less shocked. Some have even postulated that tubocurarine has an anti-shock action in its own right. There is no pharmacological evidence for this and I do not think that it is a correct observation. The good condition post-operatively of the majority of these patients, I feel convinced, is accounted for by the fact that their vasomotor compensatory mechanisms are still active after a light anaesthesia. Of course, there is likely to be a temporary fall in blood-pressure if the anaesthesia is not adequate when there is stimulation of the deep reflexes either in the abdomen or in the thorax. However, the patient is still able to compensate for these disturbances and quickly recovers (fig. 2).

A further comforting feature is that with this type of anæsthesia the condition of the patient at the end of the operation does not deteriorate when the mask is removed as is so often the case with other methods of anæsthesia, particularly if cyclopropane is used. You see the patient in his worst condition at the end of the operation and not half an hour later in bed in the ward (figs. 2 and 3).

FIG. 2.—B.P. and pulse record of a patient undergoing transthoracic oesophago-gastrectomy. Note: (a) The fall in B.P. at (3). (b) The strong circulatory condition after the close of the operation. (1) Induction. (2) Chest opened. (3) Mesenteric traction. (Anæsthesia too light.) (4) — (5) Rest. (6) Close wound. (7) Return to bed. (8) In bed.

FIG. 3.—B.P. and pulse record of a patient undergoing transthoracic oesophago-gastrectomy. Note the steady blood-pressure after removal of the anæsthetic mask. (A) Induction. (B) Operation started. (C) Pleura opened. (D) Closing up. (E) Anæsthetic completed.

Good post-operative condition of the patients despite bigger and more extensive operations and working with poorer risks is definitely a feature of this type of anæsthesia. We are seeing less shock than ever before. I attribute this to early replacement therapy, replacing the lost blood almost drop for drop, and to light anæsthesia.

(2) *Vomiting*: The actual incidence of vomiting in my own series of abdominal cases has not been significantly altered, but the length of time and severity of this vomiting is very considerably modified. Patients may still return the first drink, especially, as is so often the case, when this is given too early post-operatively, but the prolonged nausea, malaise and vomiting which used to be seen have practically disappeared from our post-operative wards.

(3) *Pulmonary complications*: With regard to pulmonary complications it is extremely difficult if not impossible to come to any clear and definite conclusion. I have a slide showing figures for pulmonary complications in a series of upper and

lower abdominal cases which I personally followed up with great zeal and care, but I consider that figures of these conditions are so misleading and mean so little that I do not intend to show it unless it is specially requested.

The percentage of chest complications which I have recorded in this series is lower by far than my own percentage before the introduction of tubocurarine and considerably lower than most of the reliable reports. Figures are of little value because so much depends upon the criterion of what is and what is not a pre-operative chest complication, on the standard of pre-operative supervision of patients, the season, the climate, and the type of operation.

It is, however, useful to examine the anæsthetic factors accepted as predisposing to pulmonary complications and see how they are affected by the anæsthetic under consideration. Among the most vital of these factors are post-operative depression of the respiration and the cough reflex, prolonged periods of narcosis and immobility with possible respiratory obstruction, and the possible aspiration of vomitus. It is true to say that 90% of our patients who have had d-tubocurarine chloride have their pharyngeal and cough reflexes fully restored at the close of the operation and the majority are co-operative and talking by the time they leave the theatre. The main contributory factors are thereby removed and I do not believe that it is possible to achieve this with certainty in major abdominal and thoracic surgery with any other method of general anæsthesia. The part played by the anæsthetic in causing pulmonary complications must be very materially reduced. I would like to stress once again, however, that if there is one thing worse than returning the patient to bed with a respiration depressed by an anæsthetic agent, it is returning him to bed with his respiration depressed by d-tubocurarine chloride. This will undoubtedly predispose to the incidence of post-operative atelectasis.

(4) *Retention of urine:* There seems to be an increased incidence of post-operative retention of urine. There is, of course, quite a considerable incidence of post-operative retention after any anæsthesia even in those cases in which the operation could have contributed little towards its occurrence. Women are particularly prone to this complication, nervous patients and elderly men with incipient prostatism are also liable to develop it. A series of 127 abdominal cases were reviewed in an attempt to see whether there were any grounds for the complaints. This series did not include those gynaecological or genito-urinary procedures which might be predisposed to urological disturbance. Retention of urine occurred in 24% of these patients and just on 9% recovered after one or more injection of carbachol and 7.9% had to be catheterized. Records of 185 patients were consulted and compared with 137 cases who had not had d-tubocurarine chloride. 15% of those who had been given d-tubocurarine chloride had to have carbachol against only 9% of those who had not had tubocurarine. I think this is a difficulty and I have seen a case following lobectomy in a young male where the patient did not micturate naturally for seven days.

(5) *Difficulty in accommodation:* Lastly there is a tendency to difficulty in accommodation following operation. Four of my cases have complained that they were unable to read a newspaper for forty-eight hours. But I would ask with what other anæsthetic are they likely to try to read a paper so soon after major surgery?

What then is to be our verdict with regard to this substance? I believe that d-tubocurarine chloride is not the final answer, but the absolute certainty of results, its comparative non-toxicity and the ease of the anæsthesia in which it is used are factors which persuade me that, although we have not reached our ultimate goal we have indeed taken a most significant step. Griffith of Montreal observed the softening of electric convulsions by tubocurarine and in a flash of inspired genius saw its application to anæsthesia. He revolutionized our specialty by removing for all time the need for deep anæsthesia.

I would like to express my thanks to all those who have worked with me and contributed so much to the results we have achieved. But very specially must I mention those volunteers who have submitted themselves week after week to anaesthesia and other indignities in the good cause.

Dr. Frankis Evans said that he had been disappointed in the use of tubocurarine in bronchoscopy, and was interested to learn that Dr. Gray was not using the drug so frequently for this procedure. On the other hand he was most impressed with it in moderate dosage (15 mg.) together with pentothal and cyclopropane for upper abdominal operations.

He had had an interesting experience in regard to the occurrence of ileus after curare. At a certain hospital they had been using for abdominal surgery pentothal 0.5 gramme for induction followed by tubocurarine 10 mg. intravenously with cyclopropane as covering anaesthesia. At the end of the operation the patient was given 1 ampoule (0.5 mg.) of prostigmine intravenously with no buffering atropine. This hospital had had a series of patients with post-operative ileus when the post-operative course should have been uneventful. Whereas the same surgeon working at St. Bartholomew's Hospital had not had a single case of ileus using a somewhat similar technique. The only difference being that at Bart's they gave 15 mg. of tubocurarine as opposed to 10 mg. and that they never gave prostigmine as they did not find it necessary. When they stopped giving the dose of prostigmine the result was dramatic, for they never had another case of ileus. As a matter of interest he had taken one hundred consecutive cases in which tubocurarine had been used and had found only one case of post-operative ileus, and this was in a patient who had well-developed general peritonitis at operation. In 50 cases in which gas-oxygen-trilene had been used for the covering anaesthesia there were double the number of pulmonary complications that occurred when cyclopropane had been used in a further 50 cases. This was not a climatic effect because the series ran concurrently. All the cases were abdominal sections.

In perineo-abdominal excision of the rectum he felt that spinal anaesthesia still held its position as there was distinctly more bleeding from the perineal end of the operation when curare was used. Admittedly blood replacement was comparatively easy, but he felt that the patient's own blood was better than the bottled variety. Dr. Gray had brought out a most interesting point about curare in that it could cause retention of urine and difficulty of micturition post-operatively.

Dr. William W. Mushin said that there is one marked disadvantage attached to the use of tubocurarine, namely, the serious bleeding that occurs at the site of operation. This had been a constant observation of his and had been confirmed by numerous colleagues up and down the country, both anaesthetic and surgical. The bleeding was probably due to the action of curare on the synapses in the sympathetic ganglia, and hyperventilation had no effect in lessening it. He gave two illustrative cases. For a long time he made a practice of infiltrating the abdominal wall with adrenaline in saline to obviate the tedium of the surgeon in tying innumerable vessels before getting on with the operation. At a meeting of this Section when anaesthesia for abdomino-perineal resection of the rectum was discussed, it was held by many present that curare was contra-indicated for this operation on account of the profuse haemorrhage during the perineal part of the operation (*Proc. R. Soc. Med.*, 1947, 40, 263).

An impression current among many junior colleagues was that spinal anaesthesia was outmoded. He was of the opinion that spinal anaesthesia still had a place in anaesthetics, and should be considered whenever a bloodless field in operations of the abdomen and pelvis had special advantages. The removal of vascular tumours in the abdomen and pelvis, and the repair of difficult herniae were instances of such operations for which spinal anaesthesia would contend with curare when the choice of anaesthetic was considered.

Dr. J. Kennedy Harper said that having used d-tubocurarine in a wide variety of cases, he felt that it was the drug of choice when muscular relaxation was required. The statement that increased bleeding

lower abdominal cases which I personally followed up with great zeal and care, but I consider that figures of these conditions are so misleading and mean so little that I do not intend to show it unless it is specially requested.

The percentage of chest complications which I have recorded in this series is lower by far than my own percentage before the introduction of tubocurarine and considerably lower than most of the reliable reports. Figures are of little value because so much depends upon the criterion of what is and what is not a pre-operative chest complication, on the standard of pre-operative supervision of patients, the season, the climate, and the type of operation.

It is, however, useful to examine the anæsthetic factors accepted as predisposing to pulmonary complications and see how they are affected by the anæsthetic under consideration. Leadbetter's Osteotomy.—F. P. FITZGERALD, F.R.C.S.

The treatment of non-union in fractures of the neck of the femur presents an incompletely solved problem. In an attempt to deal with it, Leadbetter devised an interesting operation (*J. Bone Jt. Surg.*, 1944, 26, 713).

Leadbetter's osteotomy.—This consists of a vertical osteotomy of the femoral neck. The details of the operation are as follows:

An anterior approach is made and the junction of the upper third with the lower two-thirds of the neck is defined. The outer fragment of the bone is then divided inwards as far as the fracture line. The new lower fragment is displaced medially and with force so that it rotates the head of the femur and comes to lie underneath it.

When this operation was described four years ago, the originator had treated 8 cases, and he had assessed them one year after operation. 6 were united by bone; 2 results were favourable. The author has treated 6 cases, using a modification of this method. Owing to wartime difficulties, 3 cases have not been located, and one is too recent to be able to assess the result. The remaining two fractures have got bony union and useful hips.

Modified osteotomy.—(1) It has been found easier to carry out the operation through a lateral approach, using X-ray control. (2) Leadbetter points out that it is important to cut the bone at the high level, and this is said to preserve the blood supply. This makes it difficult to rotate the head of the femur, and hence the bone has been cut at a lower level—at the junction of the lower third with the upper two-

FIG. 1.—An osteotome defines the line of bone section.

FIG. 2.—The lower fragment has been pushed medially and the head rotated. The greater trochanter has been displaced laterally.

thirds. No ill-effects have been noticed in this very small series of cases. The following case, which was demonstrated, illustrated these points.

A man, aged 50, was operated upon for an ununited fracture of the left femoral neck, using this modified osteotomy. Fig. 1 shows the fracture reduced, and the line of the bone section. Fig. 2 illustrates the end-result. Seven months from the time of operation, he was back at his full work without experiencing any pain. He is a packer, which entails standing for seven hours a day. His hip-joint is stable, and the joint movements are excellent, with the exception of rotation, which is absent. He has got just over half an inch of shortening.

followed its use needed qualification. Increase of bleeding could occur if the respiratory exchange of the patient was inadequate, thus producing an increase of carbon dioxide tension in the blood with an inevitable rise of blood-pressure. It was the anaesthetist's duty to prevent this by adequate aided respiration.

He had not seen bronchospasm in adequately anaesthetized patients. He had, however, seen the relief of bronchospasm in a chronic asthmatic patient who was given a curarizing dose of d-tubocurarine together with pentothal nitrous oxide-oxygen anaesthesia for a partial gastrectomy.

Dr. H. W. Loftus Dale was in entire agreement with Dr. Cecil Gray on his conception of the altered physiology relating to anaesthesia in the curarized patient.

It was impossible to overstress the importance of assisting inspiration to ensure against sub-oxygenation.

Dr. Gray had rightly emphasized the increased risk of "spill-over" of stomach content during gastric surgery to avoid which he intubated his patients. Dr. Loftus Dale had employed continuous gastric suction in all cases as an alternative method and had found it to be very satisfactory, having had a series of 47 partial gastrectomies with no post-operative pulmonary complications.

There was more bleeding than associated with spinal anaesthesia in the production of which capillary dilatation, diminished support to the venous system and an intact vasomotor system played a part. There was, however, another factor, the synergistic depressant action of thiopentone, cyclopropane and morphia on the respiratory centre leading to an increased tension of CO_2 , the response to which was masked by parietic muscles of respiration in the curarized patient.

Since morphia had been omitted there had been marked diminution in capillary oozing and the early rise in systolic blood-pressure reported by several observers.

For premedication he now used 100 mg. of pethidine and 1/150 grain (0.43 mg.) of hyoscine which produced adequate drying up of secretions and reasonable sedation.

No patient should be sent back to the ward curarized; if powerful poisons were used they should be eliminated before the patient left the hands of the anaesthetist. Finally the temptation to give that last 5 or 10 mg. at the end of the operation to assist closure of the peritoneum should be avoided; it was this Parthian shot which had done much to bring discredit to this most valuable aid to anaesthesia.

Dr. Donald V. Bateman drew attention to Dr. Gray's reference to the use of a face-mask and uncuffed endotracheal tube and also his mention of kemithal. He asked if Dr. Gray had some special reason for not using a cuffed tube to eliminate the hazard of inspired gastric contents and if he had the impression that kemithal was preferable to thiopentone for maintenance of a curarized patient.

Dr. Cyril Scurr mentioned a case which illustrated the value of a test dose of d-tubocurarine chloride.

The patient, a woman aged 56 and weighing 10½ stones, gave the history that a year previously she had suffered from ptosis affecting the left eye when she was tired; after three months' treatment with prostigmine this symptom cleared up. At the time of operation she was free from myasthenic symptoms and had not had any treatment for nine months.

She was given a test dose of 4 mg. of d-tubocurarine chloride intravenously; two minutes afterwards she was completely paralysed, being unable to open her eyes or move her limbs, the tidal air was much reduced. She was then given 0.25 gramme of soluble thiopentone and light general anaesthesia was maintained with cyclopropane, the respiration being assisted.

Profound muscular relaxation persisted throughout the operation for total hysterectomy, which lasted fifty minutes. At the end of operation the tidal air was adequate.

At no time were this patient's myasthenic symptoms more than minimal and in a less observant subject they might well have gone unnoticed; in the absence of information provided by the test dose, a grave overdose of d-tubocurarine might have been given.

Dr. T. C. Gray, in reply, thanked Dr. Frankis Evans for his interesting and helpful remarks. He had always considered it important to prevent the undesirable parasympathomimetic effects of prostigmine used as an antidote to tubocurarine by administering with it an adequate dose of atropine. It seemed quite possible that the administration of unbuffered prostigmine might result in depression of the intestinal movements after the initial stimulation.

In his experience this technique had proved entirely satisfactory for œsophagoscopy but less so for bronchoscopy because of the occasional occurrence of respiratory spasm. In a busy centre, however, when there were many bronchoscopies to perform in a limited time, the method was considerably less time-consuming and more pleasant for the patient than local analgesia.

He was sorry to have misled Dr. Bateman for he frequently employed a cuffed tube for upper abdominal and chest surgery, in fact whenever there was a danger of regurgitation. He agreed with Dr. Bateman that this was the safest and most satisfactory method.

At no time were this patient's myasthenic symptoms more than minimal and in a less observant subject they might well have gone unnoticed; in the absence of information provided by the test dose, a grave overdose of d-tubocurarine might have been given.

Dr. T. C. Gray, in reply, thanked Dr. Frankis Evans for his interesting and helpful remarks. He had always considered it important to prevent the undesirable parasympathomimetic effects of prostigmine used as an antidote to tubocurarine by administering with it an adequate dose of atropine. It seemed quite possible that the administration of unbuffered prostigmine might result in depression of the intestinal movements after the initial stimulation.

In his experience this technique had proved entirely satisfactory for oesophagoscopy but less so for bronchoscopy because of the occasional occurrence of respiratory spasm. In a busy centre, however, when there were many bronchoscopies to perform in a limited time, the method was considerably less time-consuming and more pleasant for the patient than local analgesia.

He was sorry to have misled Dr. Bateman for he frequently employed a cuffed tube for upper abdominal and chest surgery, in fact whenever there was a danger of regurgitation. He agreed with Dr. Bateman that this was the safest and most satisfactory method.

applied by a slightly modified Fiske's method, which allowed a total range of assisted active movement of about 90 degrees at hip and knee joints while the traction continued to act. A weight of 5 lb. was employed for the first three days, and was then gradually increased to 20 lb. by the twelfth day and retained there until three months after the operation. Faradism and static exercises to the quadriceps were started immediately, and graduated assisted active movements of the new joint (with the traction still acting) from the tenth day.

Three months after operation the traction was removed; assisted active exercises continued, but a straight back-splint had to be provided for night use on account of persistent slight limitation of active extension due to the quadriceps slack. Two weeks later the patient started walking with a hinged knee-cage, and at that time her range of movement was about 85 degrees as shown in the X-ray (fig. 1A and B).

She now has full extension and 90 degrees of flexion movement, with so little slack in the quadriceps that the back-splint has been given up. The knee is painless, cool, and free of swelling, the movement is smooth, and there remains only quite moderate lateral instability though it is felt to be safest to continue the use of the hinged knee-cage. Function is greatly improved.

This case supports Mr. Stamm's contention that a perfectly satisfactory arthroplasty can be produced without the use of metal, or of soft-tissue flaps interposed between the bone ends, provided that correct after-treatment is given, the essential points in this being: (a) Continuous traction for about three months in the case of major joints, increasing gradually from an early minimum to the maximum in about two weeks, and (b) daily assisted active movements starting in about ten days, and being performed with the traction acting all the time. In the knee-joint, I believe that removal of the posterior projecting portions of the femoral condyles is also essential.

II.—Caries of Spine: for Diagnosis.

R. W., male, aged 25.

29.12.47: Developed a pyrexial illness with dorsilumbar pain.

1.1.48: General practitioner found a localized area of tender spasm in sacrospinalis. Local injection here of procaine produced temporary relief of pain.

FIG. 2.—Case II.

7.1.48: A subcutaneous swelling appeared, in and to both sides of the mid-line, overlying and obscuring the upper lumbar spinous processes. Swinging pyrexia continued. Admitted to local hospital. Penicillin 250,000 units intramuscularly b.i.d. prescribed.

9.1.48: X-ray (fig. 2): An area of erosion in the upper and anterior part of the body of the second lumbar vertebra, with moderate marginal sclerosis and some lipping at the anterior angle. Very little disc narrowing. Blood-count: moderate polymorph leucocytosis. Aspiration of swelling: 2 oz. of thick yellow pus. Penicillin 250,000 units injected into the abscess. Cultures produced a pure growth of *Staphylococcus aureus*, penicillin-sensitive, coagulase-positive.

13.1.48: Temperature normal. Abscess had refilled. Re-aspiration of abscess: 2 oz. of thinner pus containing the same organism on culture. Penicillin 250,000 units injected into the abscess.

17.1.48: Remained apyrexial. Penicillin stopped.

16.2.48: Transferred to County Hospital, Pembury.

Symptom-free at rest. Moderate stiffness of back. Slight upper lumbar kyphosis. No sign of abscess. Lasègue's sign 80 degrees in each leg. Doubtful left extensor plantar response and doubtful bilateral ankle

[March 2, 1948]

Four Cases shown by J. H. MAYER, F.R.C.S.

I.—Arthroplasty of Knee.

Mrs. E. W., aged 55.

History.—Rheumatoid arthritis affecting hands and wrists for many years, knees since 1942 and shoulders since 1945.

The left knee had been arthrodesed in 1945, at which time the right knee functioned quite well, but since then the right knee has become worse fairly rapidly. When seen in June 1947 the joint was slightly warm, with moderate synovial thickening and slight tenderness; extension was limited by 10 degrees, and a range of less than 30 degrees of flexion was allowed from this point accompanied by considerable pain. There was great difficulty in walking, and greater in climbing stairs and in getting into and out of a chair, due to the bilateral stiff knees. E.S.R. was 26 mm. in one hour. X-rays showed gross narrowing of the joint space with marginal new bone formation. The left knee was ankylosed by bone in good position.

Operation.—Arthroplasty of the right knee was performed on 30.7.47. It was decided to try this operation despite the appearances of subacute activity in this joint because its muscles were better than those on the left, and because arthroplasty could be performed later on the left if it failed on the right, whereas if it succeeded on the right a second operation would be avoided.

Through an anterior horse-shoe incision the patella was excised and a complete synovectomy performed. All remains of articular cartilage were removed from femur and tibia, and the posterior projections of the femoral condyles were removed completely, thus leaving a convex surface of far smaller diameter than before, round

FIG. 1A—Case I.

FIG. 1B—Case I.

which the slightly hollowed tibial condyles should glide. A median antero-posterior crest was left on the tibia to articulate in the intercondylar notch of the femur in an attempt to increase the stability of the new joint. The internal and external lateral ligaments of the joint were left intact so far as possible. The incision was closed in two layers, leaving the bare cancellous surfaces of femur and tibia apposed without the intervention of tissue-flaps or other structures. An error was made in not shortening the patellar tendon, and this led to some residual slack in the quadriceps for a considerable time.

After-treatment.—From a Steinmann pin through the tibial tuberosity, traction was

but fortunately far enough back to have missed the tibial articular cartilage; it should have been inserted $\frac{1}{2}$ in. higher and have been directed rather more forwards.

After-treatment.—Apart from soft dressings, the joint was not immobilized. Immediate active exercises were prescribed, and after removal of the sutures on the twelfth day all joints regained their ranges of movement rapidly. Normally I should have applied a walking plaster boot four to six weeks after operation until removal of the screws, but in this instance the patient, a medical colleague, was allowed to go home on crutches without plaster as I could rely on his obeying instructions not to put the foot to the ground, and because he wished to leave hospital early for other reasons.

On 13.8.47, ten weeks after the first operation, the screws were removed. Active exercises were maintained, and walking was resumed two weeks after this second operation.

The patient, who is a keen sportsman, made a rapid recovery, and resumed work in general practice within a few weeks. The only abnormal physical sign now, apart from the operation scars, is a trace of limitation of plantar-flexion of the foot. He plays vigorous squash, tennis, &c., without symptoms.

I believe that all major ankle fractures with displacement of the posterior malleolus or diastasis of the inferior tibio-fibular joint should be treated by open reduction and screwing. It is practically impossible to secure perfect reduction by any other means, and screwing also allows early post-operative mobilization to ensure a good functional result. The screws should be removed after about ten weeks in view of their proximity to the joint.

IV.—Infective Arthritis of Hip-joint : Plaster Bed with Traction.

J. G., male, aged 26.

History.—Aching pain in right hip, followed later by a limp, starting in July 1947. No relevant previous history or family history.

On admission (29.11.47).—Apyrexial. Right buttock wasted. Gross limitation of all movements of right hip-joint, with pain on forcing in any direction but painless at rest. No sign of effusion or abscess.

X-ray (fig. 5): Right hip shows narrowing of joint space, with mottling of head and neck of femur and apparent sequestration of a fairly large segment of the upper part of the femoral head.

Blood-count normal. E.S.R. 4 mm. in one hour. Mantoux positive at 1 : 400, negative at all greater dilutions.

Diagnosis.—Low-grade non-specific infective arthritis of the hip-joint.

Treatment.—The patient has been immobilized in a plaster bed with traction on the affected limb. This type of plaster bed has been in use at the County Hospital, Pembury, for several years, and was developed there during the late war by Messrs. W. W. Gilford and R. H. Bolton.

The plaster bed is mounted on a metal stretcher (an ordinary E.M.S. stretcher with the wire mattress removed) by two transverse metal or wooden rods fixed to the undersurface of the bed by plaster and resting on the side-bars of the stretcher (fig. 6). One additional similar support under the head-piece of the bed rests on the upper transverse bar of the stretcher. These mountings merely rest on the stretcher, so that the whole bed can be lifted from the stretcher for turning.

This method of mounting is economical in scarce materials such as timber, and it greatly facilitates nursing. For ordinary nursing the stretcher rested on a normal bed-frame leaves space for bed-pans to be placed under the patient without lifting. Stretcher, bed and patient can be lifted easily by two to four people on to a stretcher-trolley, X-ray table, operating table, &c. Alternatively the patient can be nursed

clonus, but these were not confirmed at re-examination. X-ray appearances unchanged. Blood-count normal. Mantoux weakly positive at 1 : 10,000. Recent scar of a large boil in right scapular region, which had ruptured and discharged slowly three months before onset of present illness. No other relevant previous or family history.

Treated by very gentle mobilization, the patient remains symptom-free and lumbar mobility has increased. Lumbar kyphosis remains unchanged.

This case appears to have a double pathology: (a) Old vertebral epiphysitis previously undiagnosed, and (b) subcutaneous abscess of the back arising by hæmatogenous or lymphatic spread from the recent boil over right scapula.

The sclerosis and new-bone formation seen in the X-rays ten days after the onset of symptoms are not consistent with a diagnosis of staphylococcal osteomyelitis of the vertebra.

POSTSCRIPT.—When last seen in June, 1948 he remained symptom-free. Physical signs and radiological appearances remained unchanged apart from rather freer mobility of the spine, and there were no abnormal signs in the central nervous system.—J. H. M.

III.—Pott's Fracture treated by Internal Fixation.

K. J., male, aged 24.

The patient sustained the fracture shown in fig. 3 on 3.6.47, consisting of fractured medial and posterior malleoli of the tibia, fractured lower shaft of the fibula, posterior subluxation of the ankle-joint and slight diastasis of the inferior tibio-fibular joint. Two attempts at closed reduction elsewhere had failed to achieve good position.

Operation.—On 4.6.47 I performed open reduction and screwed the fragments back into place. The patient was placed in the prone position with his foot over the end of the table. The posterior malleolus was dealt with first, through a postero-medial incision with inward retraction of the flexor structures and stripping of the

FIG. 3A.—Case III.

FIG. 3B.—Case III.

FIG. 4A.—Case III.

FIG. 4B.—Case III.

lowest fibres of flexor hallucis longus from the fibula. This fragment is always very difficult to reduce and to retain in position, and the following method was used: A Steinmann pin was inserted into the fragment from behind and used as a lever to pull it down into position; once this had been achieved the pin was quickly driven into the tibial shaft to maintain the reduction while drilling and screwing were performed, and the pin was then removed. A long screw was then inserted across the inferior tibio-fibular joint, and finally the medial malleolus was screwed into position. The post-operative X-ray (fig. 4) shows that the second screw lies dangerously low,

[May 11, 1948]

The Technique and Application of Electronarcosis

By A. SPENCER PATERSON, M.D. and W. LIDDELL MILLIGAN, M.D.

Dr. A. Spencer Paterson:

About two years ago the situation with regard to electroshock therapy was not altogether satisfactory. In different hospitals, there were being passed through patients' brains electric currents which differed from each other in every particular and there was little experimental work to show which were safe and which were dangerous. The ill-effects produced by the most unsatisfactory types of current were considered by some psychiatrists to be sufficient grounds for employing the treatment as little as possible, if indeed they did not condemn it altogether.

Again, there were many psychiatric conditions which failed to improve when the patient was given only two or three convulsions per week. It had, however, already been demonstrated, especially at Portsmouth, that the more intense administration of electroshock could effect a recovery in otherwise intractable cases. Although the immediate and later side-effects of these heroic methods were not serious, nevertheless careful nursing was often necessary.

One was thus anxious to discover some method which would combine as good or better a therapeutic result with little discomfort or danger to the patient.

We therefore were interested to find that van Harreveld (1934), working first in Holland and later at Los Angeles in California, had been studying the effect of passing a relatively low current through the brains of animals for a period of several minutes, a procedure which he called "electronarcosis". With the distinguished pathologist, Globus (1943), he showed that in dogs currents three or four times as strong as those used initially in electronarcosis in man and lasting many times as long (even up to seventy-five minutes) produced no histological changes that could be discovered post mortem. Dr. E. B. Tietz (1947), working in a neighbouring mental hospital, and other psychiatrists reported favourable results with this method in the treatment of schizophrenia.

COMPARISON OF ELECTROSHOCK, ELECTRONARCOSIS AND CONTROLLED ELECTROSHOCK

In electroshock a relatively high current is passed through the patient's brain for a fraction of a second. The current varies with the type of machine used. Some of these allow a current of 1,200 to 1,500 ma. to pass during a fraction of a second and it is even stated of one machine on the market that "it is impossible for a current of more than 2,000 ma. to pass through the patient's brain" (fig. 1). In our electroshock machine (Paterson, 1946), however, an alternating sinusoidal current of about 250 ma. is passed for about half a second.

The typical course of events in an electrically induced convulsion is as follows: There is a sudden momentary contraction usually of the extensor muscles of the spine, often with flexion at the hips and elbows. Then there is a latent period of about seven or more seconds, when the muscles relax either partially or completely. This is followed by extreme opisthotonus and a tonic phase for about ten seconds, after which violent clonic movements occur until the forty-fifth second or later when respiration becomes re-established. The heart may be inhibited for two or three seconds at the onset.

Electronarcosis on the other hand begins with a modified convulsion. The chief points of

permanently on a trolley instead of a bed, and is in this way correspondingly more mobile when being nursed out of doors or at home, and when attending occupational therapy and other departments in the hospital.

Traction on the affected limb is applied through extension strapping applied to calf or thigh and calf. The leg-gutter of the plaster bed is prolonged distally on the affected side and has no foot support. The traction cord passes in the line of the limb from a spreader below the heel to a horizontally-mounted pulley fixed on wood at the distal end of the leg-gutter; traction at any desired tension is maintained by a spiral spring linking the cord beyond the pulley to the plaster-bed mounting (fig. 7).

FIG. 5.—Case IV.

FIG. 6.—Case IV.

FIG. 7.—Case IV.

Counter-traction is effected by friction between patient and plaster, and by the sole of the opposite foot pressing against its foot-rest. Drop-foot on the affected side is prevented by a removable arch of Kramer wire supporting a mobile foot-rest and preventing bedclothes pressure. This method allows traction with complete immobilization in optimum position for the affected joint (hip or knee), and is equally useful in adults or children.

I am extremely grateful to Messrs. Gilford and Bolton for permission to demonstrate and publish this case before the appearance of their own paper on this type of plaster bed. The credit for its invention belongs entirely to them.

[May 11, 1948]

The Technique and Application of Electronarcosis

By A. SPENCER PATERSON, M.D. and W. LIDDELL MILLIGAN, M.D.

Dr. A. Spencer Paterson:

About two years ago the situation with regard to electroshock therapy was not altogether satisfactory. In different hospitals, there were being passed through patients' brains electric currents which differed from each other in every particular and there was little experimental work to show which were safe and which were dangerous. The ill-effects produced by the most unsatisfactory types of current were considered by some psychiatrists to be sufficient grounds for employing the treatment as little as possible, if indeed they did not condemn it altogether.

Again, there were many psychiatric conditions which failed to improve when the patient was given only two or three convulsions per week. It had, however, already been demonstrated, especially at Portsmouth, that the more intense administration of electroshock could effect a recovery in otherwise intractable cases. Although the immediate and later side-effects of these heroic methods were not serious, nevertheless careful nursing was often necessary.

One was thus anxious to discover some method which would combine as good or better a therapeutic result with little discomfort or danger to the patient.

We therefore were interested to find that van Harreveld (1934), working first in Holland and later at Los Angeles in California, had been studying the effect of passing a relatively low current through the brains of animals for a period of several minutes, a procedure which he called "electronarcosis". With the distinguished pathologist, Globus (1943), he showed that in dogs currents three or four times as strong as those used initially in electronarcosis in man and lasting many times as long (even up to seventy-five minutes) produced no histological changes that could be discovered post mortem. Dr. E. B. Tietz (1947), working in a neighbouring mental hospital, and other psychiatrists reported favourable results with this method in the treatment of schizophrenia.

COMPARISON OF ELECTROSHOCK, ELECTRONARCOSIS AND CONTROLLED ELECTROSHOCK

In electroshock a relatively high current is passed through the patient's brain for a fraction of a second. The current varies with the type of machine used. Some of these allow a current of 1,200 to 1,500 ma. to pass during a fraction of a second and it is even stated of one machine on the market that "it is impossible for a current of more than 2,000 ma. to pass through the patient's brain" (fig. 1). In our electroshock machine (Paterson, 1946), however, an alternating sinusoidal current of about 250 ma. is passed for about half a second.

The typical course of events in an electrically induced convulsion is as follows: There is a sudden momentary contraction usually of the extensor muscles of the spine, often with flexion at the hips and elbows. Then there is a latent period of about seven or more seconds, when the muscles relax either partially or completely. This is followed by extreme opisthotonus and a tonic phase for about ten seconds, after which violent clonic movements occur until the forty-fifth second or later when respiration becomes re-established. The heart may be inhibited for two or three seconds at the onset.

Electronarcosis on the other hand begins with a modified convulsion. The chief points of

difference are as follows: The electroanæsthesia machine (Paterson and Milligan, 1947) has an electromagnetic device which automatically keeps the current constant and it can be regulated by means of a rotary stud. Instead of giving a sudden violent stimulus to the patient's brain from a relatively high current, one gradually raises the current from zero to 200 ma. in the course of about two seconds. This current passes for thirty seconds and is slowly reduced over a period of fifteen seconds to about 70 ma. or lower until the patient starts to breathe. The initial cardiac inhibition is generally of no greater duration than in electroshock. The patient starts to breathe again at the same time as he would have done

FIG. 1.

FIG. 2.

FIG. 3.

Comparison of electroshock, electronarcosis and controlled electroshock. Charts showing muscular reaction to current variations in relation to time (after Tietz, Olsen and Rosanoff).

after electroshock. The gradual increase or decrease of the current reduces side-effects such as headache and temporary disturbances of memory. The clonic movements begin at thirty seconds when the current is reduced. The patient's clonic movements are less violent because both agonists and antagonists are still in a state of increased tonus. The avoidance of violent clonic movements prevents fractures or injuries. The current is then slowly raised until there is flexion at the elbows and a slight degree of respiratory stridor. Further slight increases of current are continued until the end of treatment at about seven minutes (fig. 2).

The term "controlled electroshock" is given to the procedure of raising the current to 200 ma. in two seconds for seven to twenty seconds and gradually reducing it until respiration is again re-established (fig. 3).

The treatment is given three or four times a week for twelve times. After a rest of some days another course of six or twelve treatments may be given. Dr. Glyn Davies and I have given over 750 treatments.

TECHNIQUE OF ELECTRONARCOSIS

First of all in the history we ask particularly regarding diseases of the heart, lungs and vertebral column, just as we do before giving electroshock. If a patient is sufficiently robust to tolerate electroshock, it is likely that he will be sufficiently strong for electronarcosis, especially if a quick-acting barbiturate and curare are given. Where curare is given, one must include in the oxygen apparatus a bag of india-rubber which can be deflated into the patient's nose and mouth in a rhythmic manner, if respiration should ever become insufficient. One should have at hand cardiac stimulants and adrenaline, and, where curare is used, an ampoule of prostigmine, which is its antidote.

We always take an electrocardiogram before treatment.

It is better to give a quick-acting barbiturate beforehand, either 3 grains of seconal by mouth, or better 0.3 - 0.5 gramme of pentothal or sodium amytal intravenously. Sodium amytal has the advantage of keeping the blood-pressure lower and also if, as occasionally happens, the patient suffers unduly from headache or malaise, it allows him to sleep until those symptoms have disappeared so that he wakes up in a comfortable state. Its disadvantage is that it takes more time to take effect compared with pentothal. Barbiturates make it less likely that there will be any unpleasant reflex phenomena like apnoea or temporarily feeble action of the heart. One-sixtieth of a grain of atropine is also given, preferably i.v. Atropine inhibits excessive salivation, and also prevents cardiac and respiratory inhibition from overaction of the vagus nerve. We generally give curare in doses of about 2 mg. per stone of body-weight. With new patients we start with a small dose before pentothal to make sure that there is no idiosyncrasy. Ordinarily it is given after pentothal through the same needle from a different syringe. Treatment is started three minutes afterwards. Curare prevents compression of vertebrae, eases the strain on the heart and enables one to feel the pulse more readily. It does not appear to keep the blood-pressure lower.

A medium-sized pessary makes the best gag. An airway is sometimes necessary.

COMPLICATIONS ENCOUNTERED IN TREATMENT

Saliva or mucus may collect in the larynx or trachea unless prevented, as stated, by atropine. Sometimes one has to wipe ropy mucus out of the throat with a swab several times. Burns cannot occur if the electrodes are flat and make contact with the forehead by means of lint soaked in a saturated solution of salt.

Sometimes the patient complains later that he has become conscious during the treatment. He may say that he could not speak but only make movements of the arms to indicate that we must turn off the current. The experience may be very frightening because the patient may feel suffocated and also see bright flashes of light or hear loud noises. This complication is more likely to happen to older patients who require a higher current. Except in small patients or young patients with brisk knee reflexes, we seldom give less than 200 ma. for the first half-minute. If the patient begins to have clonic movements before the end of the first half-minute (that is, when the strong current is still passing), then he is more likely to become partially conscious later unless care is taken. One must regulate the dose according to the physical signs, since the necessary dose varies from patient to patient. Strong flexion at the elbows and a slight stridor show that the correct level is reached. Sometimes it is necessary before the end of treatment to put the current up to as high as even 170 ma. especially if the patient has had barbiturate.

It is necessary to examine the blood-pressure several times during treatment, especially in older patients, because a pressure which has been normal at first may rise in older subjects to as high as 260/160. If the diastolic pressure rises above 130 mm., it is better to switch off the current. The rate and volume of the pulse should also be observed. A poor volume often becomes satisfactory by lowering the current merely 5 ma. We believe that cardiac inhibition is more apt to occur in young subjects, especially those with brisk reflexes. In these cases intravenous pentothal and atropine are necessary and the current should be temporarily lowered and in severe cases cut, if there are signs of respiratory or cardiac embarrassment. We have not had any anxiety in this type of case. If in the later minutes the pulse were suddenly to become very rapid and feeble, or if there were irregularity of the pulse other than occasional extrasystoles, or if there were any signs of respiratory distress, then one should switch off at once.

difference are as follows: The electroanæsthesia machine (Paterson and Milligan, 1947) has an electromagnetic device which automatically keeps the current constant and it can be regulated by means of a rotary stud. Instead of giving a sudden violent stimulus to the patient's brain from a relatively high current, one gradually raises the current from zero to 200 ma. in the course of about two seconds. This current passes for thirty seconds and is slowly reduced over a period of fifteen seconds to about 70 ma. or lower until the patient starts to breathe. The initial cardiac inhibition is generally of no greater duration than in electroshock. The patient starts to breathe again at the same time as he would have done

ELECTRO-SHOCK Less than one second.

FIG. 1.

FIG. 2.

FIG. 3.

Comparison of electroshock, electronarcosis and controlled electroshock. Charts showing muscular reaction to current variations in relation to time (after Tietz, Olsen and Rosanoff).

after electroshock. The gradual increase or decrease of the current reduces side-effects such as headache and temporary disturbances of memory. The clonic movements begin at thirty seconds when the current is reduced. The patient's clonic movements are less violent because both agonists and antagonists are still in a state of increased tonus. The avoidance of violent clonic movements prevents fractures or injuries. The current is then slowly raised until there is flexion at the elbows and a slight degree of respiratory stridor. Further slight increases of current are continued until the end of treatment at about seven minutes (fig. 2).

TABLE II.—ELECTROSHOCK AND ELECTRONARCOSIS COMPARED IN SCHIZOPHRENIA

Of 14 cases which failed with electroshock

6 recovered with electronarcosis. 3 made greater improvement. 5 no better.

shock had helped the electronarcosis to take effect, as there is, no doubt, a synergic action between the two.

It is perhaps worthy of comment that Medlicott (1947) has found that there is a greater degree of lymphocytosis after electronarcosis than after electroshock, and also that the blood-sugar curve is both higher and of longer duration.

We may also remark here that electronarcosis is in one respect safer than insulin coma therapy, for if in electronarcosis the patient appears to have undue cardiac or respiratory distress, then we can easily switch off the current, but if the patient's condition under insulin coma gives rise to anxiety, then the administration of intravenous glucose may take time and cause some difficulty.

STATES OF SEVERE DEPRESSION

Up till three months ago we had treated 16 cases of severe depression with electronarcosis, of whom 13 had already failed with electroshock. Of these 16 cases, 12 made a good recovery. The remaining 4 did not show any lasting improvement (Table III).

TABLE III.—SEVERE MELANCHOLIA TREATED WITH ELECTRONARCOSIS

Total	Recovered	Failed
16	12	4

The following are cases in this group:

Mrs. B., aged 41, had been depressed for one year. She had had marital difficulties, as her husband was 23 years older than she. She had tried to solve her problem by becoming an energetic business woman. The onset of her illness coincided with business worries. She had been actively suicidal prior to admission. After 8 treatments with electroshock she was still actively suicidal and desperate, but after one treatment with electronarcosis she stated that this was something quite different, and she later attributed her complete recovery to the course of electronarcosis which she received.

Miss C., aged 57, had for one year gradually developed a condition of severe agitated melancholia. She said that the Devil had made her conscious of sexual desires that were driving her insane. A full course of electroshock in another hospital had caused only temporary improvement, but after 9 electronarcosis treatments she made a perfect recovery.

In cases of chronic depression where electroshock has failed, it has been usual for the psychiatrist to consider having a leucotomy performed. Since, however, it has been found that electronarcosis frequently effects a recovery after electroshock has failed, we may expect that still more patients will not be submitted to this operation.

ELECTRONARCOSIS IN THE PSYCHONEUROSES

We have treated 9 cases of severe psychoneurosis with electronarcosis. Only one of these failed to improve. Two of the most striking recoveries were in states of panic.

Mr. D., aged 42, had been a widower for nine years. He had been head of a large factory during the war and had worked often for sixteen hours a day. He had developed a duodenal ulcer seven years before and had had a severe hæmatemesis. He returned to work too soon, and later became subject to severe claustrophobia.

For two years before being seen he had suffered from attacks of panic. In the street he would cling to the railings, stagger into a telephone box and call for a taxi to take him home. His firm had been very anxious to have him back but he had not worked during these two years. Psychotherapy alone had failed to make any difference. He had a second hæmorrhage during this period.

He was given 8 treatments with electronarcosis. His physical and mental state underwent a remarkable change for the better. He could go anywhere without fear and within two months was back at work looking and feeling well, and writing a scientific monograph. He had put on 7 lb. in weight.

Mrs. E. was a young woman with two children. During the war she had suffered agonies of anxiety over her husband who was in great danger in the front line. After the birth of her second child she had developed ideas that there might be a skeleton or a ghost that would open the door and terrify her. She had to leave her house. Her attacks of panic were distressing to witness and were quite impervious to psychotherapy. She made a complete recovery after 12 treatments with electronarcosis, without any ill effects.

Two other psychoneurotics were chronic hysterics with depressive affect who improved immediately so that psychotherapy had more effect. Two were very severe obsessives with depressive affect and both were very greatly improved. One was a man who had had about 50 examinations of his urinary passages in ten years and who had been impotent for eighteen months. He stated that he would commit suicide if he were not helped. He made a

If the patient is not given a barbiturate, he will probably wake up very quickly after the treatment. I have seen three patients in one day having breakfast and smiling happily within a quarter of an hour after treatment.

Dr. Tietz sends some ambulant patients home half an hour later, a procedure, however, that we would not recommend, but which is worth mentioning if only to counteract the impression that electronarcosis is unduly dangerous.

Occasionally the following symptoms occur temporarily after treatment—headache, lassitude, a sensation of constriction round the chest, amnesia, or difficulty of focusing. There may be some euphoria or confusion. Very often, however, the patient experiences no discomfort whatever.

Although, especially in schizophrenics who have recovered, there may be amnesia for the symptoms of the past illness, there is little or no amnesia for current events after the treatment is completed.

Although the technique may be thought to be rather complicated from what I have said, yet it is really quite easy to learn and one soon acquires confidence.

RESULTS OF TREATMENT

Schizophrenia

Up to three months ago we had 35 schizophrenics whom we had treated with electronarcosis. Some of these, however, had their treatment, or part of it, at Portsmouth and are included among Dr. Milligan's cases. Although his figures for schizophrenia will be more comprehensive, yet the accompanying tables are worth quoting because they bring out different points in the results.

It will be seen that these cases fall into three groups (Table I). First there are 9 cases who had previously had a schizophrenic episode from which they recovered. Of these 9,

TABLE I.—ELECTRONARCOSIS IN SCHIZOPHRENIA

	Total	Recovered and working	Improved and working	No, or slight, improvement
GROUP I				
Previous attack with recovery	9	7 at work	1 at work	1
GROUP II				
Ill less than 1 year . .	10	7 at work	2 at work	1
GROUP III				
Ill more than 1 year.				
Av. 3.2 years	16	4 at work	3 at work	9

8 were back at work in three months, while only one was not improved. The second group consisted of 10 patients who had been ill for less than twelve months since first seen and 9 of these returned to work. Two of these, however, still showed mild symptoms. The remaining case, though not recovered, had much improved. The third group consisted of 16 patients who had been ill for more than a year when first seen, the average duration of the illness being 3.2 years. Of these 16, 4 made a complete recovery. 3 more were able to return to work but still retained mild symptoms. The other 9 were greatly improved, in some cases from being violent and disturbed to being quiet and well behaved and regaining some insight.

Both Tietz (1947) in California and Medicott (1947) in New Zealand have reported that older paranoid types do better than the younger hebephrenic groups, and these older groups I believe do better with electronarcosis than with insulin. The following is a case of a paranoid involutional patient with catatonic symptoms who made a good recovery.

Mrs. A., aged 51, had been hypochondriacal for ten years, and then depressed for six months. She was actively suicidal and razor blades were found under her pillow. She heard voices saying that she would be arrested and executed. She had periods of cataleptic stupor alternating with wild catatonic excitement. She had already had a few electroshocks elsewhere with no success. After 18 treatments with electronarcosis, however, she returned home and has been carrying out all her household duties since then, in good health.

COMPARISON OF RESULTS OF ELECTROSHOCK AND ELECTRONARCOSIS

The effect of electronarcosis on cases of schizophrenia is comparable to that of an intensive course of electroshock. I believe, however, that electronarcosis produces better results while at the same time subjecting the patient to less physical strain. We treated 14 cases of schizophrenia after electroshock had failed and in 9 of these the response was more favourable with electronarcosis. In 5 cases there was no better response with electronarcosis than with electroshock (Table II). In 6 out of 14 cases where electroshock had failed, electronarcosis effected a recovery. In these cases, however, it is likely that the previous electro-

We are still unable to explain why patients look and feel so much better after a few treatments, or why chronic skin diseases should clear up. Cerletti, for instance, told me that he effected a recovery in 14 out of 16 cases of psoriasis by means of electroshock. His theory that the brain develops a specific substance when threatened with approaching death is still unproved. It may be, however, that these remarkable changes are effected in part by endocrine means, particularly through the pituitary.

CONCLUSION

With regard to electronarcosis and kindred treatments, I believe that we are only at the beginning. At the present time the following investigations are being carried out at the West London Hospital or elsewhere: Psychological tests before and after treatment; blood-pressure investigations, including that of the retinal artery, intra-arterial blood-pressure, blood and cerebrospinal fluid changes, and changes in the electro-encephalogram.

Dr. W. Liddell Milligan: In dealing with the clinical applications of electronarcosis I intend to devote most of my remarks to its use in the treatment of schizophrenia. The case material has been provided by 120 patients treated at St. James Hospital, Portsmouth. Of that number there are 70 cases of schizophrenia, 15 of acute schizophreniform reaction or atypical schizophrenia, 10 cases of paraphrenia, 10 of melancholia and 15 of psychoneurosis, mostly anxiety states.

With regard to the schizophrenic groups the question of diagnosis immediately arises, but I have endeavoured to exclude the atypical cases which, although they exhibit evidence of schizophrenic reaction, were probably more allied to either manic-depressive or confusional states.

METHOD

As regards the method, I have nothing to add to the description already given except to confirm that if the technique is carried out properly the patient does not receive any unpleasant sensations. We have now given approximately 2,500 treatments and, except in the paraphrenic group, no patient has refused to continue treatment and there has certainly been no apprehension, indeed many impartial observers have commented upon the cheerful and composed manner of patients awaiting, let us say, their twentieth treatment. Especially in cases of schizophrenia, it is essential to give at least thirty treatments, before assuming that the therapy is not producing the desired response. In the present series, the average number of treatments per patient has been twenty.

RESULTS

When we come to results, I am giving the following without comment as it is of course much too early to draw any definite conclusions: of the 70 schizophrenics treated, complete remissions were produced in 44%, social recoveries in 17%, social defects in 8%, while 16% were improved in hospital and in 14% no improvement was obtained (Table I). This group includes 10 children under the age of 16 who had been sent to us from various parts of the country. I think that it would be better to omit these children when considering

remarkable improvement with only six treatments, becoming bright and happy and losing his obsessions. Lately, however, after six months there has been a slight return of symptoms. A woman who had had torticollis for seven years made a striking improvement for six months but she too has relapsed slightly. Another suffered from such severe torticollis that she was in constant pain. After electronarcosis the pain ceased and there was a progressive disappearance of the symptoms during the subsequent three months, so that now she is normal.

Tietz reports 9 recoveries out of 13 cases of chronic severe psychoneurotics.

RATIONALE OF ELECTRONARCOSIS

I should like to add a few words about the theoretical mode of action of electrocerebral treatment. Adolf Meyer's doctrine of reaction types has proved on the whole to be a valuable one. He speaks, for instance, of the catatonic, the manic, the melancholic, or the chronically anxious patient, as having reacted to environmental stress by adopting a special type of reaction. Meyer thought of this reaction type as being modifiable by treatment such as rest, or by withdrawing the patient to the quiet of hospital under a sympathetic and understanding physician who could influence him at the conscious level.

The remarkable and unexpected success, however, of these recent physiological treatments in the psychoses or intractable psychoneuroses suggests that we must visualize the morbid reaction type as depending on a particular reaction pattern or "set" at the autonomic level of the nervous system, for they act below the level of consciousness.

It has been found that such reaction patterns may be produced experimentally by certain drugs. Bulbocapnine, for instance, in ascending doses will produce in the macac monkey first depression of activity, then catalepsy, then a state resembling mania, and finally epilepsy (Richter and Paterson, 1931). Again, Gjessing (1939) has shown that recurrent catatonia can result from faulty protein metabolism.

Although such reaction patterns can sometimes be produced by drugs, it is of course usual for environmental stress to be a factor in their causation. The particular morbid reaction pattern adopted depends no doubt to a considerable degree on heredity, but imitation and suggestion can in some cases be the determining cause as shown by epidemics of hysteria in the Middle Ages or by the fact that the American negro shows different clinical pictures from his African cousin (Carothers, 1947).

If, therefore, the physiological basis of a commencing psychosis consists of a particular "set" or pattern of the nervous system, it is necessary to attempt immediately to alter this "set" by these electrical means. If the stupor, melancholia, mania or severe anxiety is allowed to continue, the condition may become intractable, or some complication such as suicide, inanition or intercurrent disease may ensue.

The electric current does not, we suppose, effect a recovery merely by its convulsant action, but by the autonomic changes which occur during the coma which accompanies and succeeds the convulsion. This perhaps explains why electronarcosis is more effective than electroshock.

The passage of an electric current is not merely a way of frightening the patient at the conscious level, like throwing a broody hen into a pond. It is true that the ancients thought they cured some madmen by throwing them into the sea from a cliff. Medieval monks held the heads of the insane under water till the priest had recited the *Miserere*. Erasmus Darwin spun them round in a revolving chair, and at Bethlem the patients were made to fall through a trapdoor into a cold bath. In the present treatment, however, the patient is usually first anesthetized and the treatment is carried out as stated entirely at the unconscious level. There is therefore no question of the treatment taking effect by the patient being subjected to conscious fear.

If this view is correct, then it is imperative to treat these patients as soon as the morbid state is manifest, a fact which is borne out by the higher proportion of successes with early psychotic cases. The time for rest and psychotherapy in these severe cases is after the electrocerebral treatment and not before. Many breadwinners who have broken down with depression and exhaustion have in the past been merely sent for a holiday to recover. The depression, however, has continued and they have been no better on their return, and in many cases they have lost their jobs. If they have electrocerebral treatment first, they enjoy their holiday and return to work quite well.

Some psychiatrists still hesitate to carry out these treatments at an early stage in patients who are obviously too ill for psychotherapy, because of possible injury to their brains. It is a fact, nevertheless, that in the hundreds of cases treated no complaint has been made by any patient or his relatives of any serious side-effect of the treatment.

We are still unable to explain why patients look and feel so much better after a few treatments, or why chronic skin diseases should clear up. Cerletti, for instance, told me that he effected a recovery in 14 out of 16 cases of psoriasis by means of electroshock. His theory that the brain develops a specific substance when threatened with approaching death is still unproved. It may be, however, that these remarkable changes are effected in part by endocrine means, particularly through the pituitary.

CONCLUSION

With regard to electronarcosis and kindred treatments, I believe that we are only at the beginning. At the present time the following investigations are being carried out at the West London Hospital or elsewhere: Psychological tests before and after treatment; blood-pressure investigations, including that of the retinal artery, intra-arterial blood-pressure, blood and cerebrospinal fluid changes, and changes in the electro-encephalogram.

RATIONALE OF ELECTRONARCOSIS

I should like to add a few words about the theoretical mode of action of electrocerebral treatment. Adolf Meyer's doctrine of reaction types has proved on the whole to be a valuable one. He speaks, for instance, of the catatonic, the manic, the melancholic, or the chronically anxious patient, as having reacted to environmental stress by adopting a special type of reaction. Meyer thought of this reaction type as being modifiable by treatment such as rest, or by withdrawing the patient to the quiet of hospital under a sympathetic and understanding physician who could influence him at the conscious level.

The remarkable and unexpected success, however, of these recent physiological treatments in the psychoses or intractable psychoneuroses suggests that we must visualize the morbid reaction type as depending on a particular reaction pattern or "set" at the autonomic level of the nervous system, for they act below the level of consciousness.

It has been found that such reaction patterns may be produced experimentally by certain drugs. Bulbocapnine, for instance, in ascending doses will produce in the macac monkey first depression of activity, then catalepsy, then a state resembling mania, and finally epilepsy (Richter and Paterson, 1931). Again, Gjessing (1939) has shown that recurrent catatonia can result from faulty protein metabolism.

Although such reaction patterns can sometimes be produced by drugs, it is of course usual for environmental stress to be a factor in their causation. The particular morbid reaction pattern adopted depends no doubt to a considerable degree on heredity, but imitation and suggestion can in some cases be the determining cause as shown by epidemics of hysteria in the Middle Ages or by the fact that the American negro shows different clinical pictures from his African cousin (Carothers, 1947).

If, therefore, the physiological basis of a commencing psychosis consists of a particular "set" or pattern of the nervous system, it is necessary to attempt immediately to alter this "set" by these electrical means. If the stupor, melancholia, mania or severe anxiety is allowed to continue, the condition may become intractable, or some complication such as suicide, inanition or intercurrent disease may ensue.

The electric current does not, we suppose, effect a recovery merely by its convulsant action, but by the autonomic changes which occur during the coma which accompanies and electroshock.

The passage of an electric current is not merely a way of frightening the patient at the conscious level, like throwing a broody hen into a pond. It is true that the ancients thought they cured some madmen by throwing them into the sea from a cliff. Medieval monks held the heads of the insane under water till the priest had recited the Miserere. Erasmus Darwin spun them round in a revolving chair, and at Bethlem the patients were made to fall through a trapdoor into a cold bath. In the present treatment, however, the patient is usually first anesthetized and the treatment is carried out as stated entirely at the unconscious level. There is therefore no question of the treatment taking effect by the patient being subjected to conscious fear.

If this view is correct, then it is imperative to treat these patients as soon as the morbid state is manifest, a fact which is borne out by the higher proportion of successes with early psychotic cases. The time for rest and psychotherapy in these severe cases is after the electrocerebral treatment and not before. Many breadwinners who have broken down with depression and exhaustion have in the past been merely sent for a holiday to recover. The depression, however, has continued and they have been no better on their return, and in many cases they have lost their jobs. If they have electrocerebral treatment first, they enjoy their holiday and return to work quite well.

Some psychiatrists still hesitate to carry out these treatments at an early stage in patients who are obviously too ill for psychotherapy, because of possible injury to their brains. It is a fact, nevertheless, that in the hundreds of cases treated no complaint has been made by any patient or his relatives of any serious side-effect of the treatment.

eight treatment she was still rather elated, but she was making contacts very well and entertained other patients with tap and ballet dancing. After the eleventh treatment she was well occupied in the ward and interested. She had gained weight and had improved considerably. One week after the last treatment she was transferred to a convalescent villa. She was still friendly, cheerful and was working quite well but was rather untidy and, for instance, her methods of bed-making left much to be desired. After a further two weeks she began to evince considerably more interest and care in her personal appearance. Three weeks later she was taking much more responsibility and she was then allowed full parole and proved to be useful in shopping for other patients. She remained in hospital for two and a half months and during the remainder of that period there was no sign of any relapse. After a short holiday she returned to work at her hospital and has remained perfectly well for the past eighteen months.

The second case which I should like to describe is that of a young man of 20, who while serving in the Army in 1944 began to express strange ideas regarding his body, and stated that he was slowly being devoured by insects. Apparently no one paid much attention to this delusion and he was able to continue to serve until June 1946 when he was released to take up essential work on the land. His mother, however, noted that during his period in the Army he had become increasingly suspicious, difficult and had lost all his friends. When he came home on leave he went for long-walks on his own, whereas previously he had enjoyed the company of his contemporaries. When he started work on the farm his workmates thought that he was very peculiar and stated that he would stop work for long periods and gaze at the sky. One day in August 1946 he drove his tractor into a ditch and immediately telephoned his mother, telling her to destroy all her ration and clothing books as the Government had decreed the end of all rationing. He returned home looking dishevelled and behaved in a most peculiar fashion. His mother called the local doctor and I was asked to see him. On examination he was a well-built lad who was mildly suspicious, reticent, self-absorbed and obviously only just able to retain contact with reality. He said that he heard various voices speaking to him and that "his mind was in a whirl" as he was commanded to do so many things at the same time. Emotional response was entirely lacking and he was quite unperturbed when questioned about the episode with the tractor. He was completely devoid of insight and stated that he was perfectly well, although the insects had been eating away at his body over a period of years. He also admitted that he had not been able to write letters for several months and his mother produced some completely incoherent, rambling and disconnected notes which he had written to her. During observation in hospital he proved to be very solitary, asocial, self-absorbed and would stand for long periods gazing into space. It was impossible to occupy his attention. Treatment by electronarcosis was commenced. After the first three treatments there was a remarkable improvement in his condition and he became bright, cheerful, sociable and asked to be given some work to do. He was, however, extremely childish and immature but after a further three weeks, during which time he had a total of fifteen treatments, he settled down very well and was able to apply himself diligently to various forms of occupational therapy. He left hospital three months after admission and had then remained completely symptom-free for two months. It was suggested that he was fit to take up further employment on a farm and he did this, but after a few months he decided that he would rather undertake office work of some description. He applied for his release from the land and just over a year ago obtained a post as a librarian. His employers are very satisfied with his services and he has been taken on to the permanent staff. There is no trace of any psychotic reaction and he appeared a perfectly normal young man.

A third case was that of a pharmacist, aged 33, suffering from hebephrenic schizophrenia. He had exhibited a gradual personality change over a period of years and finally gave up a good job and travelled about the country in an aimless fashion. He was vague in manner, dreamy, absent-minded and his conversation was bizarre and irrelevant. He said, for instance, "They tell me that I have made love to a lady doctor here and have taken a negro to America". That is not true for he has a perfectly good wife. He was hallucinated auditorially and walked up and down muttering to himself. After an unsuccessful attempt at treatment by electro-convulsive therapy he was given twelve electronarcosis treatments and a complete remission was produced. He has been back at work for over a year.

In many cases of schizophrenia, especially in hebephrenic and paranoid types, the treatment has the effect of activating the psychosis and these patients may become wildly excited, impulsive and violent. In such cases we have found it of benefit to give intensive electro-convulsive therapy until sufficient plasticity can be obtained to proceed with electonarcosis.

As might have been expected, the atypical schizophrenics responded extremely well to treatment by electonarcosis and a complete remission was produced in 14 out of the 15 cases, the fifteenth being a social recovery. It is probable that electro-convulsive therapy would have produced a similar result.

The 10 paraphrenics responded quite well to treatment and evidence of hallucinosis soon disappeared. These patients became less suspicious, lost their delusions and were apparently well after a course of treatment. On the other hand, we found that this paraphrenic group tended to refuse the treatment. I do not think this is to be wondered at, as it is asking the impossible in expecting a suspicious paranoid patient to accept the placing on of the head-band and the other preliminaries to treatment on several occasions during the week when he has no insight whatsoever into his condition. In St. James Hospital we admit a very

TABLE I.—ELECTRONARCOSIS IN SCHIZOPHRENIA

	Total	Degree of recovery as percentages				
		A	B	C	D	E
Adults and children	70	44	17	8	16	14
Adults alone	60	52	20	10	10	8

A Complete remission. B Social recovery. C Social defect.
D Improved in hospital. E No improvement.

the general results as the prognosis in all cases was hopeless from the start. In Portsmouth we have had the opportunity of treating a considerable number of cases of schizophrenia in children. I am sorry to say that we have not yet discovered a method of treatment which produces any material change in the condition. If, therefore, we consider the adolescent and adult group of schizophrenics, the total number being 60, we find that remissions were produced in 52%, 20% were social recoveries, 10% social defects, 10% improved in hospital and 8% not improved. I would point out that among the patients remaining in hospital, approximately 6% should be classed as family invalids as they merely continue as in-patients for social reasons.

The duration of the illness is of course an important factor and we find that of the 7 patients with a history of under one year, a complete remission was produced in all. This 100% recovery rate is of course due largely to coincidence. In 17 patients with a duration of illness under two years, 15 recovered and 2 were social recoveries. Out of 40 patients with a history of under five years, 60% recovered, 20% socially recovered, 7% social defect, 10% improved in hospital and 2% not improved. The duration of the follow-up has again been insufficient but in no case has it been less than three months; 40 of the cases have been followed up for periods ranging from a year to twenty months. None of those noted as "recovered" have relapsed, none of the social recoveries or defects have had to be readmitted to hospital, but 3% of those noted as improved in hospital have relapsed (Table II).

TABLE II.—ELECTRONARCOSIS IN SCHIZOPHRENIA

Results According to Duration of Illness (Adults)

	Total	Degree of recovery as percentages				
		A	B	C	D	E
Less than one year	7	100	—	—	—	—
Less than two years	17	88	12	—	—	—

More than five years	20	34	20	15	10	20

A Complete remission. B Social recovery. C Social defect.
D Improved in hospital. E No improvement.

In the diagnostic categories, the treatment appears to have little effect on simple types but some remarkable results have been obtained in hebephrenics. Variable responses occurred among catatonic types but there is little doubt that paranoid types on the whole respond well. This is in keeping with the findings of Tietz (1946 and 1947), Medlicott (1947) and Paterson (1948).

I would like now to give examples of actual cases, showing the response produced by the treatment.

The first is that of a nurse aged 25, who was admitted to St. James Hospital in October 1946. There was a history of some six months during which time she had become increasingly solitary, withdrawn from reality and apparently had frequent outbursts of meaningless laughter. The previous history had been very good and as far as can be ascertained there was little in the way of environmental stress to account for the onset of the condition. On admission she appeared dull, vacant, self-absorbed and exhibited various mannerisms. Her gait was peculiar and she dipped down as if curtsying at every few steps. While talking she continually moved her dentures up and down and frequently grimaced. There was evidence of considerable blocking and vagueness of thought and she expressed nihilistic ideas stating that her body was dead. She was obviously hallucinated auditorially and would frequently turn her head and reply to the voices. She exhibited a marked incongruity of affect and would say that she wished to die and then laugh and giggle in an uproarious fashion. There was no trace of depression and no real confusion. After the second treatment she was still very suspicious, and stated that her body had all gone and that only a shell was left. She was still hallucinated auditorially and stated that she was carrying on a conversation with her fiancé in Scotland. After the fourth treatment she became very much brighter and there was indeed a sudden improvement. She began to take a little interest in her surroundings and asked the nurse to send home for her dancing shoes. After the sixth treatment she started helping in the ward. There was no evidence of hallucination, but she tended to be somewhat elated in mood. After the

eighth treatment she was still rather elated, but she was making contacts very well and entertained other patients with tap and ballet dancing. After the eleventh treatment she was well occupied in the ward and interested. She had gained weight and had improved considerably. One week after the last treatment she was transferred to a convalescent villa. She was still friendly, cheerful and was working quite well but was rather untidy and, for instance, her methods of bed-making left much to be desired. After a further two weeks she began to evince considerably more interest and care in her personal appearance. Three weeks later she was taking much more responsibility and she was then allowed full parole and proved to be useful in shopping for other patients. She remained in hospital for two and a half months and during the remainder of that period there was no sign of any relapse. After a short holiday she returned to work at her hospital and has remained perfectly well for the past eighteen months.

The second case which I should like to describe is that of a young man of 20, who while serving in the Army in 1944 began to express strange ideas regarding his body, and stated that he was slowly being devoured by insects. Apparently no one paid much attention to this delusion and he was able to continue to serve until June 1946 when he was released to take up essential work on the land. His mother, however, noted that during his period in the Army he had become increasingly suspicious, difficult and had lost all his friends. When he came home on leave he went for long-walks on his own, whereas previously he had enjoyed the company of his contemporaries. When he started work on the farm his workmates thought that he was very peculiar and stated that he would stop work for long periods and gaze at the sky. One day in August 1946 he drove his tractor into a ditch and immediately telephoned his mother, telling her to destroy all her ration and clothing books as the Government had decreed the end of all rationing. He returned home looking dishevelled and behaved in a most peculiar fashion. His mother called the local doctor and I was asked to see him. On examination he was a well-built lad who was mildly suspicious, reticent, self-absorbed and obviously only just able to retain contact with reality. He said that he heard various voices speaking to him and that "his mind was in a whirl" as he was commanded to do so many things at the same time. Emotional response was entirely lacking and he was quite unperturbed when questioned about the episode with the tractor. He was completely devoid of insight and stated that he was perfectly well, although the insects had been eating away at his body over a period of years. He also admitted that he had not been able to write letters for several months and his mother produced some completely incoherent, rambling and disconnected notes which he had written to her. During observation in hospital he proved to be very solitary, asocial, self-absorbed and would stand for long periods gazing into space. It was impossible to occupy his attention. Treatment by electronarcosis was commenced. After the first three treatments there was a remarkable improvement in his condition and he became bright, cheerful, sociable and asked to be given some work to do. He was, however, extremely childish and immature but after a further three weeks, during which time he had a total of fifteen treatments, he settled down very well and was able to apply himself diligently to various forms of occupational therapy. He left hospital three months after admission and had then remained completely symptom-free for two months. It was suggested that he was fit to take up further employment on a farm and he did this, but after a few months he decided that he would rather undertake office work of some description. He applied for his release from the land and just over a year ago obtained a post as a librarian. His employers are very satisfied with his services and he has been taken on to the permanent staff. There is no trace of any psychotic reaction and he appeared a perfectly normal young man.

A third case was that of a pharmacist, aged 33, suffering from hebephrenic schizophrenia. He had exhibited a gradual personality change over a period of years and finally gave up a good job and travelled about the country in an aimless fashion. He was vague in manner, dreamy, absent-minded and his conversation was bizarre and irrelevant. He said, for instance, "They tell me that I have made love to a lady doctor here and have taken a negro to America". That is not true for he has a perfectly good wife. He was hallucinated auditorially and walked up and down muttering to himself. After an unsuccessful attempt at treatment by electro-convulsive therapy he was given twelve electronarcosis treatments and a complete remission was produced. He has been back at work for over a year.

In many cases of schizophrenia, especially in hebephrenic and paranoid types, the treatment has the effect of activating the psychosis and these patients may become wildly excited, impulsive and violent. In such cases we have found it of benefit to give intensive electro-convulsive therapy until sufficient plasticity can be obtained to proceed with electronarcosis.

As might have been expected, the atypical schizophrenics responded extremely well to treatment by electronarcosis and a complete remission was produced in 14 out of the 15 cases, the fifteenth being a social recovery. It is probable that electro-convulsive therapy would have produced a similar result.

The 10 paraphrenics responded quite well to treatment and evidence of hallucinosis soon disappeared. These patients became less suspicious, lost their delusions and were apparently well after a course of treatment. On the other hand, we found that this paraphrenic group tended to refuse the treatment. I do not think this is to be wondered at, as it is asking the impossible in expecting a suspicious paranoid patient to accept the placing on of the head-band and the other preliminaries to treatment on several occasions during the week when he has no insight whatsoever into his condition. In St. James Hospital we admit a very

large number of paraphrenic cases during the year; for instance, last year over 250 cases were treated as in-patients. We have found that intensive electro-convulsive therapy produces very good results and there seemed to be no benefit in using electronarcosis.

Of the 15 cases of psychoneurosis, 12 were suffering from anxiety states and in the remainder obsessional features predominated. The treatment was employed merely as an adjuvant to psychotherapy and was most useful in dealing with panic reactions. I would like to mention only one case to illustrate this point—that of

a 40-year-old solicitor whom I have treated for impotence of eighteen years' duration. This man had many worries in regard to his professional work and when I saw him first he complained of many of the somatic equivalents of anxiety. I felt that it was hopeless to try and treat the underlying condition without modifying the acute state to some extent. The exhibition of mild sedatives, such as seconal, did little to help and so I decided to employ electronarcosis. As he could not afford time to come into hospital I gave him eight treatments at two-day intervals as an out-patient. The result was excellent and at the end of a fortnight he had lost all trace of anxiety and was calm, composed and symptom-free. It has since been possible to cure the underlying condition.

Personally I am not in favour of giving electronarcosis—or electro-convulsive therapy—to out-patients, unless in exceptional circumstances. There is no doubt, moreover, that although the degree of confusion produced by electronarcosis is considerably less than that found after electro-convulsive therapy it would appear that a sudden brief amnesic state may occur as the result of the cumulative effect of treatment. In this connexion it may be of interest to note a condition which occurred in the patient to whom I have just referred. Two nights after the last treatment he attended a dance and although he himself maintains that he had only two small whiskies, and this is confirmed by various members of his party, he was unable to remember several salient events that had occurred during the evening.

The 10 melancholics responded very well to treatment by electronarcosis, but one would have expected electro-convulsive therapy to produce similar results. On the other hand, we have used the modified method in treating a number of elderly melancholics of varying aetiology, not included in this series. The results have been comparable to those produced by electro-convulsive therapy, but electronarcosis has the benefit of being a much smoother form of treatment and one has certainly more confidence in applying it to the elderly patient.

The modified method is of use in any case where treatment by electro-convulsive therapy would be applicable. In this case the usual *Glissando* rise (Tietz *et al.*, 1946) to 180 ma. is employed. The current is allowed to remain at this level for thirty seconds and is then reduced very slowly, to zero, the actual speed being gauged by the response of the patient. The desired result is to eliminate practically all trace of the clonic stage. At the end of approximately one minute from the commencement of treatment the current is terminated. This is certainly a much more elegant form of treatment as the convulsion is modified to such an extent as to be unrecognizable.

On the basis of these results, and of two years' experience of the method, I think that one can reasonably claim that electronarcosis forms a useful addition to our armamentarium. It certainly does seem to produce some effect in schizophrenia—all the remissions which we have obtained cannot have been coincidental and spontaneous, but only the passage of time will allow us to assess the true value of the treatment.

I am indebted to Dr. Thomas Beaton, Physician-Superintendent, St. James Hospital, Portsmouth, for permission to carry out the original experimental work, to use the case material and to publish these results.

Dr. Gerald Caplan: I wish to report briefly on a modification in the technique of electronarcosis which I have worked out recently with the help of Dr. Samuel Carden, the anaesthetist.

My apparatus is similar to that used by Spencer Paterson and Milligan. I designed it in collaboration with Mr. Oswald Sneath. It is a small light-weight apparatus weighing 19 lb., and incorporates a nonthermionic current stabilizer. A special feature of this apparatus is the inclusion in it of a voltmeter which allows a continual check to be kept on the resistance of the external circuit. If the electrode resistance increases suddenly, due to inadequate contact with the skin of the patient, this will be immediately shown by an increase in the voltage output. This is an important safety device to prevent skin burns.

The modification in technique which we have worked out with this apparatus is designed to ensure satisfactory oxygenation of the patient throughout the course of the electronarcosis. Insufflation with oxygen in the later stages of the electronarcosis is difficult because of spasm of the glottis, which manifests itself as the inspiratory stridor. In our technique this is considerably reduced by partial curarization of the patient. Three minutes before the electronarcosis is started the anaesthetist gives an intravenous injection of pentothal sodium 0.3 gramme to 0.4 gramme, plus atropine 1/60 grain and *d*-tubocurarine 12 mg. to 15 mg. He immediately afterwards commences the administration of pure oxygen and continues this throughout the treatment. The amount of curare given is not sufficient to prevent the muscular movements which are an important sign of the depth of the electronarcosis, but damps down any convulsive or preconvulsive movements which might produce fractures, and also causes sufficient relaxation of the vocal cords to allow of adequate oxygenation.

Occasionally, when the initial current dosage is not correctly estimated, there is a delay in the reappearance of the patient's spontaneous respiration. With our technique this need not cause anxiety as the patient can be kept pink by insufflation with oxygen by means of intermittent manual compression of an ordinary anaesthetic bag. On several occasions the patient has been kept in a satisfactory state of oxygenation despite the fact that he did not breathe spontaneously throughout the whole seven minutes of the electronarcosis.

In addition, the pentothal injection removes any apprehension due to the curarization, and also is a safeguard against the troublesome complication of an inadequate electronarcosis, of which the patient preserves a partial memory.

Dr. W. Grey Walter: The papers which we have just heard are an impressive demonstration of the enthusiasm and skill with which electrical methods are being applied to therapeutic problems, but I confess that from the physiological standpoint I am still somewhat sceptical as to the nature of the effects described. Eight or nine years ago, when we were starting electro-convulsive therapy, we tried to discover the margin between the maximum therapeutic and minimum lethal dose of current. In these experiments we administered prolonged shocks up to half a minute or more in duration, and of varying strengths. As a result of this, we obtained effects similar to those described this afternoon, but it never occurred to us to call them electronarcosis, since it seemed clear that the suspension of consciousness was due to gross over-stimulation of a large part of the central nervous system. The technique described this afternoon also seems to depend upon over-stimulation and the term "electronarcosis" therefore seems to me misleading, since the disturbance of consciousness seems to be due to exhaustion rather than to anything like anaesthesia.

The literature on electronarcosis and anaesthesia is very extensive and dates back to the last century but there seems little agreement as to fundamentals. Obviously, if the clinical results are satisfactory there is no more to be said from the physiological point of view, unless we can provide some rigorous explanation for the therapeutic action, but there is some hope that a true electronarcosis may be produced by other means, involving the use, perhaps, of a more intricate stimulation procedure and we are, at the moment, commencing experiments on these lines. It will be of particular interest to discover whether such a system is better or worse clinically, since it may well be that the therapeutic action does in fact depend primarily upon over-stimulation, exhaustion and reconditioning, rather than upon induced repose of a more nearly natural character.

Dr. T. F. Main: I hope we shall not be dismayed by the thought that social recoveries are of doubtful value. It is true that the half-improved and discharged patient does not make an ideal parent or mate, nor even a good uncle or aunt. It is true also that they must act as foci of psychopathic infection in the community. But these things are nothing new. We have always had social recoveries discharged from psychiatric hospitals and we are not worse off than before. But of course we are not better.

The descriptions we have heard of the technique of electronarcosis are a tribute to the skill and objectivity of the speakers. It would be wise, as they say, to be cautious about the interpretation of results. It is plain that many of their patients got better during the treatment, but it is not plain that they got better because of it, or in spite of it, or merely incidentally. There are, for instance, no controls. And the statistics of older psychiatrists who practised before the days of physical treatment do not provide us with good controls. Even twenty years ago many patients got better without the modern physical treatments. Up to then, early, mild psychiatric illness tended to be nursed at home for a long time, and many spontaneous recoveries took place. Mental hospitals did not admit in the same numbers as to-day the kind of cases which would remit early. The patients had been ill longer and therefore often more severely. Further, it cannot be sufficient to establish a control series merely by giving a number of patients no treatment. Electronarcosis, as we have seen this afternoon, raises enormous interest and considerable anxiety in doctors and nurses. The patient undergoing the treatment is surrounded with an atmosphere of excitement, care and unremitting attention, different from that which would be given to a patient who is having no physical treatment. A general emotional atmosphere of skilled care and devoted daily interest has great therapeutic value in itself, and in itself may be the significant therapeutic agent for many patients. This is not to decry physical treatments, for if they are the price the patient must pay for replacing the despair and apathy about recovery that was fairly common in mental hospitals up to a quarter of a century ago by enthusiasm, concern, interest, and intense optimistic devotion, then the patient would be surely glad to pay it.

A further lesson from the past must give us caution about the interpretation of results. None of

large number of paraphrenic cases during the year; for instance, last year over 250 cases were treated as in-patients. We have found that intensive electro-convulsive therapy produces very good results and there seemed to be no benefit in using electronarcosis.

Of the 15 cases of psychoneurosis, 12 were suffering from anxiety states and in the remainder obsessional features predominated. The treatment was employed merely as an adjuvant to psychotherapy and was most useful in dealing with panic reactions. I would like to mention only one case to illustrate this point—that of

A further lesson from the past must give us caution about the interpretation of results. None of

large number of paraphrenic cases during the year; for instance, last year over 250 cases were treated as in-patients. We have found that intensive electro-convulsive therapy produces very good results and there seemed to be no benefit in using electronarcosis.

Of the 15 cases of psychoneurosis, 12 were suffering from anxiety states and in the remainder obsessional features predominated. The treatment was employed merely as an adjuvant to psychotherapy and was most useful in dealing with panic reactions. I would like to mention only one case to illustrate this point—that of

a 40-year-old solicitor whom I have treated for impotence of eighteen years' duration. This man had many worries in regard to his professional work and when I saw him first he complained of many of the somatic equivalents of anxiety. I felt that it was hopeless to try and treat the underlying condition without modifying the acute state to some extent. The exhibition of mild sedatives, such as seconal, did little to help and so I decided to employ electronarcosis. As he could not afford time to come into hospital I gave him eight treatments at two-day intervals as an out-patient. The result was excellent and at the end of a fortnight he had lost all trace of anxiety and was calm, composed and symptom-free. It has since been possible to cure the underlying condition.

Personally I am not in favour of giving electronarcosis—or electro-convulsive therapy—to out-patients, unless in exceptional circumstances. There is no doubt, moreover, that although the degree of confusion produced by electronarcosis is considerably less than that found after electro-convulsive therapy it would appear that a sudden brief amnesic state may occur as the result of the cumulative effect of treatment. In this connexion it may be of interest to note a condition which occurred in the patient to whom I have just referred. Two nights after the last treatment he attended a dance and although he himself maintains that he had only two small whiskies, and this is confirmed by various members of his party, he was unable to remember several salient events that had occurred during the evening.

The 10 melancholics responded very well to treatment by electronarcosis, but one would have expected electro-convulsive therapy to produce similar results. On the other hand, we have used the modified method in treating a number of elderly melancholics of varying aetiology, not included in this series. The results have been comparable to those produced by electro-convulsive therapy, but electronarcosis has the benefit of being a much smoother form of treatment and one has certainly more confidence in applying it to the elderly patient.

The modified method is of use in any case where treatment by electro-convulsive therapy would be applicable. In this case the usual *Glissando* rise (Tietz *et al.*, 1946) to 180 ma. is employed. The current is allowed to remain at this level for thirty seconds and is then reduced very slowly, to zero, the actual speed being gauged by the response of the patient. The desired result is to eliminate practically all trace of the clonic stage. At the end of approximately one minute from the commencement of treatment the current is terminated. This is certainly a much more elegant form of treatment as the convulsion is modified to such an extent as to be unrecognizable.

On the basis of these results, and of two years' experience of the method, I think that one can reasonably claim that electronarcosis forms a useful addition to our armamentarium. It certainly does seem to produce some effect in schizophrenia—all the remissions which we have obtained cannot have been coincidental and spontaneous, but only the passage of time will allow us to assess the true value of the treatment.

I am indebted to Dr. Thomas Beaton, Physician-Superintendent, St. James Hospital, Portsmouth, for permission to carry out the original experimental work, to use the case material and to publish these results.

Dr. Gerald Caplan: I wish to report briefly on a modification in the technique of electronarcosis which I have worked out recently with the help of Dr. Samuel Carden, the anaesthetist.

My apparatus is similar to that used by Spencer Paterson and Milligan. I designed it in collaboration with Mr. Oswald Sneath. It is a small light-weight apparatus weighing 19 lb., and incorporates a nonthermionic current stabilizer. A special feature of this apparatus is the inclusion in it of a voltmeter which allows a continual check to be kept on the resistance of the external circuit. If the electrode resistance increases suddenly, due to inadequate contact with the skin of the patient, this will be immediately shown by an increase in the voltage output. This is an important safety device to prevent skin burns.

Infra-Orbital Neuralgia

By G. C. KNIGHT

THERE are frequent points of contact between the specialities of Oto-rhino-laryngology and Neurosurgery. The object of this communication is to examine one facet at which our specialities overlap—namely that of pain in the territory of the trigeminal nerve which may occasionally be deceptive and lead to difficulty in diagnosis and treatment.

The trigeminal nerve runs a long course and there is a very close association between its branches and the nasal air cells. Occasionally the sphenoidal air sinus may extend as far as the semilunar ganglion or foramen ovale, and it is a fact that the introduction of cocaine into the sphenoidal sinus may produce complete trigeminal anaesthesia, indicating how thin a layer of dividing bone separates the sinus from the nerve.

The close relationship of the sphenopalatine ganglion to the nasal mucosa is also remarkable; hence it is that certain cases of trigeminal pain occasionally have their origin in acute intranasal disease, but it is also true that atypical forms of primary trigeminal neuralgia may closely simulate the symptoms of primary intranasal suppuration.

It has been my experience that in the majority of cases intranasal operations are not followed by chronic pain and that many of those patients who suffer from persistent pain after nasal operations do so, not on account of some unrelieved condition in the nose, but from the persistence of a state that was present prior to operation which may occasionally be a psychalgia or atypical neuralgia that was mistakenly diagnosed as arising from intranasal causes.

The leading feature of psychalgic pain is that it is constant. Pain that is unremitting, that never leaves the patient, that changes in form but never in severity is always suspect, for true pain of organic origin must wax and wane as the causative disease varies in intensity; it is sometimes better and sometimes worse, whilst typical or atypical trigeminal neuralgia occurs in characteristic paroxysmal outbursts. One should always beware of the patient with a distressing background or with little responsibility, ample means, and no vital interests who complains of pain that never leaves her.

With this passing reference to psychalgia it is proposed to confine the remainder of this discussion to two subjects, namely, infra-orbital neuralgia and sphenopalatine neuralgia, each of which may occur as primary lesions independently of nasal infection and yet may simulate the pain symptomatology of antral disease or affection of the deeper air cells. With this object it is necessary to review the pathways for the conduction of pain stimuli from the paranasal regions.

The trigeminal nerve is the only pathway for the conduction of pain from the nasal air cells. I do not believe in the existence of sympathetic pathways which can produce pain in the head or in the paranasal region. It is true that referred pain in the *neck and shoulder* may occasionally be attributed to reference through the sympathetic system, but after a complete section of the trigeminal nerve it is impossible to elicit pain in the nasal region by traumatizing the nasal mucosa although the sphenopalatine ganglion and vidian nerve are still intact. Painful sensations that continue after a sensory root section are either psychalgic in origin or attributable to the escape of a few fibres in the sensory root which has left the trigeminal pathways partially intact as a result of an incomplete operation.

The major portion of the trigeminal supply from the nose is conducted in the second division of the trigeminus, only a relatively small proportion returning in the first division. The first or ophthalmic division passes through the sphenoidal fissure conducting pain

the previous physical treatments has justified the high hopes placed on it after its innovation. The later figures have not been as good as the earlier enthusiastic ones. It occurs to me that all of these treatments are either dangerous or dramatic, and while nurses and doctors were learning the techniques, they themselves were anxious and uneasy on behalf of the patients, giving daylong skill and unremitting interest, supporting the patient with all the professional anxiety they could command. Since the techniques of these treatments have been established, and they have become safer and more "ordinary", there is less excitement about them. They have become conventionalized and routine and comparatively dull. This meant also a change in the attitude to the patient undergoing the treatment. There is less anxiety for the patient, and less therapeutic effect. This has occurred with continuous narcosis, electro-convulsive therapy, and insulin coma. To-day's papers, to the credit of the authors, show the same intensity and concern for the patient and the treatment method. When the technique of electronarcosis becomes clearly established and of less concern to the therapists, the atmosphere round the patient will, of course, change in the same way as with the other physical treatments, and we must hold our hand before writing the final assessment of results. But we need not despair. Electricity is a wonderful thing and human ingenuity knows no bounds. We may be sure that when electronarcosis is familiar and undramatic, new dramatic and perhaps dangerous forms of using electricity for patients will arise and will stimulate again medical excitement and nursing devotion, and the patients will continue to benefit from an active atmosphere of sincerity and minute-by-minute concern on their behalf. And if we continue to get earlier and milder cases admitted to our mental hospitals, the published figures will continue to improve.

It may be that electronarcosis has direct and specific values of its own, but these are at present obscure and unproven and I doubt whether theorizing about "normalizing electrical patterns of the brain" is justified. Our tribute must be to the authors' skill and scientific detachment and one hopes that research into the effects of electricity upon nervous tissue will continue.

Electronarcosis must also be considered as a total experience to the patient with a significance of its own for him. I have been impressed by observing the behaviour of a patient who in his past life, particularly in his career, where he persistently refused promotion and undertook unrewarding but dangerous work, showed himself to have deep and quite unconscious masochistic tendencies. He liked electronarcosis and loved the doctors who gave it to him and who admired his spirit of eagerness for the treatment. He made one complaint on recovering from his fourth treatment—"That was nothing. Too easy; in fact it may seem odd but I am a little bit disappointed". The point here is that in unpleasant experiences there are sometimes deep unconscious satisfactions. We know, too, that the best results of electronarcosis are plainest in those people who have intrapunitive wishes extending to suicidal ideas—namely, in depression. We should be wise to acknowledge the possibility that by electronarcosis we sometimes satisfy a need which has psychological rather than electrical values. Masochism is a fairly universal human component and it is usually deeply unconscious. When unpleasant experiences are given by medical authority and administered with kindness, devotion and care, we should not be tempted to think in terms of electricity only.

In post-herpetic neuritis the pain is usually widespread and involves a greater area than the territory of the infra-orbital nerve. Infra-orbital avulsion is therefore seldom to be considered in these cases, but I would recall that I have had experience of two patients in whom infra-orbital avulsion alone has succeeded in curing the pain. I would like to mention especially the case of a doctor in whom pain was experienced in the infra-orbital territory in the region of the canine tooth, in the lower lid of the eye and in the whole of the upper cheek, and also deeply behind the eye and deeply in the nose. The presence of pain in the eye and within the nose made me suspect that infra-orbital avulsion would fail, but in view of the great age and frail physique of the patient, who was forced to take large doses of opiates, it seemed that a small operation under local anaesthesia should be tried. A particularly large portion of the nerve was removed at operation and complete relief of pain was obtained except for some sore discomfort that continued in the nose in the region of a perforation of the nasal septum which received its supply through branches of the nasopalatine division.

I find that infra-orbital avulsion is ineffectual as a means of relieving chronic pain resulting from infection of the paranasal sinuses, presumably on account of the wider area of their nerve supply, excepting in those cases where pain is confined entirely to the region of the maxilla and canine fossa and upper teeth. Deep pain that is experienced in the region of the eye, the side of the nose, and hard palate requires an operation on the sensory root of the trigeminus in order to interrupt the important fibres that are supplied from the sphenopalatine ganglion.

SPHENOPALATINE NEURALGIA

The sphenopalatine or nasal ganglion is a small triangular reddish grey body with the apex downwards, situated in the upper portion of the sphenomaxillary fossa—lying beneath the second division of the trigeminal nerve—in close proximity to the nasal mucosa—at a depth varying in different dissections from 1–2 to 7–9 millimetres. It may occasionally occupy a direct submucous position or be replaced by two separate and smaller ganglia which are related to the sphenopalatine nerves.

The structure of the ganglion consists of sensory branches of the trigeminus and motor branches of the facial that are prolonged through its substance together with sympathetic ganglia cells which occupy a posterior position in the ganglion at its junction with the vidian nerve.

The sensory roots of the ganglion consist of two or three stout filaments of the sphenopalatine branches which pass through the ganglion to the nose and palate without being in any way incorporated with the cells of the ganglion mass.

The motor root is supplied by the great superficial petrosal from the geniculate ganglion of the facial. This nerve also conveys taste fibres from the anterior two-thirds of the tongue which have passed via the chorda tympani to the geniculate and thence through the great superficial petrosal to Meckel's ganglion and will finally join the second division of the trigeminal nerve.

The sympathetic root of the ganglion consists of the great deep petrosal branch from the carotid plexus which joins the great superficial petrosal beneath the gasserian ganglion in the region of the foramen lacerum medium to form the vidian root.

The branches of distribution have been already referred to, but we may emphasize again that the trigeminal fibres of the sphenopalatine nerves are to be regarded as the splanchnic components of the trigeminus supplying internal structures as contrasted to the somatic peripheral branches of the first, second and third divisions. The pain arising from involvement of these branches differs from that of ordinary trigeminal neuralgia both in distribution and type. The distribution of the pain corresponds closely to the branches of distribution of the ganglion and also to the territory of the infra-orbital nerve.

In sphenopalatine neuralgia pain is experienced in the alar region of the nose and spreads laterally into the cheek and up to the infra-orbital region. At the height of the paroxysm the pain is also experienced deep inside the nose and in the hard palate and gums. The pain is of a continuous burning type and may last for twenty minutes or for many hours in each paroxysm, tending to spread to involve wider and wider areas during the attack; it is often associated with a sensation of tension in the affected area; it differs from trigeminal neuralgia in the longer duration of the paroxysms. Occasionally the symptoms will include loss of taste in the anterior two-thirds of the tongue. Physical examination, which is usually entirely negative, may reveal a slight reduction of sensation over the soft palate on the affected side and of the pharynx as far down as the tonsil. Vasomotor and secretory disturbances are occasionally observed in association with the attack, consisting of reddening of the conjunctiva and profuse secretion of tears. These phenomena have given rise to speculation as to the part that the sympathetic pathways may play in the causation of this pain,

sensations from the eyeball and lacrimal gland, from the upper portion of the nasal mucosa, and the skin of the upper eyelid and mid-line of nose, and from the forehead and scalp as high as the vertex.

The second or maxillary division passes from the foramen rotundum across the sphenomaxillary fossa to the infra-orbital canal. In the sphenomaxillary fossa it gives off its main supply to the paranasal sinus, being connected to the sphenopalatine ganglion of Meckel by two or three stout filaments, the sphenopalatine nerves. These constitute the sensory roots of the ganglion and pass directly from the maxillary division to the upper border of the ganglion, passing through the ganglion without forming contact with the ganglion cells, to be continued as the important sensory branches of distribution, which together innervate the greater portion of the nose, nasopharynx and accessory air cells, the area of distribution covering the nasal mucosa, except in the region of the inferior turbinate, the roof and septum of the nose, the hard palate in the region of the incisors, the sphenoid and ethmoidal air cells and the nasopharynx in the region of the fossa of Rosenmüller.

<i>Branches of distribution of sphenopalatine ganglion</i>				<i>Area of sensory distribution</i>
Ascending or orbital	{ Sphenoid Posterior ethmoids Periosteum orbit Nasal mucosa, except region of anterior and inferior turbinate Hard palate Inside of gum Tonsil and soft palate
Descending or large posterior palatine				
Accessory	
Internal or posterior, superior, nasal, nasopalatine	
Posterior or pterygopalatine	{ Posterior superior nasal fossa. Roof and septum and hard palate in region of incisors Nasopharynx fossa of Rosenmüller

These internal branches of distribution are to be regarded as the splanchnic distribution of the trigeminus as opposed to the somatic branches which, through the first, second and third divisions innervate the peripheral structures of the skin and jaws. Disturbances arising from the splanchnic territory may well have a different clinical character to similar disturbances arising in the area of somatic supply.

Anterior to the sphenopalatine ganglion the infra-orbital nerve enters the infra-orbital canal and is then distributed in branches to the wall of the maxillary antrum and to the incisor, canine and the first premolar teeth (the second premolar and molars receiving a separate supply through the posterior superior alveolar branch), and finally emerges from the infra-orbital foramen to supply the skin of the infra-orbital region. Pain arising from involvement of the infra-orbital nerve will therefore be confined to the cheek in the region of the ala of the nose, and the anterior portion of the upper alveolus, especially in the region of the canine fossa.

INFRA-ORBITAL NEURALGIA

Paroxysmal infra-orbital neuralgia occurs in two forms: It may appear as a presenting feature of trigeminal neuralgia and later spread to involve other branches of the trigeminus, or it may arise from local causes following upon dental extractions in the canine region and other operations in the region of the canine tooth, in which case the pain will remain entirely localized to the infra-orbital territory. Complete relief of pain may be obtained by infra-orbital avulsion in cases that have a local cause, but avulsion is an unsatisfactory method of treatment in trigeminal neuralgia as the pain will later extend to involve other branches.

Paroxysmal explosive attacks of pain of brief duration simulating the pain of trigeminal neuralgia may be seen in cases that have a local origin. Alternatively the pain may be continuous with exacerbations and remissions.

I recall the case of a Dutch seaman whose pain commenced following the extraction of his canine tooth. A constant pain was present in the region of extraction and in adjacent portions of the superior alveolus: there was a feeling of dull heavy pain in the cheek below the eye—an associated antral infection was suspected. The antrum was punctured, with negative results. Paroxysmal explosive outbursts of pain of great severity then commenced and occurred infrequently during the first year but later became more frequent. Complete relief followed avulsion of the infra-orbital nerve.

In other cases local pain has followed alveolectomy and in these, too, it has been possible to relieve the discomfort by infra-orbital avulsion provided that the pain was strictly confined to the region of the anterior portion of the upper jaw.

In post-herpetic neuritis the pain is usually widespread and involves a greater area than the territory of the infra-orbital nerve. Infra-orbital avulsion is therefore seldom to be considered in these cases, but I would recall that I have had experience of two patients in whom infra-orbital avulsion alone has succeeded in curing the pain. I would like to mention especially the case of a doctor in whom pain was experienced in the infra-orbital territory in the region of the canine tooth, in the lower lid of the eye and in the whole of the upper cheek, and also deeply behind the eye and deeply in the nose. The presence of pain in the eye and within the nose made me suspect that infra-orbital avulsion would fail, but in view of the great age and frail physique of the patient, who was forced to take large doses of opiates, it seemed that a small operation under local anaesthesia should be tried. A particularly large portion of the nerve was removed at operation and complete relief of pain was obtained except for some sore discomfort that continued in the nose in the region of a perforation of the nasal septum which received its supply through branches of the nasopalatine division.

I find that infra-orbital avulsion is ineffectual as a means of relieving chronic pain resulting from infection of the paranasal sinuses, presumably on account of the wider area of their nerve supply, excepting in those cases where pain is confined entirely to the region of the maxilla and canine fossa and upper teeth. Deep pain that is experienced in the region of the eye, the side of the nose, and hard palate requires an operation on the sensory root of the trigeminus in order to interrupt the important fibres that are supplied from the sphenopalatine ganglion.

SPHENOPALATINE NEURALGIA

The sphenopalatine or nasal ganglion is a small triangular reddish grey body with the apex downwards, situated in the upper portion of the sphenomaxillary fossa—lying beneath the second division of the trigeminal nerve—in close proximity to the nasal mucosa—at a depth varying in different dissections from 1–2 to 7–9 millimetres. It may occasionally occupy a direct submucous position or be replaced by two separate and smaller ganglia which are related to the sphenopalatine nerves.

The structure of the ganglion consists of sensory branches of the trigeminus and motor branches of the facial that are prolonged through its substance together with sympathetic ganglia cells which occupy a posterior position in the ganglion at its junction with the vidian nerve.

The sensory roots of the ganglion consist of two or three stout filaments of the sphenopalatine branches which pass through the ganglion to the nose and palate without being in any way incorporated with the cells of the ganglion mass.

The motor root is supplied by the great superficial petrosal from the geniculate ganglion of the facial. This nerve also conveys taste fibres from the anterior two-thirds of the tongue which have passed via the chorda tympani to the geniculate and thence through the great superficial petrosal to Meckel's ganglion and will finally join the second division of the trigeminal nerve.

The sympathetic root of the ganglion consists of the great deep petrosal branch from the carotid plexus which joins the great superficial petrosal beneath the gasserian ganglion in the region of the foramen lacerum medium to form the vidian root.

The branches of distribution have been already referred to, but we may emphasize again that the trigeminal fibres of the sphenopalatine nerves are to be regarded as the splanchnic components of the trigeminus supplying internal structures as contrasted to the somatic peripheral branches of the first, second and third divisions. The pain arising from involvement of these branches differs from that of ordinary trigeminal neuralgia both in distribution and type. The distribution of the pain corresponds closely to the branches of distribution of the ganglion and also to the territory of the infra-orbital nerve.

In sphenopalatine neuralgia pain is experienced in the alar region of the nose and spreads laterally into the cheek and up to the infra-orbital region. At the height of the paroxysm the pain is also experienced deep inside the nose and in the hard palate and gums. The pain is of a continuous burning type and may last for twenty minutes or for many hours in each paroxysm, tending to spread to involve wider and wider areas during the attack; it is often associated with a sensation of tension in the affected area; it differs from trigeminal neuralgia in the longer duration of the paroxysms. Occasionally the symptoms will include loss of taste in the anterior two-thirds of the tongue. Physical examination, which is usually entirely negative, may reveal a slight reduction of sensation over the soft palate on the affected side and of the pharynx as far down as the tonsil. Vasomotor and secretory disturbances are occasionally observed in association with the attack, consisting of reddening of the conjunctiva and profuse secretion of tears. These phenomena have given rise to speculation as to the part that the sympathetic pathways may play in the causation of this pain,

but bearing in mind the function of the great superficial petrosal nerve which is the secretomotor nerve to the lacrimal gland, the excessive tear secretion is easily understandable.

Sphenopalatine neuralgia may arise as a primary and independent condition without any associated intranasal suppuration. The syndrome is therefore by no means indicative of intranasal disease. With this qualification it is necessary in any discussion of this subject to pay tribute to the work of Dr. Greenfield Sluder for his extensive clinical and anatomical studies of the sphenopalatine syndrome. Sluder's original description of the sphenopalatine syndrome was published on May 23, 1908, in the *New York Medical Journal*, 87, 989; in it he gives an excellent description of the symptomatology:

"Occasionally it has been my lot to be consulted by patients who were in every way healthy and normal, but who suffered much of the time from headache which did not follow any of the known rules. Sometimes it was referred to behind the eyes, sometimes to the upper jaw in front, and sometimes to the hard or soft palate. Occasionally the nose was said to ache in the back, or the teeth were described as sore, or the pain was referred to the temple. Sometimes an indefinite sense of stiffness was described. These symptoms appeared from day to day, alternating one with the other, or associated two or three together. On one occasion I had them all described at once. I have seen some high grade inflammatory troubles in the posterior ethmoidal and sphenoidal sinuses, which have subsided and healed, usually within a week or two, but have left the train of symptoms, as described, in their wake, and these have continued on more or less indefinitely. This exceedingly irregular train of symptoms cannot be explained on a basis of inflammatory troubles in the accessory sinuses."

He points out the possibility of infection of the ganglion by the extension of sepsis from the nose and concludes:

"The distribution of the nerve processes of this ganglion corresponds closely with many of the regions to which pain is referred by these patients."

Sluder, in his numerous monographs, draws attention to the anatomical relationship of the sphenopalatine ganglion; he points out the close proximity of the ganglion to the sphenopalatine foramen, a relatively exposed position which he thought might lead to the passage of infection from the nose to the ganglion. He also drew attention to the fact that the sphenomaxillary fossa was related superiorly to the thin bone of the sphenoidal sinus and sphenoidal process of the palate bone, and posteriorly to the occasional prolongation of the sphenoid downward within the pterygoid process and great wing, and anteriorly to the thin posterior wall of the maxillary sinus. He maintained that infection might transude from the thin bone in this situation and lead to inflammatory changes in the ganglion with resulting pain. However, he drew attention to the fact that anteriorly the sphenopalatine ganglion was in relationship with the descending palatine artery and the sphenopalatine artery with their corresponding veins, and that these structures, together with surrounding connecting tissue, formed a protective pad which separated the ganglion by some 3 to 4 mm. from the wall of the maxillary sinus forming the anterior boundary of the fossa; a finding which he thought might explain his belief that the characteristic disturbances of sphenopalatine neuralgia were more likely to follow upon inflammation of the ethmoid and sphenoidal sinus but were not at all likely to ensue from extension of infection from the posterior wall of the maxillary antrum. Soon, however, evidence appears that even Sluder himself was beginning to doubt that all cases of sphenopalatine neuralgia were really of nasal origin.

In 1910 in a communication to the Section of Internal Medicine of the St. Louis Medical Society (*New York med. J.*, 91, 850) he described two cases of typical sphenopalatine neuralgia occurring without previous nasal sinus infection and, in 1913, twelve cases of "systemic toxic origin" (*Trans. Sect. Laryng. Otol., Amer. med. Ass.*).

It may of course be true that an infection of the ganglion might follow upon infection of the nasal air cells in the manner that Sluder suggests. This is a matter upon which I would appreciate your helpful comments in the subsequent discussion. If it is true that sphenopalatine neuralgia CAN be a complication of nasal disease, it is equally true that paroxysmal explosive attacks of sphenopalatine neuralgia may arise as a primary condition as a variant of the more usual trigeminal neuralgia occurring in patients who have never had any evidence of nasal suppuration whatsoever.

TREATMENT

In the past, many cases exhibiting the sphenopalatine syndrome have had their treatment commenced by various operative procedures on the nose, carried out in the belief that their pain arose from nasal causes. In view of the fact that a nasal origin for this syndrome is by no means proven, I would suggest that intranasal operation should be undertaken in this condition only when positive proof has been obtained of the co-existence of intranasal infection and that operations which are exploratory in character should be rigidly avoided.

Local measures designed to produce a temporary relief of pain consist of cocaineization of the sphenopalatine ganglion. The application of cocaine to the region of the sphenopalatine foramen produces a transitory effect which lasts approximately half an hour. This short period of temporary relief may succeed in abating an attack and may cut short the severe symptoms of hypersecretion of tears and excessive nasal secretion that are sometimes associated with the syndrome. Local measures of this kind can of course produce no permanent effect in those cases in which paroxysms of pain are frequently repeated.

Injection of the sphenopalatine ganglion is also an uncertain and unsatisfactory method. It is no mean feat to plant an injection directly into a structure 5 mm. in length which occupies an inconstant depth from the surface of the nasal mucosa. Many of the injections that have been performed have for this reason been merely periganglionic and have led to an exacerbation of the existing disturbance by production of scar tissue and inflammatory reaction around the ganglion itself. In other cases if certain anatomical variations are present, or if the course of the needle is not perfectly directed, quite serious injury may be caused by attempted injection. Cases are recorded of injury to the nerves lying in the sphenoidal fissure produced by a needle that was imperfectly directed from the posterior palatine canal.

Sluder's technique of using a straight needle that is introduced beneath the posterior tip of the middle turbinate 0.66 cm. from its posterior margin appears to be the safest method of approach, but the results of these measures have been extremely inconstant. The injection of solutions of 5% phenol in alcohol has had to be repeated in many cases from three to ten times. Injection may be accompanied by a considerable pain reaction after a short period of comfort, and this reaction, which is the result of inflammatory disturbances in the region of the ganglion, tends to become more and more severe each time the injection is repeated—as Sluder says: "Severe cases of this kind are not only a terrible affliction for the patient. They may also put the Surgeon at his wits' end for judgment, perseverance, and skill." I would suggest that perhaps it were better not to embark upon so hazardous a course.

I would now like to recount two cases of sphenopalatine neuralgia arising as primary disease, independently of any intranasal suppuration, that have been completely relieved by sensory root section of the trigeminus.

CASE I.—Male, aged 42, complaining of paroxysms of pain in the left side of the face which had been present for seventeen years, occurring at intervals of approximately six to seven hours throughout the whole of that time. In 1930 this patient began to experience pain: the paroxysms began just lateral to the nostril and then spread laterally into the cheek and up to the infra-orbital region. At the height of the paroxysm he would also experience pain deeply inside the left side of his nose and also on his hard palate and gums on the left side. This pain was of a continuous burning type, lasting for about twenty minutes, then subsiding gradually and leaving his face sore. His paroxysms occurred approximately every six to seven hours and were usually of the same intensity. They were brought on by going out in the cold wind but there did not appear to be any special trigger area. He stated that if he had a cold he became free from the attacks or that they became less severe. His trigeminal nerve had been injected on four occasions with some analgesia but no relief from symptoms. Examination revealed no abnormal signs in the central nervous system.

In view of the suggestion that pain of this type might be conveyed through sympathetic pathways, an attack was elicited by stimulating the posterior part of the septal aspect of the left middle turbinate. This produced symptoms clearly recognized by the patient as the earlier stages of a typical attack; they included throbbing in the area of the pain, lacrimation in the left eye and a peculiar "early" pain deep in the face which preceded the full development of pain. The left cervical and thoracic sympathetic was then injected beneath the first rib by the posterior route; five minutes later sympathetic paralysis became evident with the development of a left Horner's syndrome. The left upper limb became hot and flushed, the left-sided nasal mucosa became very congested.

Repeated stimulation of the nasal mucosa again produced exactly the same symptoms of pain with lacrimation of the left eye, and some three minutes later he had a spontaneous and typical attack of pain at a time when the sympathetic paralysis was well developed, thus indicating that sympathetic block does not modify the onset or character of the attacks. At a later date a complete sensory root section was performed and from that date the patient has had no further attacks of pain.

CASE II.—Male, aged 38. He experienced similar attacks of pain for four years and was completely relieved by a subtotal sensory root section designed to interrupt the fibres of the first and second divisions only, and in this patient also there was no evidence of any intranasal disease.

To summarize, it would appear that sphenopalatine neuralgia may occur as a variant of trigeminal neuralgia, independently of associated inflammation in the paranasal sinuses, that it is capable of complete and lasting relief by sensory root section; that the sympathetic pathways appear to play no part in the conduction of pain stimuli. It is possible that this condition may be of post-herpetic origin and comparable to herpes of the geniculate ganglion.

E. D. D. Davis said that for many years the Royal Dental Hospital had sent cases to his clinic at Charing Cross. The most common condition was alveolar pain following extraction. This was purely

but bearing in mind the function of the great superficial petrosal nerve which is the secretomotor nerve to the lacrimal gland, the excessive tear secretion is easily understandable.

Sphenopalatine neuralgia may arise as a primary and independent condition without any associated intranasal suppuration. The syndrome is therefore by no means indicative of intranasal disease. With this qualification it is necessary in any discussion of this subject to pay tribute to the work of Dr. Greenfield Sluder for his extensive clinical and anatomical studies of the sphenopalatine syndrome. Sluder's original description of the sphenopalatine syndrome was published on May 23, 1908, in the *New York Medical Journal*, 87, 989; in it he gives an excellent description of the symptomatology:

"Occasionally it has been my lot to be consulted by patients who were in every way healthy and normal, but who suffered much of the time from headache which did not follow any of the known rules. Sometimes it was referred to behind the eyes, sometimes to the upper jaw in front, and sometimes to the hard or soft palate. Occasionally the nose was said to ache in the back, or the teeth were described as sore, or the pain was referred to the temple. Sometimes an indefinite sense of stiffness was described. These symptoms appeared from day to day, alternating one with the other, or associated two or three together. On one occasion I had them all described at once. I have seen some high grade inflammatory troubles in the posterior ethmoidal and sphenoidal sinuses, which have subsided and healed, usually within a week or two, but have left the train of symptoms, as described, in their wake, and these have continued on more or less indefinitely. This exceedingly irregular train of symptoms cannot be explained on a basis of inflammatory troubles in the accessory sinuses."

He points out the possibility of infection of the ganglion by the extension of sepsis from the nose and concludes:

"The distribution of the nerve processes of this ganglion corresponds closely with many of the regions to which pain is referred by these patients."

Sluder, in his numerous monographs, draws attention to the anatomical relationship of the sphenopalatine ganglion; he points out the close proximity of the ganglion to the sphenopalatine foramen, a relatively exposed position which he thought might lead to the passage of infection from the nose to the ganglion. He also drew attention to the fact that the sphenomaxillary fossa was related superiorly to the thin bone of the sphenoidal sinus and sphenoidal process of the palate bone, and posteriorly to the occasional prolongation of the sphenoid downward within the pterygoid process and great wing, and anteriorly to the thin posterior wall of the maxillary sinus. He maintained that infection might transude from the thin bone in this situation and lead to inflammatory changes in the ganglion with resulting pain. However, he drew attention to the fact that anteriorly the sphenopalatine ganglion was in relationship with the descending palatine artery and the sphenopalatine artery with their corresponding veins, and that these structures, together with surrounding connecting tissue, formed a protective pad which separated the ganglion by some 3 to 4 mm. from the wall of the maxillary sinus forming the anterior boundary of the fossa; a finding which he thought might explain his belief that the characteristic disturbances of sphenopalatine neuralgia were more likely to follow upon inflammation of the ethmoid and sphenoidal sinus but were not at all likely to ensue from extension of infection from the posterior wall of the maxillary antrum. Soon, however, evidence appears that even Sluder himself was beginning to doubt that all cases of sphenopalatine neuralgia were really of nasal origin.

In 1910 in a communication to the Section of Internal Medicine of the St. Louis Medical Society (*New York med. J.*, 91, 850) he described two cases of typical sphenopalatine neuralgia occurring without previous nasal sinus infection and, in 1913, twelve cases of "systemic toxic origin" (*Trans. Sect. Laryng. Otol., Amer. med. Ass.*).

It may of course be true that an infection of the ganglion might follow upon infection of the nasal air cells in the manner that Sluder suggests. This is a matter upon which I would appreciate your helpful comments in the subsequent discussion. If it is true that sphenopalatine neuralgia can be a complication of nasal disease, it is equally true that paroxysmal explosive attacks of sphenopalatine neuralgia may arise as a primary condition as a variant of the more usual trigeminal neuralgia occurring in patients who have never had any evidence of nasal suppuration whatsoever.

TREATMENT

In the past, many cases exhibiting the sphenopalatine syndrome have had their treatment commenced by various operative procedures on the nose, carried out in the belief that their pain arose from nasal causes. In view of the fact that a nasal origin for this syndrome is by no means proven, I would suggest that intranasal operation should be undertaken in this condition only when positive proof has been obtained of the co-existence of intranasal infection and that operations which are exploratory in character should be rigidly avoided.

Section of Anæsthetics

[March 5, 1948]

The Present Position of Myanesin in Anæsthesia¹

Clinical Aspects

By F. BARNETT MALLINSON

SINCE the first report on myanesin, more than a year has passed. As I indicated in it (1947*a*), that report was intended to stimulate interest in and promote the acquisition of further experience with a promising agent for the advance of the technique of curarization.

It is estimated that since then more than 10,000 administrations of myanesin have taken place. There has been much comment and a number of papers, mostly favourable, which include those of Lyall (1947), Wilson (1947), Turnbull (1947), Ballantyne (1948), and Wilson and Gordon (1948), but also one or two critical, notably those of Pugh and Enderby (1947) and Hewer and Woolmer (1947).

I do not propose to waste time in further descriptions of technique, but I think it is worth while briefly to mention a few points in connexion with the use of the drug in special operations and manœuvres.

Further experience of myanesin has confirmed my opinion that there is no combination of it with pentothal which makes it a worth-while aid to intubation under that anæsthetic. I would add that I am also confirmed in the opinion I expressed here last year (1947*b*) that there is likewise no combination of curare with pentothal for this purpose that is both effective and justifiable.

My opinion is confirmed that myanesin will abolish laryngeal spasm; but for it to be really effective the patient must be actually under anæsthesia, and not merely in the second stage.

The statement that myanesin is usually effective in first plane anæsthesia still holds good but with one notable exception. Patients who have an irritated peritoneum, such as those with perforated peptic ulcer, need anæsthesia in the second plane, to secure really good relaxation.

Generally speaking the principal field of use for myanesin remains that of abdominal surgery. Exceptions are the operation of hæmorrhoidectomy, where a combined injection of pentothal with myanesin produces a perfectly relaxed and patulous anus; and colpopræneal repairs.

I have also found myanesin useful in securing a relaxed and tranquil pharynx in tonsillectomy performed under the now widely adopted technique of pentothal and intra-tracheal gas-oxygen. The need for supplemental ether in children is thus entirely eliminated, even in young children anæsthetized without intubation in whom I have used a pentothal-myanesin mixture with satisfactory results down to the age of 3 years. In the absence of etherization this technique ensures a rapid recovery of the cough reflex because less pentothal is needed. For children I make up a mixture to 20 c.c. with pentothal 1 gramme and myanesin 1 gramme (10 c.c.). This mixture is used for a slow induction and the needle kept in the vein throughout the operation while gas-oxygen is insufflated through the Boyle-Davis gag; $\frac{1}{4}$ -1 c.c. of the mixture is added as it is needed. The same mixture is also useful for ophthalmic surgery in children under general anæsthesia, because it eliminates the tendency to sudden twitching movements which are characteristic of pentothal anæsthesia in them unless carried dangerously deep.

For anæsthesia in cesarean section, 0.25 gramme pentothal with 10 c.c. of myanesin are used for induction followed by gas-oxygen; as a result of the minimal amount of pentothal the babies are born in a satisfactory state of vigour (Table I) whilst a quiet and smooth anæsthesia for the mother under gas-oxygen only is assured.

¹The paper read by Dr. S. W. F. Underhill at this meeting will appear in *Anæsthesia*.

a local pain and he came to the conclusion that it was due to a periostitis, possibly following upon absorption of bone subsequent to extraction. The treatment was to incise right down to the bone, and that procedure was successful in a few cases only. The relief afforded by injections of novocain was temporary. These cases often occurred in nervous, anxious women.

Infra-orbital neuralgia was a rare condition and was purely subjective. There were no visible signs and he believed these cases were part of a trigeminal neuralgia and the pathology or aetiology was obscure. There was nothing in the nose that he had found to account for the pain and nothing objective in the face. The pain in the auriculo-temporal nerve from a lower molar tooth or some painful condition of the mandible was very characteristic. It spread to the ear and the side of the head, almost up to the vertex. No local cause could be found in most cases of sphenopalatine neuralgia. He considered that it was a part of trigeminal neuralgia. He had not seen sphenoidal sinus suppuration or neoplasm accompanied by sphenopalatine neuralgia.

The speaker recalled a visit he had paid to a clinic in Paris, when some cases of sphenopalatine neuralgia were shown. These patients were treated by the application of wool soaked in cocaine on the area of the ganglion. They returned regularly to the clinic for their treatment and appeared to become cocaine addicts.

Another type of case which was difficult was the patient who complained of pain near the intra-nasal antral window made in the inferior meatus by an operation. He believed that this was due to scarring involving one of the dental nerves.

J. A. Harpman, after referring to the use of cocaine on the sphenopalatine ganglion area for pain which in some cases he thought was vascular in origin, possibly sometimes with an allergic basis, said that it was now widely accepted that in some pain syndromes a peripheral interaction takes place between sensory nerve fibres subserving pain and sympathetic nerve fibres. He quoted some observers (e.g. Pollock) who, he thought, had found that sufferers from sphenopalatine ganglion neuralgia were not always relieved by cutting trigeminal nerve fibres. For these pains medical lines of treatment, such as the administration of nicotinic acid, benadryl or salicylates, frequently helpful for a while, often eventually failed to relieve. In women, sphenopalatine ganglion neuralgia was occasionally found to be worse just before a menstrual period and could then sometimes be relieved by progesterone. But by far the most satisfactory line of treatment he had yet found was cocaineization of the sphenopalatine ganglion region followed by treating it with 1% to 2% silver nitrate solution; stronger solutions were liable to be irritating and sometimes caused a temporary flare-up of the pain.

G. C. Knight, in reply, said that Mr. Davis had asked him whether he had encountered ulceration of the nose in association with sensory root section. He had seen herpetic ulceration in the nose follow this operation.

Another speaker had brought up the question of the pathway of the sympathetic as a means of conducting pain. It was perfectly true that pain could be referred through the sympathetic, but he would not accept for one moment that the persistence of pain after sensory root section necessarily meant that it had found its way back through the sympathetic. Anybody who had done trigeminal root sections would admit that he was bound to miss a few fibres occasionally. There might be just one or two fibres left but it was quite amazing what an area those fibres could supply. It seemed to him that pain in the face and palate could not be sympathetic in origin, but pain in the shoulder and neck might be a referred pain.

Film: Lesions of the Larynx

G. Ewart Martin introduced a film of lesions of the larynx prepared by Dr. Louis Clerf of Jefferson Hospital, Philadelphia, who had kindly lent the film for exhibition in this country.

The film first showed a normal larynx. This was followed by vocal nodules and papilloma of the larynx and also papilloma of the trachea coming up between the cords. Following on this there was a case of keratosis of the cords; of carcinoma of the cords and epiglottis; and of tubercle of the larynx. That part of the film which showed tubercle of the larynx was, perhaps, not so instructive because any duplication of a colour film tended to emphasize the reds and the photographs of the tubercle of the larynx did not show the characteristic pallor. Paralysis of the cords was also filmed and a very interesting case of functional aphonia, and finally injuries to the larynx.

Ewart Martin said that Dr. Clerf's film indicated a means of teaching students the appearance of the more common lesions of the larynx which was more impressive than drawings or even actual still photographs. Dr. Clerf had already published his method of filming the larynx with indirect laryngoscopy. The advantage from the teaching point of view was that it showed a mirror image of the larynx exactly as would be seen on indirect examination. It illustrated the difficulties that the student or practitioner might have in viewing the appearance and movements of the cords.

The film was also shown with the idea of stimulating those interested in cine photography to record their cases of lesions of the larynx.

The only serious worry I have encountered has been in connexion with possible hæmolytic and, as a result, possible derangement of kidney function. After over a hundred perfectly satisfactory cases, one patient (a boy aged 9 years) suddenly passed an apparently bloody urine. This was unfortunately thrown away before I could obtain it for pathological investigation. The phenomenon was not repeated and the patient made an uninterrupted recovery. The urea concentration tests before operation and five days afterwards and again a month later failed to reveal any alteration in kidney function. About this time also, following a very long and difficult hysterectomy during which severe hypotension and shock developed, another patient passed one apparently bloody urine. Again owing to poor staff work the specimen was lost (it had been reported as definite *hæmaturia*) but the patient proceeded to develop uræmia and died on the eighth day from pulmonary oedema and heart failure. The cause of this death was not satisfactorily cleared up until I was able to obtain a kidney section which I submitted to E. M. Darmady who has done such brilliant work on traumatic uræmia (1946, 1947a). He demonstrated to me conclusively that this case belonged to the traumatic uræmia syndrome, the appearances of the kidney section being typical of his classical description of "crush syndrome without crush injury", also described by Bywaters and Belsey (1942) amongst others, and a conception now well recognized. It has been considered to be due to renal anoxia following severe hypotension from hæmorrhage or shock by most workers, notably Bywaters and Beall (1941), Darmady *et al.* (1944), Macgrath, Harvard and Parsons (1945), Phillips *et al.* (1946), and Selkurt (1946). By Trueta, however, it is suggested that the condition may be due to renal ischæmia resulting from afferent stimuli (1945). The cause of death in this case then was clearly unconnected with myanesin.

It is also worthy of note that in this case pigment was conspicuous by its absence in the section, indicating that there was none in circulation and thus that there had been no hæmolytic. A second case occurred soon after this with an identical train of symptoms, also following a difficult and very prolonged shock-producing operation, for gall-stones. This patient, after remaining ill for some weeks, recovered after dialysis by Bywaters on the Kolff artificial kidney (Bywaters and Joekes, 1948). Her cardiac and general condition were much better than that of the first case. Subsequent investigations have shown only slight renal damage still persisting and I consider that this patient should undoubtedly also be labelled post-operative traumatic uræmia. After these cases imperative instructions were issued to those responsible regarding the saving of abnormally coloured urines, following myanesin injection and a number of investigations were started.

First, a series of exhaustive analyses was made of the urines of patients who had received myanesin. Two of these urines showed an apparently bloody appearance and several were very dark, as will be seen in Table II. Special emphasis was laid on the presence or absence

of iron in these analyses. According to Dr. F. M. Berger who performed the analyses (1947) in no case was a band denoting the presence of iron detected with the Hartridge reversion spectrocope.

Second, urea clearance estimations were carried out on a further series of patients before and five to seven days after operation, (a) after myanesin, (b) after various other anaesthetic techniques. As will be seen from Table III nothing could be concluded from this investigation

Apart from surgery, myanesin has been used in a variety of medical states from different spastic conditions in which Buckley Sharp (1947) has achieved some success by oral administration, to tetanus in which Belfrage (1947) has had encouraging results. In one case of tetanus in a boy aged 9 years, the dosage, compared to surgical doses, was enormous; no less than 78 grammes (780 c.c.) in five days. This patient recovered.

A very recent and exceedingly interesting development has been the use of myanesin in veterinary surgery. Mrs. M. Sheppard, M.R.C.V.S., has found it of considerable advantage for abdominal surgery in cats and dogs (1948). Relaxation is obtained with less than half the usual dose of pentothal (the standard anæsthetic technique in this work) with consequent marked improvement in mortality of poor-risk patients.

A number of anæsthetists have commented that myanesin causes respiratory depression. I have not found this to be the case in my own experience; but I have found that the central respiratory depressant effect of pentothal is potentiated by myanesin, and that a short period of apnoea can easily occur when both drugs are given together in the course of an anæsthesia. Potentiation of the one drug by the other was described by Berger and Bradley (1946, 1947) in their work with myanesin on animals. This phenomenon is a *central* depression similar to that produced by pentothal alone and dealt with by intermittent pressure on the rebreathing bag for a minute or two disappears as readily. To the modern anæsthetist then, it is without significance.

It is very different from the dangerous state of *peripheral* respiratory failure with flaccid and toneless thoracic musculature, and loss of resilience and elastic recoil, so disconcertingly like the state of the apparently drowned, which one often experiences as the result of a big dose of curare, and which for reasons I have previously stated here (Mallinson, 1947c) is in my view a frequent cause of serious post-operative morbidity and a major contributing cause of death following the latter drug.

An interesting characteristic of myanesin is that the divergent eyeball sign of first plane anæsthesia is not markedly affected by it, which helps to differentiate between first and second plane anæsthesia when using the curarization technique.

It has been suggested that myanesin causes increased bleeding. No reasons accompany this suggestion in so far as I am aware. This sort of controversy has for years raged round every new anæsthetic introduced, most notably cyclopropane; and in regard to the latter agent still seems far from being settled. One cannot see how the point ever can be settled until a very large series of cases is studied in which all the many variables are controlled in each case—a formidable task. Personally I must record the fact that there have been no complaints about increased bleeding from the surgeons to whose cases I have administered myanesin.

At a meeting of the Section of Anæsthetics held here on April 11, 1947, several speakers reported an alarming series of cases of spreading thrombosis and phlebitis following myanesin. I have found thrombosis of a vein exceedingly uncommon after myanesin both personally and by report, comparable with its incidence after the administration of pentothal; I have never seen phlebitis. I think the answer to this question as regards both drugs is to be found in the technique employed. A fine needle (16–17 gauge hypodermic) *really sharp*, a quick and accurate entry into the vein (all factors which minimize trauma to the vein), and a slow steady injection at about six to eight seconds per c.c. (for the solution is hypertonic) will ensure that the operator is rarely troubled with thrombosis.

In my own experience of some 1,500 myanesin injections I have only once or twice encountered thrombosis of limited degree, not developing into phlebitis, and I have no idea as to whether the lesion occurred at the site of a pentothal or a myanesin injection. I have had several patients come to operation with veins already thrombosed by uroselectan injections, blood transfusions, &c., but these have not developed any further lesions with myanesin. It seems to me in any event that a great deal has been made of a minor complication which is after all, according to Dickson Wright (1948), “annoying rather than dangerous” and is rarely even noticed by the patient.

no definite hæmolysis in this mixture, even after incubation for forty-five minutes, the curve this time showed rupture commencing at 0.65% which was complete at 0.5%. This indicates that myanesin in sufficient concentration (4%) renders the red cells more fragile and therefore that they will hæmolyse more readily when subjected to the trauma of withdrawal through a needle and squirting into a glass vessel. It does *not* indicate that myanesin causes hæmolysis *in vivo*. It suggests that the hæmolysis observed by Pugh and Enderby might have been an artefact. Further experiments by Dr. Gray on the blood of patients receiving myanesin during operation strengthen this suggestion. Samples of blood were withdrawn from a series of 20 patients during anaesthesia, before the administration of myanesin (to serve as a control) and at varying intervals afterwards. A method was devised of estimating the proportion of free hæmogoblin present in the serum of the samples, using King's methyl red standard for bilirubin. No hæmolysis could be observed with the naked eye at readings below 1.4; therefore readings below 1.4 can be taken as clinically normal. To avoid the tedium of considering a whole series of tables from 20 patients with similar readings, the results are averaged here in one graph (Graph I). The highest reading in the

GRAPH I.—Degree of hæmolysis in samples of blood withdrawn after myanesin 10% — average of 20 cases.

whole series was 6.4, the lowest control reading was 0.3. Now if hæmolysis took place in the body on the injection of myanesin it would surely show its maximum effect almost immediately, as the liberated hæmogoblin spread rapidly through the circulation. If on the other hand the effect of myanesin was not to liberate hæmogoblin but to cause increased fragility of the red cells, as is suggested by Dr. Gray's first experiment, one would expect the number of cells rendered more fragile in the samples (and therefore the degree of hæmolysis produced on their withdrawal) to increase slowly, as the damaged cells spread throughout the circulation up to a maximum and then to start falling as these damaged cells were removed from the blood-stream by the reticulo-endothelial system. Such in fact is the case. There is little evidence of any hæmolysis in the sample withdrawn ten minutes after the administration of myanesin. The maximum is reached only after twenty minutes on the average from the time of the injection. At thirty minutes the reading is falling, and at forty minutes it is still falling. In my view therefore the experiments described by Pugh and Enderby to show that hæmolysis is caused *in vivo* by a dose of myanesin injected at a reasonably slow rate (say six to eight seconds per c.c.) into a rapidly moving blood-stream in a vein the calibre of an antecubital vein are fallacious; and their conclusion that myanesin is a dangerous drug to inject is unsubstantiated. Belfrage (1947) records that his tetanus cases (referred to earlier) had no evidence of hæmolysis despite the colossal doses they received. Furthermore I have not myself as yet been able to adduce any sure evidence that the colour in the urine is due to hæmogoblin, with one notable exception. In a third coloured urine obtained since the urine analyses described earlier, iron has been detected by chemical analysis. The proportion was not large, 1.6 mg. in a 250 c.c. specimen, equivalent to 6.4 mg. per litre. The normal content of iron in the urine is given by Hawk, Oser, and Summerson (1947), as varying between 0.7 to 3 mg. per litre, or 1 to 5 mg. daily. This patient had also received, at the same time as the myanesin injected, no less than 20 c.c. of 30% lithocaine into a varicose vein. This substance is a known hæmolysant and according to Foote (1948) should never be employed in doses in excess of 5 c.c.

Whilst the possibility of occasional slight hæmoglobinuria due to a slight degree of late hæmolysis of some of the fragilized red cells cannot at present be excluded (and so far as

U.C.T. = Urea Clearance Test.

except that some deterioration of renal function after operation and anæsthesia appears to be frequent though not invariable, as is well known from the work of Beecher (1938), Hawk, Orth, and Pohle (1941), Darmady (1947*b*), and others, and that this deterioration cannot be definitely related to any particular anæsthetic though it appears to be more marked after spinals and is possibly related to some extent to the degree of trauma.

About this time there appeared a paper by Pugh and Enderby (1947) describing "apparent hæmoglobinuria" following myanesin administration and experiments to demonstrate the occurrence of hæmolysis with myanesin *in vitro*. No details were given as to the methods of handling the blood in these *in vitro* experiments, such as the anticoagulant employed, whether the cells were washed, &c., and no account seems to have been taken of the degree to which these or other factors such as trauma to the red cells on withdrawal through a syringe and needle may have been responsible for the hæmolysis thus demonstrated. Deductions were made from this hæmolysis *in vitro*, postulating a dangerous degree of hæmolysis *in vivo*; supported by one or two isolated experiments in which myanesin (diluted with distilled water, itself a hæmolytic agent) was injected into a wrist vein (almost certainly a vein of small calibre) and at an unknown rate, and blood simultaneously withdrawn from a vein immediately above. These experiments of Pugh and Enderby, however, contained another fallacy, which was demonstrated to me by Dr. Davidson Gray (1947) whose interest and unselfish help I gratefully acknowledge. Dr. Gray plotted a fragility curve with washed red cells from a normal person suspended in normal saline. The curve was within normal limits, no cells rupturing in falling concentrations of NaCl down to 0.45%. This curve was repeated with more of the same cells whose suspension had been made up to contain myanesin in 2% concentration. The mixture was incubated with the cells for forty-five minutes. The fragility curve was the same. The same experiment was again repeated this time using 4% myanesin-saline suspension. Although there was

NPS = No Pulmonary Symptoms.

I am aware fewer than 20 cases with apparently hæmoglobinuric urine have so far been reported out of an estimated 10,000 administrations of myanesin) it is known that coloured degradation products of myanesin occur. In addition small quantities of red and brown oily-like substances have been extracted from perfectly normal urines of patients, following myanesin administration, by Hartley and Bradley (1948). This suggests that in some patients, possibly with an inborn variation of metabolism, myanesin like some other chemical substances is capable of colouring the urine. In the majority of patients passing coloured urines then, it seems likely that an explanation on these lines must be sought and the matter needs further investigation. In the minority of cases, if true hæmoglobinuria can be proved, one must consider the possibility that it is due to a few fragilized cells suffering delayed rupture in a patient whose red cell fragility is greater than normal. In the meantime it is clear that these urines, when they do make their rare appearances, need to be examined with the utmost caution before they are labelled hæmoglobinuric.

It can be predicted, however, from our experiments that the slower the rate of injection of myanesin or the smaller the percentage of the drug in the injection the less will be the proportion of fragilized cells circulating. In order to confirm this prediction a further series of cases was studied on the lines of Dr. Gray's second experiment, using 1% myanesin. There was no evidence of hæmolysis in the samples after their withdrawal from the circulation and therefore no increased fragility of red cells produced by 1% myanesin. This chart (Graph II) is typical of the series. The administration of 1% myanesin is simple and trouble-

GRAPH II.—C. H., aged 50. Gastrectomy. Degree of hæmolysis in samples of blood withdrawn after myanesin 1%. Anæsthesia: Pentothal 1.3 g.— N_2O-O_2 —myanesin 1%. Total pentothal: 1.35 g. Total myanesin: 300 c.c. 1%.

free. The apparatus for continuous pentothal described by Macintosh and Pask (1941) has been adapted for the purpose. The screw-topped bottle is graduated in units of 20 c.c. and 100 c.c. up to a half litre. Filled with normal saline it is autoclaved. 50 c.c. of myanesin solution are added before use. Thus each 20 c.c. of the solution is equal to 2 c.c. of myanesin 10%. If all the solution is not used during an operating session the remainder can be re-autoclaved and kept for a subsequent occasion. A larger needle is advisable to get a rapid flow; 1 gramme myanesin can thus be administered in two to three minutes.

I should like to record a series of abdominal and perineal cases illustrating the clinical results of the use of myanesin as a muscle-relaxant. This series consists of 310 cases and is a small one for two reasons. First because it only includes cases in which myanesin has been employed when a relaxing agent was really needed and contains no amputations, orthopædic operations and the like. Secondly it consists only of those cases which could be adequately followed up and excludes many nursing home and other patients where time, distance, or lack of reliable assistance precluded accurate observation. Table IV indicates the types of operation and anæsthetic concerned; the risk distribution is also shown, and by its proportion of B and C grades emphasizes that there has been no bias towards selection of favourable cases.

The same may be said of the age distribution. The age range of myanesin has been from 3 to 90 years. Table V shows the incidence of post-operative vomiting which has been satisfactorily low, when the high proportion of gynæcological cases (generally agreed to have a high vomiting rate according to Russell Davies (1941) and others) is noted. Table VI shows the incidence of post-operative pulmonary complications. The figures are higher than those I published in 1943 and 1944, not only because the age-groups are higher than one's wartime patients, but also because one is now dealing with a civilian population debilitated by a long period of rationing, and in the last two years by an actual and increasing shortage of good food. Here again one type of case, the hernia, well known as having a high morbidity rate, is responsible for a high proportion of the total complications, no less than half its group in fact. Even so the percentages are well below the best of Lucas's series (1944) on chest complications in hernias. It may also be observed that *no complication* of any severity occurred in any patient whose respiratory tract was healthy before operation. This illustrates well the advisability, often stressed but seldom acted upon, of postponing elective operations, whenever possible, till the respiratory tract is satisfactory.

DISCUSSION

To define the present position of myanesin as a therapeutic agent is not easy. It seems to me that we still have a long way to go both with curare and myanesin before a true evaluation of either is possible.

There is no question in my hands of the efficiency of myanesin as a muscle relaxant under light anaesthesia. The papers published and already referred to are in agreement on this point. The summarized opinion of my surgical colleagues is that relaxation with myanesin is as good as with curare. Both drugs have their disadvantages. Some of those associated with curare are formidable. Bronchospasm now seems established as a characteristic reaction of curare according to the work of Landmesser (1947) and although clinically it does not appear to be so common as might be expected, it is an exceedingly dangerous state of affairs when it does occur. Another potentially dangerous characteristic of curare described by many writers including Gross and Cullen (1945), Landmesser (1947), Durrans (1947), Dawkins (1947), and Lyall (1947), is its capacity for producing severe post-operative hypotension. Satisfactory relaxation without complete intercostal paralysis is often difficult to achieve with curare, and not infrequently there is diaphragmatic paralysis as well. These are phenomena to be avoided unless there is a very good and sufficient reason for their toleration. It has been suggested that, *inter alia*, one of curare's greatest disadvantages, largely as a result of the aforementioned characteristics, is the imperative need for its employment to be restricted to the experienced administrator.

All this, however, is not necessarily to condemn the use of curare. Many other anaesthetic agents in common use to-day have astonishing potentialities for causing damage; far greater than those of curare. Much cerebral congestion amongst anaesthetists has been caused by the introduction in myanesin of a drug which possibly causes occasional slight haemoglobinuria, ignoring the fact that a number of drugs employed every day are known haemolysants and producers of haemoglobinuria such as lithocaine, N.A.B. and many others. It might be worth while to recall that Coller and Eastman (1943) showed that cyclopropane anaesthesia was attended by a significant decrease in glomerular filtration rate, and that this phenomenon associated with blood loss or shock could cause sufficient hypotension to result in total renal failure; and not infrequently resulted in renal impairment lasting up to a week. Again, Bastedo (1932) states that patients may occasionally develop nephritis with albuminuria and haematuria after ether anaesthesia, and MacNider (1920) described anuria following ether in 43 out of 131 dogs. Finally Underhill (1948) has shown that even pentothal appears to be capable of marked haemolysis.

With curare the number of deaths so far reported added to the unofficial deaths make up no mean total. Although curare and myanesin are both highly efficient relaxants in light anaesthesia, the hazards of the former (if the number of deaths only is considered) seem to me to be significantly greater than those of the latter. Furthermore, although curare has an undoubted place in the anaesthetist's armamentarium, its dangers and critical dosage circumscribe its general application and restrict its employment only to the highly expert. Myanesin on the other hand has a very wide margin of safety in dosage and 10,000 administrations have brought to light no deaths clearly resulting from its employment and only one significant possible complication. That possible complication, haemoglobinuria, would appear to be rare, and in any event its dangers seem to me to have been perhaps a little exaggerated.

Thus I would suggest from our experience up to date of myanesin that its continued use as a muscle relaxant in anaesthesia is at least as justified as is that of curare; that it can with advantage replace curare for many purposes; and that on balance it has increased the safety of the technique of muscle-relaxation by the method of "curarization".

averaging only 1.12 grammes for an average operation time of seventy-two minutes. The benefit of these minimal amounts of a potent anæsthetic agent is reflected in the improved general state of the patients after operation.

There have been six deaths in this series occurring within seven days of operation, or from complications arising within that period (Table VIII). I think it will be agreed that the

TABLE VIII
Post-operative Deaths: First Seven Days

Age and Sex	Operation	Risk	Condition	Opn. time	Time death	Cause and post-mortem

Dr. G. E. Hale Enderby: Dr. Mallinson has tried to persuade us that the hæmolysis occurring with myanesin does not matter. He also apparently goes so far as to doubt whether hæmoglobinuria does occur, and whether the work which Dr. Pugh and I did on this subject is, in fact, correct. In answer I must refer Dr. Mallinson to our publication (Pugh, T. J., and Enderby, G. E. Hale, 1947, *Lancet* (ii), 387), where all the details of our experiments are given, which show conclusively that hæmolysis occurs in the blood-stream, and hæmoglobin has been found in the urine of three cases.

Mention was made of hæmolysis following such commonplace injections as pentothal, and I must agree that it does occur to a very small extent with this drug. However, it is obvious that the degree of hæmolysis is the important factor, and with myanesin the hæmolysis is immediate and extensive, accompanied by an alarming protein precipitation. Those who still use this drug must have observed the immediate lysis occurring in the syringe following aspiration of blood, and how different this is with pentothal, where half an hour may show little change. I personally know three anæsthetists who will not use this drug again, for they consider it very dangerous.

I would repeat the suggestion I originally made to British Drug Houses that they investigate whether it is the drug itself or the solvent which is producing these undesirable effects. It appears to me that the solvent may be the cause, for it is made up of many chemicals (which I call "anti-freeze"), and furthermore the oral myanesin which has no solvent does not apparently produce these effects.

I must thank Dr. Mallinson for his courage in presenting the details of the fatal cases which he has had. He ascribes death in two of them to traumatic uræmia, which facile explanation I personally cannot accept, particularly in view of the case reported by Hewer and Woolmer (1947, *Lancet* (ii), 909). I consider these cases have a direct relationship with the observed phenomena of hæmolysis and protein precipitation.

Dr. Mallinson mentions the boy with tetanus who received large doses of myanesin. Is it not true that this case developed a complete anuria, but eventually recovered?

Dr. T. Cecil Gray expressed gratitude to Dr. Mallinson for his interesting paper and for giving the Section the opportunity to discuss this dangerous substance, and went on to state that he had had experience of only a small series of cases anæsthetized with the help

of myanesin. The series was small because it very soon became apparent both to himself and the surgeons that in reasonable dosage this substance was ineffective in adults and potentially dangerous.

It was ineffective because in a light plane of anæsthesia it did not give good relaxation. The purpose of a relaxant drug should be to give good operating conditions using only minimal amounts of toxic anæsthetic agents. This myanesin did not do. In regard to its potentiation of the barbiturates it was his experience that this substance did not in any way enhance their analgesic powers and the potentiation was only evidenced by a longer time of narcosis post-operatively which was undesirable.

Myanesin was potentially dangerous because of its hæmolytic properties about which a great deal had already been said, and although Dr. Mallinson stated that many drugs have hæmolytic properties the fact remained that there was yet to be reported a case dying from renal failure due to hæmoglobinuria following the use of thiopentone or of any other anæsthetic agent. In Dr. Mallinson's series it was said that the hysterectomy case had died as a result of traumatic uræmia. Surely this complication following hysterectomy must be very rare indeed, and it would seem more reasonable to attribute the uræmia to the known properties of this new agent.

Moreover, myanesin was dangerous because of the incidence of thrombosis which followed its use and he had had one very severe case of this complication. This occurred in a man of 62 undergoing a gastrectomy for carcinoma who received 1.2 grammes of thiopentone and 40 ml. of myanesin. As could be seen from the slide [shown] the forearm and hand on the evening of the operation were grossly œdematous and violently discoloured. Every vein right up to the axilla was thrombosed. In this case there was no question of intra-arterial injection for the injections were given through an intravenous drip and the arterial side of the circulation was undamaged. It was only by the greatest good fortune that the arm recovered.

Dr. Mallinson would doubtless point out that this might be attributable to the thiopentone, but which of those present with all their collective experience had ever seen such a picture following the use of thiopentone administered through large or small needles by rapid or slow injection.

Dr. Mallinson said that myanesin had proved of great use in veterinary surgery; it might be better if the ampoules of this substance were labelled "For use in veterinary surgery only".

Dr. A. J. H. Hewer: Two experiments were performed on cats in which 25 mg. of myanesin per kilogram body-weight were given in a 1% solution at a standard rate.

In the first cat experiment the solution was prepared by diluting the 10% solution supplied by the makers down to 1% with normal saline.

In the second experiment, a 1% solution of myanesin powder was made in normal saline. Blood taken from the first cat five minutes after injection showed more hæmolysis than that taken from the second. This suggests that the solvent is capable of causing hæmolysis as well as myanesin itself.

Dr. A. R. Hunter said that Miss Waterfall and he had been able to do some work on myanesin at the Manchester Neurosurgical Unit.

Their interest in the possibilities of the use of myanesin in hyperkinetic states was aroused when he had had the misfortune to produce, by the injection of 30 c.c. of myanesin (a dose which was entirely necessary to produce adequate muscular relaxation in the patient concerned), a simultaneous failure of circulation and respiration which was almost certainly of central origin. This was at once reversed by the intravenous injection of 5 c.c. of nikethamide, which, in addition, abolished the muscular relaxation. Since most analeptic drugs were also convulsants, acting centrally on the brain, he decided to try the effect of myanesin in various hyperkinetic states. Miss Waterfall and he had given the drug on several occasions to patients in status epilepticus, and found that the convulsions ceased almost immediately after its injection. Further, the time which elapsed between the injection of the drug and the cessation of the fits was exactly the same as that which had elapsed on previous occasions, when thiopentone or hexobarbitone had been given for the same purpose. Myanesin was also given to a woman with Parkinsonism, and her movements ceased, but the dosage necessary in her case was about three times that required to make epileptiform convulsions stop. Respective figures were 26 mg. per kilo, and 8 mg. per kilo. Dr. Stephen, of the Montreal Neurological Institute, has also given myanesin to patients with Parkinsonian tremors, and found a like dosage necessary to arrest the movements. He also noted that the drug relieved thalamic pain. He was able too to do electro-encephalograms on his patients and found that myanesin had no effect on the cortical action potentials. In addition he carried out, with Dr. Chandy, a series of observations on

the action currents of muscle and nerve after direct and reflex stimulation under myanesin, and was able to show that the drug had no effect on these phases of neuromuscular activity. It therefore seemed, on the evidence available, that myanesin acted mainly on that part of the brain which gave rise to epileptic activity, and to a lesser extent on the portion which caused the movements of Parkinsonism. The time required between its injection and the appearance of its action was the same as that required for other drugs acting on the cerebrum. It was therefore reasonable to conclude that myanesin affected mainly the motor apparatus of the basal ganglia.

Dr. Ronald Woolmer said that he would like to associate himself with the remarks of Dr. Cecil Gray. He had found the muscle-relaxing effect of myanesin disappointing. Large doses had to be given to produce satisfactory relaxation, and even then the effect was fleeting and uncertain.

Dr. H. W. Loftus Dale had records of 150 cases, 148 before hæmolysis report and two after; one of the latter developed methæmoglobinuria (Report from laboratory).

The operations in which myanesin had been used were lower abdominals, appendices, suprapubic cystotomies, prostatectomies, oophorectomies and myomectomies. The action was found to be unreliable; relaxation might be good in one case and in a similar case poor or absent, or good until the surgeon produced some stimulus, such as pulling on a mesentery, when the abdomen would close on his wrist like a rat trap.

Since the results which anæsthetists were obtaining with curare were eminently satisfactory from every angle, the surgeons were unwilling to risk myanesin on an upper abdominal operation, hence none were included in this series.

Relaxation of skeletal muscles and abdominal muscles in the absence of stimulation of the peritoneum was found to be good, hence some use was made of myanesin in gynæcology, good relaxation obtained for examinations under anæsthesia and it was a help in getting the patients into the lithotomy position, less thiopentone being required.

In obstetrics, in one case of external version, there was complete failure to get any relaxation which was finally obtained by the use of no less ether than had this agent been used by itself. Dr. Loftus Dale himself did not see this case which had been handled by a competent resident anæsthetist.

In orthopædics myanesin had been used in three cases of manipulation of the spine; the surgeon had put the patients through the most amazing contortions with great ease and facility with the addition of 0.5 gramme thiopentone.

In six cases of major fractures in muscular males, reduction had been effected with great ease under minimal amounts of thiopentone. One unusual case was that of a bull-necked heavily built man with trismus due to a quinsy; 1 gramme of myanesin and a little general analgesia with trilene enabled his mouth to be opened and the situation dealt with in a most satisfactory manner both as regards safety and comfort.

Complications: There were three deaths in the series, none of which was associated with anæsthesia. There were three post-operative "chests", two following male herniorrhaphies and one termination of pregnancy and sterilization in an insane female. In this last case the very large amount of sedatives required both pre- and post-operatively would appear to be the cause.

There were three cases of venous thrombosis, two minor and one very extensive.

The number of cases in this series is too small to justify any conclusions, but, when added to the findings of other workers, may be of some value in assessing the merits or demerits of the substance in question.

Dr. O. P. Dinnick: Myanesin was used for a short series of abdominal cases as a supplement to thiopentone and N_2O-O_2 anæsthesia. The use of the drug was abandoned before the series was completed for the following reasons: (1) The relaxant effect was not nearly so pronounced as that produced by curare or by an intercostal block, and the surgeons commented adversely. (2) The post-operative stupor or sleep was prolonged. (3) There was obvious damage to veins.

In one case thrombosis developed during the operation and spread within half an hour from the site of injection in the forearm up to the shoulder. Next day there was marked inflammation along the infected vein—there was, however, no retrograde or collateral spread of the thrombus. The patient recovered without evidence of emboli.

In two other cases the veins for several inches proximal to the injection site developed a "stickiness" of the intima, and became like perished rubber tubing. In one of these cases the condition was followed by a thrombosis.

In all these cases only myanesin had been injected into the affected veins. The pentothal was injected into adjacent veins which developed no immediate or post-operative thrombosis.

There was one post-operative death in this series—in a trained athlete aged 26 with a carcinoma of the rectum. At laparotomy, when 30 c.c. of myanesin failed to give really satisfactory relaxation, the growth was found to be inoperable and a left iliac colostomy was performed. The condition of the patient next morning was satisfactory, but he died five days later with a blood urea of 350 mg. %. Post-mortem examination was refused. Pugh and Enderby's paper (1947) had not then been published, but his urine was not reported as being discoloured.

Dr. Dinnick hesitated to present this case with so little pathological evidence, and hesitated even more to draw any conclusions. He would only say that their clinical impression—like that of Hewer and Woolmer (1947)—was that this death was unexpected and that the myanesin could not be exempted from suspicion.

It would appear that there were definite risks inherent in the administration of myanesin, and he would say that this drug, in the form at present supplied, had no place in clinical anaesthesia.

 PUGH, J. L., and ENDERBY, G. E. N. (1947) *Lancet* (ii), 387.

Dr. H. Bruce Wilson said he had initiated an investigation at the Royal Aberdeen Hospital for Sick Children into the properties of myanesin primarily to determine if the drug were effective, and secondly, did it harm the patient? To determine the first, they took a series of children suffering from acute appendicitis, gave them identical premedication, induced anaesthesia with nitrous oxide, oxygen and ether, intubated them with a tube lubricated with nupercaine paste, and then lightened the anaesthesia to Plane 1. At this stage as would be expected, relaxation of the abdominal muscles was not present, but on the surgeon reaching peritoneum, a dose of myanesin was injected, and in all cases except 3, in a series of 60, adequate relaxation was obtained. In those cases where relaxation was not obtained, the anaesthesia was deepened, and the important finding was that relaxation was achieved at a lighter plane of anaesthesia than if myanesin had not been used. This satisfied them that myanesin had the power of lowering the tone of the abdominal muscles and allowing the surgeon adequate conditions for operating. He would emphasize that the relaxation obtained with myanesin was not to be compared with the extreme relaxation which one obtained when using *d*-tubocurarine chloride, but he felt it to be an honest clinical finding that there was lowered tone of the abdominal muscles when myanesin was used.

To determine if the drug had any harmful effect, they charted all cases on Nosworthy Cards, did routine pre- and post-operative urinary examinations, and, in addition, routine urea clearance tests. All these proved negative. It was only after Pugh and Enderby's report of haemoglobinuria that they carried out spectroscopic tests of the urine (these were negative) and examination of the blood before induction of anaesthesia, once anaesthesia was established, and after myanesin had been injected. They found that in every case where myanesin was introduced into the blood-stream, some degree of intravascular haemolysis occurred, along with a definite increase in the fragility of the red blood cells. As the patients showed no clinical ill-effect and no abnormal urinary constituents were discovered, they felt justified in proceeding with the investigation. Since the publication of their initial report, they had had two cases of haemoglobinuria but with no apparent ill-effect. They felt that the solvent and not the myanesin itself was the agent responsible for the haemolysis. Colleagues had been using oral myanesin in orthopaedics and had had no ill-effect. Further investigation into the question of haemolysis was required before one could confidently employ myanesin.

Dr. F. Barnett Mallinson in reply: Dr. Enderby will remember that in the text of the paper I have just read, I was careful to avoid stating that myanesin does not cause haemoglobinuria; only that I had not, as yet, any certain evidence of it.

I think Dr. Underhill has demonstrated conclusively that *in vitro* experiments cannot be applied to this problem—otherwise we must stop using thiopentone, a strong haemolytic *in vitro*.

With regard to Belfrage's case of tetanus: the boy did not develop anuria. A severe drop in urine output was recorded (not a surprising thing in a patient so gravely ill).

Myanesin was stopped following laboratory findings on the blood urea the figures of which were afterwards found to have been erroneously reported.

Dr. Gray starts off by referring to "this dangerous substance" even before he attempts to show that, in fact, it is so; thus one is immediately led to suspect a biased approach. Dr. Gray then tells us that myanesin is ineffective, but admits that he has only used it in a few cases. Regarding these points then he answers himself. I can only suggest to him a perusal of the half-dozen papers I have just quoted in which the authors' careful study of the drug is manifested by the properly recorded series of cases with which they support their favourable opinion.

I should like to pay tribute to Dr. Gray's work on curare which shows very properly his enthusiasm for this substance, following the recent use of which the reported (and unreported) deaths have already caused a considerable number of anæsthetists to express no little anxiety concerning it. Personally I still adhere to the opinions expressed on curare in my preliminary report of its first use in this country (1945, *Lancet* (ii), 75), but still use it, because I am aware of the dangers inherent in any potent drug if mishandled. Myanesin after some 10,000 administrations has yet to show a death clearly due to its employment. Regarding the hysterectomy upon which Dr. Gray comments, I incline to the diagnosis of an acknowledged expert expressed after examination of an actual pathological section.

Dr. Gray shows a slide of an arm whose condition he says supervened following myanesin injection. He now admits that this slide was an artist's impression. I have studied the work of Picasso, Matisse and Chagall and am forced to the conclusion that art is not as scientific a medium as photography for recording facts. In this case Dr. Gray tells us that the myanesin injections were made through an intravenous drip. Not so long ago I unsuspectingly made a number of injections of pentothal into an I.V. drip exceedingly neatly set-up (and bandaged up) in the ward before operation, which was quietly leaking into the tissues all the time. A considerable percentage of the blood and pentothal thus given diffused out into the tissues and produced an arm exactly like this slide. No myanesin had been given.

I have not suggested that any deaths have followed pentothal; but such deaths have been known to occur following various hæmolytic drugs in use clinically.

Dr. Hunter: I would like to thank Dr. Hunter for his contribution to the discussion, from which I have learnt much that interests me. I have used myanesin in Parkinsonism and can confirm his findings.

Dr. Loftus Dale has given us an account of the phenomena which were apparently produced by the injection of myanesin into 150 patients. Many of these appear to have been the very types I pointed out in my paper as having been omitted from my series because there was no point in giving them the drug; cases such as examination under anaesthesia, dilatation and curettage, and orthopaedic operations.

MEETING HELD AT THE ROYAL NATIONAL HOSPITAL FOR
RHEUMATIC DISEASES, BATH

Amyloid Disease and Rheumatoid Arthritis. [Abridged]

By L. C. HILL, M.D., F.R.C.P.

My apology for introducing this subject to-day rests upon my having a patient apparently suffering from this disease at present in one of my beds at the Rheumatic Hospital. The association is so rare that every authentic or even suspected case is of interest. In most of the cases hitherto published amyloidosis has occurred in children with Still's disease. The association with adult rheumatoid arthritis was first noted in 1903, almost simultaneously by Whitman and Spitzzy. Little further was heard of it until 1927 when Carrol and Nelson published a case. Since then, well under 40 cases have been described. It is not sufficiently realized that the fibrinoid degeneration of acute rheumatic infection can continue to the stage of amyloid degeneration (Mervyn Gordon, 1948). Beattie (1906) described four instances of this in pure rheumatism.

It is perhaps permissible to mention briefly some of the features of amyloid disease, and to begin by quoting Hadfield's definition of amyloid as a "structureless, glyco-protein found in the tissues as an insoluble gel and first appearing between the scanty cells of the endothelial lining of capillary blood-vessels". From the pathological point of view it occurs outside the cells and ultimately results in great thickening of the blood-vessel walls. It is steadily progressive and leads to great enlargement and translucency of the affected organs. There are three types:

(1) Primary mesodermal type is rare and arises independently of protein loss or chronic infection. May form large tumour-like masses in larynx, tongue, lymph glands, &c.

(2) In association with multiple myelomatosis with Bence-Jones proteinuria. It is here probably associated with rise in plasma globulin.

(3) Secondary or common type occurs as a complication of long-continued infection, with gross loss of body protein. It affects the capillaries and small vessels of those organs rich in reticulo-endothelium.

The secondary type has been described in a large variety of apparently unrelated processes, all of which have had in common tissue destruction and usually chronic suppuration, but of late secondary type cases have been largely confined to institutions dealing with advanced pulmonary tuberculosis. Recent statistics show it to be present in 40% of all cases of pulmonary tuberculosis which come to post-mortem, and of those diagnosed clinically, approximately 60% are dead within six months. Unfortunately, it is still only recognized clinically in about 25% of cases ultimately proved at post-mortem, which is a pity in view of the fact that radical surgery at an early stage may lead to its retrogression. Whenever in a chronic disease process, a significant fall in the albumin content of the plasma occurs, together with an absolute or relative increase in the globulin, amyloidosis should be suspected. Involvement of the kidneys is serious and the clinical picture produced is usually that of nephrosis. Urea retention or hypertension are very rarely found and in spite of considerable albuminuria, oedema occurs late. It is probably the only manifestation of amyloidosis which can be a direct cause of death. It always alters the prognosis in any disease by increasing the loss of plasma proteins, especially the albumin, via the urine. The urine is usually pale, of consistently low specific gravity, containing a considerable quantity of albumin, and hyaline casts, which of course do not, as was originally taught, contain amyloid. Occasional granular casts are also present.

Myanesin was stopped following laboratory findings on the blood urea the figures of which were afterwards found to have been erroneously reported.

Dr. Gray starts off by referring to "this dangerous substance" even before he attempts to show that, in fact, it is so; thus one is immediately led to suspect a biased approach. Dr. Gray then tells us that myanesin is ineffective, but admits that he has only used it in a few cases. Regarding these points then he answers himself. I can only suggest to him a perusal of the half-dozen papers I have just quoted in which the authors' careful study of the drug is manifested by the properly recorded series of cases with which they support their favourable opinion.

I should like to pay tribute to Dr. Gray's work on curare which shows very properly his enthusiasm for this substance, following the recent use of which the reported (and unreported) deaths have already caused a considerable number of anaesthetists to express no little anxiety concerning it. Personally I still adhere to the opinions expressed on curare in my preliminary report of its first use in this country (1945, *Lancet* (ii), 75), but still use it, because I am aware of the dangers inherent in any potent drug if mishandled. MEETING HELD AT THE ROYAL NATIONAL HOSPITAL FOR
RHEUMATIC DISEASES, BATH

Amyloid Disease and Rheumatoid Arthritis. [*Abridged*]

By L. C. HILL, M.D., F.R.C.P.

My apologia for introducing this subject to-day rests upon my having a patient apparently suffering from this disease at present in one of my beds at the Rheumatic Hospital. The association is so rare that every authentic or even suspected case is of interest. In most of the cases hitherto published amyloidosis has occurred in children with Still's disease. The association with adult rheumatoid arthritis was first noted in 1903, almost simultaneously by Whitman and Spitzzy. Little further was heard of it until 1927 when Carrol and Nelson published a case. Since then, well under 40 cases have been described. It is not sufficiently realized that the fibrinoid degeneration of acute rheumatic infection can continue to the stage of amyloid degeneration (Mervyn Gordon, 1948). Beattie (1906) described four instances of this in pure rheumatism.

It is perhaps permissible to mention briefly some of the features of amyloid disease, and to begin by quoting Hadfield's definition of amyloid as a "structureless, glyco-protein found in the tissues as an insoluble gel and first appearing between the scanty cells of the endothelial lining of capillary blood-vessels". From the pathological point of view it occurs outside the cells and ultimately results in great thickening of the blood-vessel walls. It is steadily progressive and leads to great enlargement and translucency of the affected organs. There are three types:

(1) Primary mesodermal type is rare and arises independently of protein loss or chronic infection. May form large tumour-like masses in larynx, tongue, lymph glands, &c.

(2) In association with multiple myelomatosis with Bence-Jones proteinuria. It is here probably associated with rise in plasma globulin.

(3) Secondary or common type occurs as a complication of long-continued infection, with gross loss of body protein. It affects the capillaries and small vessels of those organs rich in reticulo-endothelium.

The secondary type has been described in a large variety of apparently unrelated processes, all of which have had in common tissue destruction and usually chronic suppurative, but of late secondary type cases have been largely confined to institutions dealing with advanced pulmonary tuberculosis. Recent statistics show it to be present in 40% of all cases of pulmonary tuberculosis which come to post-mortem, and of those diagnosed clinically, approximately 60% are dead within six months. Unfortunately, it is still only recognized clinically in about 25% of cases ultimately proved at post-mortem, which is a pity in view of the fact that radical surgery at an early stage may lead to its retrogression. Whenever in a chronic disease process, a significant fall in the albumin content of the plasma occurs, together with an absolute or relative increase in the globulin, amyloidosis should be suspected. Involvement of the kidneys is serious and the clinical picture produced is usually that of nephrosis. Urea retention or hypertension are very rarely found and in spite of considerable albuminuria, oedema occurs late. It is probably the only manifestation of amyloidosis which can be a direct cause of death. It always alters the prognosis in any disease by increasing the loss of plasma proteins, especially the albumin, via the urine. The urine is usually pale, of consistently low specific gravity, containing a considerable quantity of albumin, and hyaline casts, which of course do not, as was originally taught, contain amyloid. Occasional granular casts are also present.

Myanesin was stopped following laboratory findings on the blood urea the figures of which were afterwards found to have been erroneously reported.

Dr. Gray starts off by referring to "this dangerous substance" even before he attempts to show that, in fact, it is so; thus one is immediately led to suspect a biased approach. Dr. Gray then tells us that myanesin is ineffective, but admits that he has only used it in a few cases. Regarding these points then he answers himself. I can only suggest to him a perusal of the half-dozen papers I have just quoted in which the authors' careful study of the drug is manifested by the properly recorded series of cases with which they support their favourable opinion.

I should like to pay tribute to Dr. Gray's work on curare which shows very properly his enthusiasm for this substance, following the recent use of which the reported (and unreported) deaths have already caused a considerable number of anaesthetists to express no little anxiety concerning it. Personally I still adhere to the opinions expressed on curare in my preliminary report of its first use in this country (1945, *Lancet* (ii), 75), but still use it, because I am aware of the dangers inherent in any potent drug if mishandled. Myanesin after some 10,000 administrations has yet to show a death clearly due to its employment. Regarding the hysterectomy upon which Dr. Gray comments, I incline to the diagnosis of an acknowledged expert expressed after examination of an actual pathological section.

Dr. Gray shows a slide of an arm whose condition he says supervened following myanesin injection. He now admits that this slide was an artist's impression. I have studied the work of Picasso, Matisse and Chagall and am forced to the conclusion that art is not as scientific a medium as photography for recording facts. In this case Dr. Gray tells us that the myanesin injections were made through an intravenous drip. Not so long ago I unsuspectingly made a number of injections of pentothal into an I.V. drip exceedingly neatly set-up (and bandaged up) in the ward before operation, which was quietly leaking into the tissues all the time. A considerable percentage of the blood and pentothal thus given diffused out into the tissues and produced an arm exactly like this slide. No myanesin had been given.

I have not suggested that any deaths have followed pentothal; but such deaths have been known to occur following various hæmolysant drugs in use clinically.

Dr. Hunter: I would like to thank Dr. Hunter for his contribution to the discussion, from which I have learnt much that interests me. I have used myanesin in Parkinsonism and can confirm his findings.

Dr. Loftus Dale has given us an account of the phenomena which were apparently produced by the injection of myanesin into 150 patients. Many of these appear to have been the very types I pointed out in my paper as having been omitted from my series because there was no point in giving them the drug; cases such as examination under anaesthesia, dilatation and curettage, and orthopaedic operations.

Effect of Blood Transfusion on Rheumatoid Arthritis

By N. R. W. SIMPSON, M.B., D.Phys.Med., and D. HALL BROOKS, B.M.

Dr. Simpson: Blood transfusion as a method of treatment of rheumatoid arthritis has been employed by Copeman (1931 *a, b*), Appelqvist and Holsti (1947), Hartung (1943), Hench (1938), Holbrook (1936) and others. The aim of this investigation was to find the effect of transfusions of whole blood, concentrated red cells and plasma, on the blood picture and general condition of patients suffering from the rheumatoid type of poly-arthritis. We have at the moment completed only the preliminary work, and we are as yet unable to form any definite conclusions from the results. Serial plasma protein estimations, sedimentation rates, crude and corrected suspension stability readings, by the spa method of Collins, Gibson, Race and Salt (1939), hæmatocrit readings and hæmoglobin estimations were made in all cases, and red cell counts were done when it was thought they might be useful. The tests were done initially before transfusion and thereafter at weekly intervals. As far as possible experimental errors were eliminated; for instance, one person has been responsible for each estimation during the whole period and the technique has been standardized.

The biuret method has been used for the estimation of the plasma proteins and this and the other estimations have been made by Dr. H. J. Gibson and his staff by routine methods in his laboratory. We are grateful to him for this service and also for his personal help and advice over the whole problem.

As yet we have not done our own controls over a large enough series of cases—but intend to do so later—so we have taken the normal figures for total plasma proteins from G. A. Harrison's *Chemical Methods in Clinical Medicine*, 3rd edition 1947, and the average figures from Samson Wright's *Applied Physiology*, 8th edition 1947:—

Plasma proteins. Normal values.—Total protein 5·8–8·6 grammes %; average 6·5 grammes %. Fibrinogen 0·2–0·4 gramme %; average 0·25 gramme %. Albumin 3·4–6·7 grammes %; average 4·5 grammes %. Globulin 1·2–2·9 grammes %; average 2·5 grammes %.

A/G ratio = 4:1 to 1·2:1; average 2:1.

I shall describe the results of plasma protein estimations obtained initially in 24 cases of rheumatoid arthritis, and 5 cases of ankylosing spondylitis, and the effects of blood transfusions on 21 cases of rheumatoid arthritis which we have followed up for at least one month.

FIG. 1.—Initial plasma protein figures in 24 cases of rheumatoid arthritis.

Analysis of initial findings of 24 cases of rheumatoid arthritis.—The chart (Fig. 1) is divided into three columns reading from left to right: high values, normal values, low values. The number of cases is represented on the ordinate. It will be seen that 21 cases of rheumatoid arthritis show normal total protein figures and 3 cases show slightly low figures. Fibrinogen readings are high in 15 cases and normal in 9. Where normal they were at the upper limit of normality (0·35–0·4 gramme %). Albumin was normal in 18 cases, in 6 it was low and in these cases it was associated with a raised globulin in every case but one. The globulin shows a normal figure in 13 cases, a high figure in 5 cases and a low figure in 6 cases. The A/G ratio shows a normal figure in 15 cases, a high figure in 3 cases (in every case due to a low globulin), and a low figure in 6 cases, the latter being due to a raised globulin and an associated low albumin.

Analysis of initial findings in ankylosing spondylitis.—5 cases only were examined. The total protein was high in 3 cases (9·0 grammes % in each case), and within normal limits in 2 cases. Fibrinogen values were high in all cases. Albumin readings were normal in all cases. Globulin was high in 2 cases and normal in 3 cases and the A/G ratio was normal in every case.

The abnormal readings in rheumatoid arthritis were associated with extensive involvement and marked activity as judged from the clinical evidence, from the degree of anaemia, and from the sedimentation rate. The cases showing initial normal readings tended to be either more chronic or very early types. This does not include the fibrinogen figures which tended to be high in all cases.

The most recent method of diagnosis depends upon the capacity of amyloid tissue to combine with or absorb certain substances in solution in the blood plasma, notably congo red. This rapid absorption of congo red from the plasma is the basis of the Paunz test. In it the dye is injected in the proportion of 1.5 mg. per kg. of body-weight, and samples of the blood are taken at the end of one, two and three hours. If all traces of the dye have disappeared in one hour the result can be considered strongly positive, if at the end of two hours it is highly suspicious.

F. C., aged 37. A gardener.

CASE HISTORY

Admitted to hospital complaining of extensive rheumatoid involvement of joints (28.11.46).

Past history.—Psoriasis and deafness since infancy. Onset of rheumatoid arthritis 1943. Three blood transfusions in 1945, and a course of gold (myocrisin). No improvement.

Family history.—One sister also with psoriasis developed rheumatoid arthritis in 1943, was treated in this hospital on several occasions without apparent benefit, and died aged 44, in December 1947, with a diagnosis of amyloidosis which does not appear to have been confirmed at autopsy.

On examination.—Extensive rheumatoid arthritis with severe generalized muscular wasting, and fibrillary tremors, psoriasis and complete deafness (otosclerosis). X-rays: Typical rheumatoid arthritis appearances.

Blood: Severe microcytic anaemia; Hb 65% = 9.5 grammes. Haematocrit 38%. C.S.R. 56%, plasma uric acid 6.3 mg.%. Berger 2 negative. Blood urea 20 mg.%.
Urine: N.A.D. Urea clearance (Van Slyke) = 184.3% normal.

Treatment.—Physiotherapy, baths, rest, plasters, vitamins, iron, &c., chrysarobin. No improvement.

Readmitted (13.9.47).—Blood: As before, Hb 73%. Blood cholesterol 161 mg.%. Plasma proteins (30.10.47): Total 5.0; fib. 1.05; albumin 1.2, globulin 2.75 grammes %. Ratio, A : G = 1 : 2.

Paunz Test positive. Complete clearance of dye in one hour.

Treatment.—Rest, mild physiotherapy, high protein diet, casydrol. No improvement.

Readmitted (3.2.48).—Steady deterioration. Oedema now generalized. Spleen palpable.

Treatment.—Transfused with 300 c.c. of concentrated plasma, with no improvement in oedema, but plasma protein ratio returned to a more normal level. Total 5.0; fib. 0.7, albumin 3.6, globulin 0.7, Ratio, A : G = 5 : 1. It was not until he was put on to urea in doses of 30 grains t.d.s. that his oedema diminished. The diuretic effect was immediate. General condition improved.

From a study of the literature it seems that when the association occurs the rheumatoid infection is always progressive and intractable and is usually associated with an unusually severe anaemia and emaciation. In most of the recent cases, at least one course of gold and usually more have been given. In the few cases examined alteration in the plasma protein ratio was noted, with a lowering in the albumin level and a relative or absolute rise in the globulin. Renal involvement is always present, and in most cases death can be attributed directly or indirectly to this. The picture is that of the nephrotic kidney, with no evidence of urea-retention or hypertension to the end.

SUMMARY OF INTERESTING FEATURES IN THE ABOVE CASE

- (1) The occurrence in a brother and sister of psoriasis and rheumatoid arthritis is reported. In each case the former began in infancy and the latter in 1943.
- (2) In each a severe hypochromic anaemia was present throughout, and measures to deal with it were relatively unsuccessful.
- (3) The rheumatoid infection was acute in the onset, progressed rapidly and failed to respond to treatment. Gold was given (two courses to the brother, four courses to the sister) without apparent benefit.
- (4) The diagnosis of amyloidosis was suggested in both patients and supported in the brother by a strongly positive Paunz test.
- (5) The nephrotic state in which this patient now is, and from which his sister apparently died, was associated with a violent alteration in the albumin : globulin ratio. Whereas this was corrected by intravenous concentrated plasma, oedema was unaffected and the patient's general condition showed no obvious improvement. Urea and later ammonium chloride, produced an immediate diuresis with all-round improvement.

Effect of Blood Transfusion on Rheumatoid Arthritis

By N. R. W. SIMPSON, M.B., D.Phys.Med., and D. HALL BROOKS, B.M.

Dr. Simpson: Blood transfusion as a method of treatment of rheumatoid arthritis has been employed by Copeman (1931 *a, b*), Appelqvist and Holsti (1947), Hartung (1943), Hench (1938), Holbrook (1936) and others. The aim of this investigation was to find the effect of transfusions of whole blood, concentrated red cells and plasma, on the blood picture and general condition of patients suffering from the rheumatoid type of polyarthritis. We have at the moment completed only the preliminary work, and we are as yet unable to form any definite conclusions from the results. Serial plasma protein estimations, sedimentation rates, crude and corrected suspension stability readings, by the spa method of Collins, Gibson, Race and Salt (1939), hæmatocrit readings and hæmoglobin estimations were made in all cases, and red cell counts were done when it was thought they might be useful. The tests were done initially before transfusion and thereafter at weekly intervals. As far as possible experimental errors were eliminated; for instance, one person has been responsible for each estimation during the whole period and the technique has been standardized.

The biuret method has been used for the estimation of the plasma proteins and this and the other estimations have been made by Dr. H. J. Gibson and his staff by routine methods in his laboratory. We are grateful to him for this service and also for his personal help and advice over the whole problem.

As yet we have not done our own controls over a large enough series of cases—but intend to do so later—so we have taken the normal figures for total plasma proteins from G. A. Harrison's *Chemical Methods in Clinical Medicine*, 3rd edition 1947, and the average figures from Samson Wright's *Applied Physiology*, 8th edition 1947:—

Plasma proteins. Normal values.—Total protein 5.8–8.6 grammes %; average 6.5 grammes %. Fibrinogen 0.2–0.4 gramme %; average 0.25 gramme %. Albumin 3.4–6.7 grammes %; average 4.5 grammes %. Globulin 1.2–2.9 grammes %; average 2.5 grammes %. A/G ratio = 4:1 to 1.2:1; average 2:1.

I shall describe the results of plasma protein estimations obtained initially in 24 cases of rheumatoid arthritis, and 5 cases of ankylosing spondylitis, and the effects of blood transfusions on 21 cases of rheumatoid arthritis which we have followed up for at least one month.

FIG. 1.—Initial plasma protein figures in 24 cases of rheumatoid arthritis.

Analysis of initial findings of 24 cases of rheumatoid arthritis.—The chart (Fig. 1) is divided into three columns reading from left to right: high values, normal values, low values. The number of cases is represented on the ordinate. It will be seen that 21 cases of rheumatoid arthritis show normal total protein figures and 3 cases show slightly low figures. Fibrinogen readings are high in 15 cases and normal in 9. Where normal they were at the upper limit of normality (0.35–0.4 gramme %). Albumin was normal in 18 cases, in 6 it was low and in these cases it was associated with a raised globulin in every case but one. The globulin shows a normal figure in 13 cases, a high figure in 5 cases and a low figure in 6 cases. The A/G ratio shows a normal figure in 15 cases, a high figure in 3 cases (in every case due to a low globulin), and a low figure in 6 cases, the latter being due to a raised globulin and an associated low albumin.

Analysis of initial findings in ankylosing spondylitis.—5 cases only were examined. The total protein was high in 3 cases (9.0 grammes % in each case), and within normal limits in 2 cases. Fibrinogen values were high in all cases. Albumin readings were normal in all cases. Globulin was high in 2 cases and normal in 3 cases and the A/G ratio was normal in every case.

The abnormal readings in rheumatoid arthritis were associated with extensive involvement and marked activity as judged from the clinical evidence, from the degree of anaemia, and from the sedimentation rate. The cases showing initial normal readings tended to be either more chronic or very early types. This does not include the fibrinogen figures which tended to be high in all cases.

FIG. 2.—Example of abnormal plasma proteins becoming normal.

Effect of blood transfusions on 21 cases of rheumatoid arthritis.—We found that we could divide the cases into three types.

Type 1: 11 cases which showed abnormal protein values initially became normal after transfusion, packed cells being given in every case but one. This case was given whole blood and it also showed a return of normal protein values after transfusion. One of these cases showed a return of abnormal values within a month after transfusion, but not within fourteen days. The other 10 maintained the normal values for at least a month during which time they were observed. Fig. 2 illustrates one case.

FIG. 3.—Example of normal plasma proteins becoming abnormal.

The dotted line represents corrected suspension stability readings and it will be noted that these show a temporary improvement accompanying the reversal of the abnormal plasma protein values.

Type 2: 5 cases which were normal before transfusion showed abnormal readings during the month after transfusion, but in each case an interval of fourteen days had elapsed before this occurred (see Fig 3). In one case later readings showed a return to normal again.

Type 3: 3 cases which had normal plasma protein readings before transfusion showed no change afterwards (Fig. 4).

FIG. 4.—Example of normal plasma proteins staying normal.

Two cases which were transfused with plasma alone had normal figures before transfusion, and continued to show normal figures afterwards.

We intend to find the effect of plasma on cases showing initial abnormal plasma proteins as soon as possible.

So far we do not find it easy to correlate these changes with other changes found in the blood. We find that the return to normal values is coincident with a betterment in the general condition of the patient. We do not think that there is any immediate objective improvement in the articular condition but this is very difficult to assess.

Dr. D. Hall Brooks : Dr. Simpson has mentioned, in passing, the temporary improvement in the corrected suspension stability and sedimentation rate in some cases. I shall show how the blood picture as a whole is altered by blood transfusion, using the same examples and the same types as previously mentioned, i.e. (1) initial abnormal plasma proteins becoming normal after transfusion; (2) normal plasma proteins becoming abnormal after transfusion; and (3) normal remaining normal.

The normal figures we have taken for these factors are: Hæmoglobin 100% = 14 grammes %. Hæmatocrit 42-45%. Sedimentation rate (Wintrobe's method) 0-15 mm. in 1 hour (female); 0-10 mm. in 1 hour (male). Corrected suspension stability 85-95% in 1 hour (Spa Hospitals method).

On the graphs will be seen the hæmatocrit, hæmoglobin and the corrected and crude suspension stability rates. The crude sedimentation rate by Wintrobe's method paralleled almost exactly the suspension stability values. In all these cases blood transfusion resulted in a rise in the hæmatocrit and hæmoglobin values. The crude and corrected suspension stability improved temporarily with the lessening of anæmia and improvement of the plasma protein picture. At the same time the general condition of the patient improved markedly.

FIG. 2.—Example of abnormal plasma proteins becoming normal.

Effect of blood transfusions on 21 cases of rheumatoid arthritis.—We found that we could divide the cases into three types.

Type 1: 11 cases which showed abnormal protein values initially became normal after transfusion, packed cells being given in every case but one. This case was given whole blood and it also showed a return of normal protein values after transfusion. One of these cases showed a return of abnormal values within a month after transfusion, but not within fourteen days. The other 10 maintained the normal values for at least a month during which time they were observed. Fig. 2 illustrates one case.

FIG. 3.—Example of normal plasma proteins becoming abnormal.

The dotted line represents corrected suspension stability readings and it will be noted that these show a temporary improvement accompanying the reversal of the abnormal plasma protein values.

Type 2: 5 cases which were normal before transfusion showed abnormal readings during the month after transfusion, but in each case an interval of fourteen days had elapsed before this occurred (see Fig 3). In one case later readings showed a return to normal again.

Type 3: 3 cases which had normal plasma protein readings before transfusion showed no change afterwards (Fig. 4).

FIG. 4.—Example of normal plasma proteins staying normal.

Two cases which were transfused with plasma alone had normal figures before transfusion, and continued to show normal figures afterwards.

We intend to find the effect of plasma on cases showing initial abnormal plasma proteins as soon as possible.

So far we do not find it easy to correlate these changes with other changes found in the blood. We find that the return to normal values is coincident with a betterment in the general condition of the patient. We do not think that there is any immediate objective improvement in the articular condition but this is very difficult to assess.

Dr. D. Hall Brooks : Dr. Simpson has mentioned, in passing, the temporary improvement in the corrected suspension stability and sedimentation rate in some cases. I shall show how the blood picture as a whole is altered by blood transfusion, using the same examples and the same types as previously mentioned, i.e. (1) initial abnormal plasma proteins becoming normal after transfusion; (2) normal plasma proteins becoming abnormal after transfusion; and (3) normal remaining normal.

The normal figures we have taken for these factors are: Hæmoglobin 100% = 14 grammes %. Hæmatocrit 42-45%. Sedimentation rate (Wintrobe) 0-15 mm. in 1 hour (female); 0-10 mm. in 1 hour (male). Corrected suspension stability 85-95% in 1 hour (Spa Hospitals method).

On the graphs will be seen the hæmatocrit, hæmoglobin and the corrected and crude suspension stability rates. The crude sedimentation rate by Wintrobe's method paralleled almost exactly the suspension stability values. In all these cases blood transfusion resulted in a rise in the hæmatocrit and hæmoglobin values. The crude and corrected suspension stability improved temporarily with the lessening of anæmia and improvement of the plasma protein picture. At the same time the general condition of the patient improved markedly.

Chart I is an example of initial abnormal proteins becoming normal after transfusion. It will be noticed that hæmatocrit, hæmoglobin and suspension stability, both crude and corrected, all improved temporarily and that four weeks after transfusion, the hæmoglobin and hæmatocrit were still higher than on admission, but the corrected suspension stability had returned to the original abnormal value. The maximal improvement, both clinical and biochemical, occurred seven to ten days after transfusion, after the plasma proteins had returned to within normal limits. The next chart is of the second type where initial normal plasma protein readings temporarily became abnormal after transfusion.

CHART I.—Abnormal plasma protein values becoming normal after transfusion.

CHART II.—Normal plasma protein values becoming abnormal after transfusion.

CHART III.—Normal plasma protein values before and after transfusion.

CHART IV.—Plasma transfusion.

In Chart II a rise in hæmatocrit, hæmoglobin and suspension stability occurred, but whilst the hæmoglobin was still maximal as a result of transfusion, the crude and corrected suspension stability values and hæmatocrit had dropped, coincident with the change to abnormal

albumin and globulin values. The fibrinogen readings, however, remained unchanged.

In Chart III an example will be seen of the third type where normal plasma protein values remain normal after transfusion. There is a rise in the hæmatocrit, hæmoglobin and crude suspension stability, but the corrected suspension stability remains substantially the same throughout the five weeks during which the case was under review.

Effects of transfusion.—*Subjectively:* The patients state that the pain was a little easier and they have less stiffness and more energy, feeling stronger in themselves and they find they are less easily fatigued and less depressed. *Objectively:* Trophic and other peripheral changes appear to be considerably improved. There is little or no obvious change in the appearance of the joints, either clinically or radiologically. The blood picture shows evidence of at least temporary improvement.

Chart IV is an example of one of the two cases which received 400 ml. of reconstituted plasma. It will be seen that there is little change after transfusion.

This is only the preliminary work, and we do not wish to draw any conclusions from the small number of results so far obtained. It is our intention to continue these studies with adequate normal controls for all the biochemical and hæmatological methods used and attempt to discover what constituent of blood is responsible for the improvements noted. The follow-up period of one month has been so limited because this hospital admits patients for an average duration of only six weeks, but these patients are being readmitted at regular intervals for further observation.

Gout: a Case showing Unusually Rapid Progress.—G. D. KERSLEY, F.R.C.P.

Dr. G. D. Kersley showed a case of gout in a young man aged 23, who gave a history of two attacks in his left knee, five years previously. Four years ago the condition became chronic with acute exacerbations, the hands and feet also becoming affected. Shortly after this, tophi appeared first on the ears and then on the hands and feet. Two years ago, when first seen at the Royal National Hospital for Rheumatic Diseases, he showed deformity with ulnar deviation and swelling of his hands and swollen ankles and feet. He had lost a great deal of weight, was anæmic and had a plasma uric acid of 16 mg.% (blood urea 44 mg.%). In the past, gold therapy had made the condition worse and a muscle biopsy had shown no evidence of any rheumatoid factor. There was no family history of gout. He reacted well to colchicine and was controlled on a low-purine low-fat diet and extra fluids, after elimination of gross dental sepsis, the application of splints and sedative eliminative physical treatment. Since his first admission he has had several relapses, life being only bearable while he took colchicine, and when this was withdrawn on one occasion, he was admitted in a critically ill condition, with a temperature of 102° F., dehydrated, and with acute pain and swelling of both hands and both feet. Atophan appeared to have little effect in controlling the condition. The biochemical findings were—plasma uric acid 16 mg.%, blood urea 44 mg.%, sedimentation stability 58% (maximal), hæmoglobin 49%, W.B.C. 9,800, cholesterol 50 mg.%.

Dr. Kersley outlined the criteria which, in this case only when taken together, were diagnostic of gout—the acute onset, complete remissions in the early stages, the raised plasma uric acid, X-ray changes, reaction to colchicine and later the appearance of tophi—also the value of the negative muscle biopsy. Unusual factors in a case with a comparatively short history were the marked loss of weight, the anæmia and the absence of family history of the condition. He outlined in this connexion the work of Talbot on sex linkage of a hereditary factor in rise of blood uric acid (occurring in 25% of the non-gouty relatives of gouty patients, 80% of those with high blood uric acid levels being males).

No trigger factors—particular foods, sensitivity to sepsis, trauma or worry—had been discovered in this case. The value of colchicine in small dosage between attacks—a

Gout: a Case showing Unusually Rapid Progress.—G. D. KERSLEY, F.R.C.P.

Dr. G. D. Kersley showed a case of gout in a young man aged 23, who gave a history of two attacks in his left knee, five years previously. Four years ago the condition became chronic with acute exacerbations, the hands and feet also becoming affected. Shortly after this, tophi appeared first on the ears and then on the hands and feet. Two years ago, when first seen at the Royal National Hospital for Rheumatic Diseases, he showed deformity with ulnar deviation and swelling of his hands and swollen ankles and feet. He had lost a great deal of weight, was anæmic and had a plasma uric acid of 16 mg. % (blood urea 44 mg. %). In the past, gold therapy had made the condition worse and a muscle biopsy had shown no evidence of any rheumatoid factor. There was no family history of gout. He reacted well to colchicine and was controlled on a low-purine low-fat diet and extra fluids, after elimination of gross dental sepsis, the application of splints and sedative eliminative physical treatment. Since his first admission he has had several relapses, life being only bearable while he took colchicine, and when this was withdrawn on one occasion, he was admitted in a critically ill condition, with a temperature of 102° F., dehydrated, and with acute pain and swelling of both hands and both feet. Atophan appeared to have little effect in controlling the condition. The biochemical findings were—plasma uric acid 16 mg. %, blood urea 44 mg. %, sedimentation stability 58 % (maximal), hæmoglobin 49 %, W.B.C. 9,800, cholesterol 50 mg. %.

Dr. Kersley outlined the criteria which, in this case only when taken together, were diagnostic of gout—the acute onset, complete remissions in the early stages, the raised plasma uric acid, X-ray changes, reaction to colchicine and later the appearance of tophi—also the value of the negative muscle biopsy. Unusual factors in a case with a comparatively short history were the marked loss of weight, the anæmia and the absence of family history of the condition. He outlined in this connexion the work of Talbot on sex linkage of a hereditary factor in rise of blood uric acid (occurring in 25 % of the non-gouty relatives of gouty patients, 80 % of those with high blood uric acid levels being males).

No trigger factors—particular foods, sensitivity to sepsis, trauma or worry—had been discovered in this case. The value of colchicine in small dosage between attacks—a

therapeutic principle becoming more widely recognized lately—was well borne out in the progress of the case. The danger of colchicine idiosyncrasy must be recognized as a rare complication to the initial administration, but mild toxic symptoms of diarrhoea should act as a guide to a decision on the correct full dosage to be used in an acute attack for any individual patient.

Gold Dermatitis (Two Cases).—J. B. BENNETT, M.B., Ch.B.

Two cases of gold dermatitis treated by B.A.L. were recorded by Simpson (Simpson, N. R. W., 1948, *Brit. med. J.* (i), 545). The second of the two cases was shown at the Section Meeting.

The patient was admitted to the Royal National Hospital for Rheumatic Diseases, Bath, on November 12, 1946. He was a man of 43 years and showed typical signs of early rheumatoid arthritis of about twelve months' duration. The diagnosis was upheld by the hæmatological findings, i.e. B.S.R. by Spa Method 54%.

He was given intramuscular injections of myocrysin to a total of 0.66 gramme and was discharged in January 1947 with a request to his private doctor to complete the course to a total of 1.0 gramme. After receiving 0.86 gramme he developed an extensive and severe exfoliative dermatitis.

He was readmitted to hospital on 3.6.47. He had then complete acute dermatitis but his arthritic symptoms had entirely disappeared and his B.S.R. was 92%. He had regained his normal weight. Treatment of his skin by ordinary methods was of no avail. He was discharged on 14.7.47.

The patient was readmitted on 21.10.47 when it was found that the skin had become grossly indurated and was desquamating freely. The arthritic symptoms were in abeyance and the B.S.R. was 88%. Treatment by B.A.L. was then instituted on 24.10.47 and after about six days considerable improvement was observed. The skin became paler and the exfoliation, which had previously necessitated diurnal sweeping of his bed, almost entirely stopped. In all he was given 56 ml. starting with 2 c.c. four-hourly on the first day, twice daily for three days, daily for eleven days, alternate days for eight days.

He was discharged on 3.12.47. His skin had ceased to desquamate and had become soft although still discoloured with a violet hue.

He was readmitted on 16.3.48. There were no clinical signs of arthritis although the patient complained of some pain and stiffness in the left shoulder. His B.S.R. was 94%. Apart from some violet pigmentation of the skin of his abdomen and thighs there were no other residual effects of the dermatitis. The patient remarked that he had had an abscess of the buttock as a result of the B.A.L. injection but regarded it as of no consequence compared with the relief of his skin trouble.

The clinical result of the myocrysin injection was entirely satisfactory in that a complete cure was apparently effected. The patient will be kept under observation for some years.

Gold dermatitis is a devastating complication for both patient and doctor. The condition may drag on for months and months in spite of all efforts to control it. In this particular case B.A.L. undoubtedly produced an immediate and lasting improvement, with the prospect of return of the skin to complete normality.

Gold, which at present is considered to be the most effective drug in the treatment of rheumatoid arthritis, is quite rightly regarded as potentially dangerous. Of the three most important complications, i.e. blood dyscrasia, nephritis and exfoliative dermatitis, the last-mentioned would now appear to be controllable.

The patient here referred to is in no doubt that the price he paid in discomfort from his skin was well worth the relief of his arthritis.

Ankylosing Spondylitis.—H. LOVELL HOFFMAN, M.D.

Dr. Hoffman showed a case of ankylosing spondylitis and discussed the methods of treatment used for this disease at the Royal National Hospital for Rheumatic Diseases.

He explained that treatment consists of: (a) A plaster bed in which the patient rests for the greater part of the day. This is renewed after several weeks, when the spine has become straighter. (b) Deep X-ray treatment which almost invariably relieves pain and consequent muscle spasm. (c) Movements to the large joints such as hips, knees, and shoulders in the Hot Pool. (d) Breathing exercises also in the Hot Pool, the results being

controlled by periodic measurements of vital capacity and chest expansion. (e) When these measures have controlled pain and deformity, and the disease is becoming less active, a modified Goldthwaite brace is fitted, to be worn during that part of the day when the patient is not on his plaster bed.

Regarding the merits and demerits of preserving spinal mobility by forced active movements, his view was that except in those cases where involvement of the spine is minimal and there is a considerable degree of residual movement, ankylosis should be allowed to occur in the best possible position. In a patient with a stiff spine the burden of any forced movement is likely to fall on one particular intervertebral joint as a fulcrum. This can only, in his opinion, increase the activity of the disease.

In order that the recommendations made in hospital can be carried out, it is necessary to enquire into the patient's home conditions, and to enlist the aid of social and health organizations in the district.

Indications for Joint Manipulation

By JOHN BASTOW, M.D., F.R.C.S.

THE three chief indications for the manipulation of a joint are pain; limitation of movement; deformity; but before embarking on any such procedure, it is wise to make sure that there is a reasonable chance of success and none of disaster supervening.

The first essential before undertaking a manipulative operation is to make a correct diagnosis by (a) careful clinical history—stressing mode of onset and progress of case; (b) thorough clinical examination; (c) X-ray examination; (d) laboratory tests, especially blood sedimentation rate.

Neglect of these elementary precautions may lead to such tragedies as the following:

(1) A child with a "ricked neck" after fishing, due to turning his head suddenly when his cast became caught up in a tree behind him—an injudicious manipulation to free his "locked" neck was followed by a high temperature and an early death, due to pyæmia.

The case was one of "spontaneous hyperæmic dislocation of the cervical spine" following an attack of tonsillitis, and manipulation caused rapid dissemination of the infection and septicæmia.

(2) A boy with a "peroneal spasm" and a painful flat foot—manipulated to restore mobility—with the result that there was an acute flare-up of a latent tuberculous synovitis of the subastragaloid joint, followed by sinus formation and a long illness, the patient being fortunate to recover with an ankylosed foot.

(3) An elderly patient with a "sacro-iliac strain" caused by tripping over a chair-leg and followed by sciatica.

Manipulation caused an acute exacerbation of his symptoms and death followed not long afterwards from carcinomatosis—an unsuspected bony metastasis from a "silent cancer of the prostate" being the cause of his original lesion.

Such stories could be multiplied and serve to remind us that the art of the manipulator demands constant vigilance; that in no case can one afford to relax the essential precautions enumerated above, which can be summed up as "establish a diagnosis" in every case. Never manipulate "on spec".

Now supposing the diagnosis to have been established, what type of case does respond well to manipulation?

(1) The most successful cases are those following "minor trauma".

Here persistent pain, typically on movements in one or two specific directions and often accompanied by local tenderness and some swelling, which persists for weeks after a sprain or twist—and where a bony lesion has been excluded by X-ray and an inflammatory or neoplastic lesion by careful study of the case—is usually due to an adhesion which responds readily to manipulation under anæsthesia.

Joints chiefly affected are: (a) The mid-tarsal and metatarsal joints of the foot; (b) the ankle; (c) the knee; (d) the lumbar region of the spine; (e) the cervical spine; (f) the shoulder; (g) the wrist.

Where the adhesion does not lie in the synovial membrane or capsular ligaments of a joint but in the attachment of a tendon or muscle, or between a tendon and its synovial

therapeutic principle becoming more widely recognized lately—was well borne out in the progress of the case. The danger of colchicine idiosyncrasy must be recognized as a rare complication to the initial administration, but mild toxic symptoms of diarrhoea should act as a guide to a decision on the correct full dosage to be used in an acute attack for any individual patient.

Gold Dermatitis (Two Cases).—J. B. BENNETT, M.B., Ch.B.

Two cases of gold dermatitis treated by B.A.L. were recorded by Simpson (Simpson, N. R. W., 1948, *Brit. med. J.* (i), 545). The second of the two cases was shown at the Section Meeting.

The patient was admitted to the Royal National Hospital for Rheumatic Diseases, Bath, on November 12, 1946. He was a man of 43 years and showed typical signs of early rheumatoid arthritis of about twelve months' duration. The diagnosis was upheld by the hæmatological findings, i.e. B.S.R. by Spa Method 54%.

He was given intramuscular injections of myocrysin to a total of 0.66 gramme and was discharged in January 1947 with a request to his private doctor to complete the course to a total of 1.0 gramme. After receiving 0.86 gramme he developed an extensive and severe exfoliative dermatitis.

He was readmitted to hospital on 3.6.47. He had then complete acute dermatitis but his arthritic symptoms had entirely disappeared and his B.S.R. was 92%. He had regained his normal weight. Treatment of his skin by ordinary methods was of no avail. He was discharged on 14.7.47.

The patient was readmitted on 21.10.47 when it was found that the skin had become grossly indurated and was desquamating freely. The arthritic symptoms were in abeyance and the B.S.R. was 88%. Treatment by B.A.L. was then instituted on 24.10.47 and after about six days considerable improvement was observed. The skin became paler and the exfoliation, which had previously necessitated diurnal sweeping of his bed, almost entirely stopped. In all he was given 56 ml. starting with 2 c.c. four-hourly on the first day, twice daily for three days, daily for eleven days, alternate days for eight days.

He was discharged on 3.12.47. His skin had ceased to desquamate and had become soft although still discoloured with a violet hue.

He was readmitted on 16.3.48. There were no clinical signs of arthritis although the patient complained of some pain and stiffness in the left shoulder. His B.S.R. was 94%. Apart from some violet pigmentation of the skin of his abdomen and thighs there were no other residual effects of the dermatitis. The patient remarked that he had had an abscess of the buttock as a result of the B.A.L. injection but regarded it as of no consequence compared with the relief of his skin trouble.

The clinical result of the myocrysin injection was entirely satisfactory in that a complete cure was apparently effected. The patient will be kept under observation for some years.

Gold dermatitis is a devastating complication for both patient and doctor. The condition may drag on for months and months in spite of all efforts to control it. In this particular case B.A.L. undoubtedly produced an immediate and lasting improvement, with the prospect of return of the skin to complete normality.

Gold, which at present is considered to be the most effective drug in the treatment of rheumatoid arthritis, is quite rightly regarded as potentially dangerous. Of the three most important complications, i.e. blood dyscrasia, nephritis and exfoliative dermatitis, the last-mentioned would now appear to be controllable.

The patient here referred to is in no doubt that the price he paid in discomfort from his skin was well worth the relief of his arthritis.

Ankylosing Spondylitis.—H. LOVELL HOFFMAN, M.D.

Dr. Hoffman showed a case of ankylosing spondylitis and discussed the methods of treatment used for this disease at the Royal National Hospital for Rheumatic Diseases.

He explained that treatment consists of: (a) A-plaster bed in which the patient rests for the greater part of the day. This is renewed after several weeks, when the spine has become straighter. (b) Deep X-ray treatment which almost invariably relieves pain and consequent muscle spasm. (c) Movements to the large joints such as hips, knees, and shoulders in the Hot Pool. (d) Breathing exercises also in the Hot Pool, the results being

controlled by periodic measurements of vital capacity and chest expansion. (e) When these measures have controlled pain and deformity, and the disease is becoming less active, a modified Goldthwaite brace is fitted, to be worn during that part of the day when the patient is not on his plaster bed.

Regarding the merits and demerits of preserving spinal mobility by forced active movements, his view was that except in those cases where involvement of the spine is minimal and there is a considerable degree of residual movement, ankylosis should be allowed to occur in the best possible position. In a patient with a stiff spine the burden of any forced movement is likely to fall on one particular intervertebral joint as a fulcrum. This can only, in his opinion, increase the activity of the disease.

In order that the recommendations made in hospital can be carried out, it is necessary to enquire into the patient's home conditions, and to enlist the aid of social and health organizations in the district.

Indications for Joint Manipulation

By JOHN BASTOW, M.D., F.R.C.S.

THE three chief indications for the manipulation of a joint are pain; limitation of movement; deformity; but before embarking on any such procedure, it is wise to make sure that there is a reasonable chance of success and none of disaster supervening.

The first essential before undertaking a manipulative operation is to make a correct diagnosis by (a) careful clinical history—stressing mode of onset and progress of case; (b) thorough clinical examination; (c) X-ray examination; (d) laboratory tests, especially blood sedimentation rate.

Neglect of these elementary precautions may lead to such tragedies as the following:

(1) A child with a "ricked neck" after fishing, due to turning his head suddenly when his cast became caught up in a tree behind him—an injudicious manipulation to free his "locked" neck was followed by a high temperature and an early death, due to pyæmia.

The case was one of "spontaneous hyperæmic dislocation of the cervical spine" following an attack of tonsillitis, and manipulation caused rapid dissemination of the infection and septicæmia.

(2) A boy with a "peroneal spasm" and a painful flat foot—manipulated to restore mobility—with the result that there was an acute flare-up of a latent tuberculous synovitis of the subastragaloid joint, followed by sinus formation and a long illness, the patient being fortunate to recover with an ankylosed foot.

(3) An elderly patient with a "sacro-iliac strain" caused by tripping over a chair-leg and followed by sciatica.

Manipulation caused an acute exacerbation of his symptoms and death followed not long afterwards from carcinomatosis—an unsuspected bony metastasis from a "silent cancer of the prostate" being the cause of his original lesion.

Such stories could be multiplied and serve to remind us that the art of the manipulator demands constant vigilance; that in no case can one afford to relax the essential precautions enumerated above, which can be summed up as "establish a diagnosis" in every case. Never manipulate "on spec".

Now supposing the diagnosis to have been established, what type of case does respond well to manipulation?

(1) The most successful cases are those following "minor trauma".

Here persistent pain, typically on movements in one or two specific directions and often accompanied by local tenderness and some swelling, which persists for weeks after a sprain or twist—and where a bony lesion has been excluded by X-ray and an inflammatory or neoplastic lesion by careful study of the case—is usually due to an adhesion which responds readily to manipulation under anaesthesia.

Joints chiefly affected are: (a) The mid-tarsal and metatarsal joints of the foot; (b) the ankle; (c) the knee; (d) the lumbar region of the spine; (e) the cervical spine; (f) the shoulder; (g) the wrist.

Where the adhesion does not lie in the synovial membrane or capsular ligaments of a joint but in the attachment of a tendon or muscle, or between a tendon and its synovial

sheath, manipulation without anaesthesia is more effective, as the patient's involuntary resistance to the movement is essential to the success of the operation.

For example: (a) "*Tennis elbow*", affecting origin of extensor tendons of forearm. (b) Tendon adhesions in the long head of the biceps or in the extensor tendons of the wrist. (c) Adhesions between the small muscles of the back.

In such cases, the tissues are otherwise normal and a normal range of movement may be expected to be obtained.

(2) *Post-fibrositic stiffness*—either following an acute attack of fibrositis, which has subsided leaving some loss of function or persistent pain, or else as the sequel of long-continued chronic fibrositis. Usually the osteopath's spinal lesion is of this type—especially affecting the joints of the neck, the shoulders and the lumbar spine, and again a full range of movement may be obtained.

(3) In a similar category are the stiff neck following brachial neuritis and the stiff shoulder following adhesive pericapsulitis, but only when the acute stage has subsided.

Here it is usually wise to warn the patient that two or three serial manipulations may be required, and some temporary exacerbation of symptoms may follow each operation.

(4) *In osteo-arthritis* manipulation is of definite value, but great care must be taken to study the radiographs and attempt to regain only such a range of movement as the alteration in the contour of the articular surfaces and the contractures in the surrounding muscles and ligaments will allow.

Each manipulation must be followed by conscientious active exercises on the part of the patient, if any improvement gained by the movement is to be retained.

The deep Hot Pool bath with an attendant in the water to assist in the patient's movements is especially valuable in this condition.

Hips, shoulders, knees and spinal joints respond well on the whole.

(5) *In rheumatoid arthritis*, manipulation should never be employed in the acute stage with the idea of increasing movement of a joint. It may be used to correct flexion contracture if the joint is immediately immobilized by splintage in the corrected position, with the proviso that after twenty-four hours the splint is removed for a period daily to allow active movement and so prevent the development of ankylosis.

In the chronic stage, manipulation is often of value in increasing the range of movement of a stiff joint, but the radiograph must first be carefully studied to determine the amount of articular erosion that has taken place.

A full, normal range of movement can hardly ever be expected, and so manipulation must be guarded and no more force employed than the decalcified bones and fibrotic extra-articular tissues will stand.

Serial manipulations—only about 15% to 20% increase in movement being attempted at each stage—are very useful in this condition. Joints that respond well are shoulders, cervical joints, knees and feet. Elbows do not respond well and should rarely be manipulated in rheumatoid arthritis.

(6) *In gout*, manipulation must never be performed in the acute stage, and should only be used under an umbrella of colchicine in the quiescent stage, for fear of an acute flare-up.

Serial movements, especially active assisted movements in the Deep Pool, are usually the safest to employ.

Lempert Fenestra Nov-Ovalis for the Restoration of Practical Unaided Hearing in Clinical Otosclerosis: Its Present Status¹

By JULIUS LEMPert, M.D., New York, U.S.A.

WHEN I first became interested in the surgical treatment of clinical otosclerosis I decided to direct my efforts towards developing and perfecting this surgery to a degree high enough to render its use by the otologist practical and its benefits to the deafened patient desirable and durable. It soon became obvious to me that to reach this objective I would have to:

(1) Create a technically safe and practical one-stage surgical procedure for the restoration of practical hearing in clinical otosclerosis.

(2) Find means for ascertaining preoperatively the likelihood of obtaining practical, serviceable and unaided hearing in a deafened ear following the use of such a technique.

(3) Find definitely prescribed ways and means of assuring the permanency of the practical hearing improvement once obtained following such surgical intervention.

In *Archives of Otolaryngology* (1938, 28, 42-97) I described the first practical one-stage fenestration technique for the improvement of hearing in clinical otosclerosis. During the last ten years I have developed many technical improvements in the surgery for clinical otosclerosis. These were based upon a continuous study and analysis of the various results obtained following 3,700 fenestration operations which I have performed, the observations I have made during the performance of 450 revisions and the histologic findings of scientifically controlled animal research.

The restoration of practical hearing following fenestration surgery was observed to be influenced by factors of preoperative, operative and postoperative origin.

PREOPERATIVE FACTORS INFLUENCING THE RESTORATION OF PRACTICAL HEARING

The preoperative diagnosis of clinical otosclerosis is not difficult. In performing the fenestra nov-ovalis operation stapedial foot-plate ankylosis has been observed in almost 100% of cases diagnosed as clinical otosclerosis.

In the only two cases that later came to autopsy of irrelevant causes the otosclerotic lesion was histologically present.

The fenestration operation serves those deafened as a result of otosclerosis best, when their preoperative cochlear nerve function reservoir has remained adequate enough to permit the restoration of practical serviceable unaided hearing.

If the restoration of practical hearing in clinical otosclerosis is to be the objective of the fenestration operation it is essential that the preoperative bone conduction hearing for the 512, 1,024 and 2,048 pure tone frequencies should not be lower than the 30 decibel level and that the decibel level of the bone conduction hearing should be at least 25 to 30 decibels higher than the decibel level of the air-conduction hearing.

Experience has shown that an improvement in hearing for air-conducted sound following fenestration must reach at least the 30 decibel level in the 512, 1,024 and 2,048 frequencies to be considered as serviceable enough for social and economic purposes and obviating the necessity of wearing a hearing aid.

Hearing can be restored to the practical level or higher, even as high as the normal level by the fenestration operation, providing the reservoir of unused cochlear nerve

¹The Paper was followed by the projection of a colour film illustrating every detail of the operation.

function still present at the time of operation is sufficient to permit such restoration of hearing. In the presence of an adequate cochlear nerve function reservoir the degree of the preoperative hearing loss for airborne sound, no matter how great, will nevertheless not interfere with the restoration of practical hearing.

The correct determination preoperatively of the cochlear nerve function reservoir remaining untapped by the functionally impaired air-conduction mechanism is not difficult if the otologist possesses a good old-fashioned clinical sense plus an appreciation of the psychology of the deafened. By supplementing the audiometric testing with intelligent use of the old-fashioned 512, 1,024 and 2,048 frequency steel tuning forks for testing bone conduction hearing for pure tones, plus the use of the outmoded speaking tube for testing the intelligibility for the spoken voice, the otologist can obtain much more valuable information as to the possibility of restoring practical hearing with the fenestration operation in a given ear than by accepting the reports of conclusions reached by physicists and acoustic engineers with the use of extremely complicated apparatus in their psycho-acoustic laboratories.

No otologist should perform a fenestration operation without first personally testing the patient to determine his chances for the restoration of practical hearing. He must never operate solely on the findings of another otologist.

Though the need for newly developed accurate tests for differentiating between middle and inner ear deafness is greater to-day than ever before, only the development of simple non-complicated tests practical enough for the average otologist to employ in his office will be acceptable in the long run.

If, following a well-performed fenestration operation, an impressive hearing improvement cannot be audiometrically demonstrated despite the presence of a strongly positive response to the fistula test it may be concluded that the cochlear nerve function reservoir was incorrectly evaluated preoperatively. It would be highly speculative to deduct from such a result, which is not uncommon, that in addition to the preoperatively diagnosed stapedia foot-plate ankylosis there also must exist in such a case an obstructive otosclerotic lesion in the region of the round window membrane. Histologically otosclerotic lesions in the round window niche, sufficient to interfere with the mobilization of the round window membrane by airborne sound, have been only rarely observed. Furthermore, the preoperative bone conduction hearing in such cases would not as a rule be found to be good enough to consider such an ear as suitable for the fenestration operation.

POINTS OF OPERATIVE TECHNIQUE WHICH INFLUENCE THE RESTORATION OF PRACTICAL HEARING

The creation of a new vestibular fenestra to replace the functionally impeded oval window results in improved mobilization of endolymph by airborne sound which in turn can result in the restoration of practical hearing if the existing cochlear nerve function is adequate.

A tympanic air-space hermetically sealed with the tympanic membrane is essential following fenestration so that the endolymph could be mobilized by airborne sound.

The fact that practical hearing cannot be restored by fenestration in the presence of a perforated tympanic membrane is suggestive that a hermetically sealed tympanic air space acts as a phase changer for the mobilization of the endolymph by airborne sound following the fenestration operation.

The newly created vestibular fenestra must be sealed with a viable tympano-meatal flap to protect the membranous labyrinth from degenerating with total loss of hearing resulting. Since mass influences the transmission of airborne sound to the perilymph space, the thinnest employable portion of the tympano-meatal flap should be facing the newly created vestibular fenestra.

The tympano-meatal membrane, though it is a continuous membrane, cannot

conduct a sound wave from the tympanic membrane to the cutaneous portion which covers the new fenestra. The maintenance of continuity between the dermal layer of the tympanic membrane and that of the cutaneous portion of the tympano-meatal flap is essential for reasons apart from sound transmission. To assure the survival of the cutaneous portion of the tympano-meatal flap it is essential that it be nourished by the blood supply of the tympanic membrane.

The intermediate portion of the tympano-meatal flap becomes firmly adherent to bone between the tympanic air-space and the newly created vestibular window and therefore does not permit airborne sound striking the tympanic membrane to be transmitted effectively to the cutaneous portion sealing and covering the new fenestra. Further proof that mobilization of the tympano-meatal membrane as a whole and transmission of sound waves from its tympanic membrane to the fenestra segment does not take place following fenestration is the fact that practical hearing can be obtained when the cutaneous portion of the flap is accidentally severed from the tympanic portion, providing the cutaneous portion is replaced and adheres so that both the tympanic air-space and the newly created window remain hermetically though independently sealed.

Sound most likely enters simultaneously and independently both the round cochlear window and the newly created vestibular window and mobilizes the endolymph out of phase. It enters the round window through the tympanic portion of the tympano-meatal membrane and the new oval window through that part of the cutaneous portion of the tympano-meatal membrane which covers and seals it.

Since part of the tympano-meatal membrane remains adherent to bone and is therefore not mobilizable as a whole by airborne sound, the maintenance of the incus in its original position after removing the head and neck of the malleus can serve no useful acoustic purpose because it cannot act to enhance the mobilization of endolymph by airborne sound. The fenestra nov-ovalis operation has conclusively proven that just as good, or better, improvements in hearing are obtainable since incus is being removed.

By the same token neither is the retention of the mucous membrane covering the tympanic portion of the facial canal necessary since it cannot result in better post-operative hearing.

The absence of an audiometric hearing improvement for airborne sound coupled with a negative response to the fistula test following the fenestration operation is usually the result of accidental surgical injury to the membranous external semi-circular canal.

POSTOPERATIVE FACTORS INFLUENCING RESTORATION OF PRACTICAL HEARING

A further loss in the hearing level following the fenestration operation in the presence of a negative fistula test may as a rule be attributed to severe postoperative labyrinthitis. Extensive injury of the perilymphatic trabecular blood-vessels, the creation of the fenestra in the presence of bleeding from the mastoid wound, the sealing of the fenestra with the tympano-meatal flap in the presence of bleeding, excessive postoperative inflammation or infection of the tympano-meatal flap, any of these could at one time or another be the responsible factor for such an untoward result.

However, postoperative labyrinthitis is to-day no longer a problem of this surgery. The meticulously careful performance of the fenestration operation with instantaneous surgical control of each and every bleeding point, when supplemented by daily administration of 300,000 units of penicillin for a period of ten postoperative days, has reduced the frequency of postoperative labyrinthitis with resulting further loss of hearing to less than 1%. Penicillin, by reducing postoperative inflammation of the tympano-meatal flap to a minimum, in addition to its antibiotic action, has made this possible where all other means including the sulpha drugs have failed.

POSTOPERATIVE FACTORS INFLUENCING THE PERMANENCY OF RESTORED PRACTICAL HEARING

A drop of the air-conduction hearing level in the three speech frequencies from the best postoperative level to a level below that necessary for practical hearing is as a rule representative of osteogenesis taking place within the fenestra rim. Though the hearing recession may not yet have reached the preoperative level it will ultimately decline to that level when bony closure of the fenestra is sufficiently advanced.

When the improved postoperative hearing level does not show a tendency to drop, a negative response to the fistula test is not a sign of bony closure. However, when the hearing level shows a tendency to drop below the practical level, a positive fistula test is no proof that window is not undergoing bony closure, since a positive fistula test is obtainable even when the newly created fenestra is reduced to the size of a pin-point.

An otologist doing fenestration surgery cannot possibly acquire an appreciation of the complexity of the problems involved in this surgery, nor hope to improve himself or the surgery itself unless he insists upon revising and carefully studying his failures.

Repeated revisions of an osteogenetically closed fenestra do not as a rule result in a permanently open window, and endanger the well-being of the endolymphatic labyrinth.

Though the frequency of osteogenetic closure of the newly created fenestra has been greatly reduced since the general adoption and employment of the fenestra nov-ovalis operation its occurrence is, however, not yet as infrequent as some otologists believe it to be.

If this surgery is done with an open mind and with a critical evaluation of results the occurrence of window closures will inevitably be recognized. However, if one's mind is shut to this surgery and one is easily satisfied with the results obtained, then nothing but open windows will be seen.

Careful study of the newly created fenestra region in the post-fenestrated human subjects during revisions and the histologic observations made in the experimentally controlled post-fenestrated rhesus monkeys have shown that when osteogenesis takes place following fenestration it does so either in the region of the fenestra rim or in the perilymph space and also in both the fenestra rim and the perilymph space.

Further investigation of this problem has revealed that osteogenetic closure of the new fenestra is influenced mainly by:

(1) *The site chosen for the creation of the fenestra.*—As a result of careful analysis of the observations made during revisions of osteogenetically closed fenestras in post-fenestrated human ears I developed the fenestra nov-ovalis technique which I described in November 1941 (*Archives of Otolaryngology*, 34, 880-912).

By changing the fenestra site and moving it forward over the ampulla of the external semicircular canal and immediately anterior to it—which region forms the surgical dome of the vestibule—one of the great factors responsible for osteogenetic closure of the newly created fenestra is removed.

A fenestra created in this region communicates directly with the perilymphatic cisterna of the vestibule which is 3 mm. wide and 5 mm. deep. The formation of a fibrous connective tissue matrix which could aid and abet osteogenetic closure of the fenestra is less likely to take place in this region than in a fenestra created posterior to the ampulla of the external semicircular canal into a perilymphatic space the circumference of which is only about 0.8 mm.

The universal adoption and employment of the fenestra nov-ovalis technique has for the first time in the history of this surgery sharply reduced the frequency of osteogenetic closure of the newly created fenestra.

(2) *The inherent natural tendency for osteogenetic repair of the freshly injured histologic bony layers of the fenestra rim.*—In a discussion of osteogenesis following the fenestration operation in the human (*Archives of Otolaryngology*, 1940, 31, 711-779) I stated as follows:

From my observations during revisions of the fenestra, I was forced to conclude that new bone regeneration within the fenestra begins not in the periosteal but in the endosteal layer of the bony capsule and either may stop there, without involving the periosteal layer, or may eventually involve the periosteal layer of the bony walls of the fenestra.

Fig. 1 shows the three histologic layers of the labyrinthine bony capsule.

In the November 1947 issue of the *Archives of Otolaryngology*, 46, 590, Lindsay, in an analysis of his histologic observations of the results following fenestration of the labyrinth in the rhesus monkey, corroborated the observations which I have made in the human and stated as follows:

Failure to maintain an open fistula was in most cases due to the osteogenetic process which took origin from the endosteal surface at the margins.

Fig. 2 shows closure of the fenestra caused by osteogenetic repair of the endosteal bony layer only.

Neither the removal of the periosteal layer down to the enchondral layer of the bony fenestra rim, nor the removal of both the periosteal and enchondral layers of the fenestra rim down to the endosteal layer, prevents bone regeneration of the endosteal layer. Whether bony closure of the fenestra is the result of endosteal osteogenesis alone or osteogenesis involving all the three histologic layers is quite immaterial as to its effect upon the end-result. None of the three histologic layers is immune to osteogenesis. This has been amply demonstrated histologically in the rhesus monkey.

Scientifically controlled experimentation in the rhesus monkey has demonstrated that burnishing the fenestra rim with pure lead inactivates the histology within the freshly injured bony fenestra rim and prevents osteogenetic closure of the fenestra (*Arch. Otolaryng.* (1947) 46, 512-527).

The use of lead burnishing in 800 consecutive patients since December 1947 seems to be corroborative of our experimental findings in the rhesus monkey.

In only 5 of the 170 cases which are now more than one year postoperative is there any apparent clinical evidence of bone regeneration. However, one more year will have to pass before final evaluation of the lead-burnishing technique can be made.

Prior to the use of lead burnishing signs and symptoms of bone regeneration at the end of one year would be discernible in about 25% to 30% of the cases.

(3) *Bone dust and bone splinters left behind in the region of the fenestra gap and within the perilymphatic space.*—In the surgical treatment for clinical otosclerosis, bone sand and bone splinters have always been by-products of fenestrating the bony labyrinthine capsule with the electrically driven burr. When the final endosteal bony layer is fractured inward and pulverized, bone dust and bone splinters are pushed in the direction of the perilymph space with most of them coming to rest upon the shredded endosteal membrane and the endolymphatic labyrinth. It has been a well-recognized fact that when these bone particles are not meticulously removed from the fenestra region they may stimulate and enhance the naturally existing tendency for osteogenesis in the freshly cut bony walls of the fenestra rim.

It is for this reason that various means of meticulously removing the fractured and pulverized endosteal layer of the bony capsule, which is seen resting upon the shredded endosteal membrane and the endolymphatic labyrinth, are being practised by otologists doing fenestration surgery.

However, every careful otologist practising fenestration surgery could not help

but observe that in fracturing and pulverizing the endosteal bony layer of the fenestra region, bone dust and bone splinters unavoidably fell into the perilymph space and frequently disappeared beyond sight and reach.

Lindsay, after having made similar observations following experimental fenestration surgery in the rhesus monkey, stated in the November 1947 issue of the *Arch. Otolaryng.*, 46, 590, as follows:

The histologic examination has demonstrated that although at operation the technique appeared to be carried out faultlessly the complete removal of bone dust and fragments was rarely accomplished.

Attempts at removal of bone splinters from the perilymph space often result in severance of some of the perilymphatic trabeculae with hæmorrhage from the trabecular blood-vessels into the perilymph space.

Figs. 3, 4, 5 and 6 show normally present perilymphatic trabeculae and trabecular blood-vessels in the vestibular labyrinth.

The endolymphatic labyrinth can easily be injured by a bone splinter left within the perilymph space or torn by attempts to remove such a splinter from the perilymph space.

Fig. 7 shows injury to endolymphatic labyrinth sustained as a result of bone splinters lost in the perilymphatic space of experimentally fenestrated rhesus monkey.

As a result of my careful observations in the performance of 450 revisions of fenestrated human ears, and the observations made in my histologic studies of the temporal bones in our experimentally fenestrated rhesus monkeys (*Arch. Otolaryng.* (1947) 46, 512-527), I am convinced that bone dust and bone splinters entering the perilymph space are a much more serious threat to the hope of obtaining and continuously maintaining practical serviceable hearing as a result of fenestration surgery than bone dust and bone splinters resting in the region of the fenestra rim. This is so because bony fragments lost in the perilymph space are often not removable, while bone particles in the region of the fenestra rim can, as a rule, be completely removed.

In my postoperative clinical study of the 3,700 fenestration operations which I performed, I was able to observe two distinct clinical pictures both of which could be indicative and suggestive of an osteogenetic process having taken place post-operatively.

Clinical Picture Number One

A patient who had practical hearing restored and after having maintained this improvement at that high level for six months to a year suddenly begins to lose his hearing again and slowly his hearing acuity returns to the preoperative level and remains more or less at this level for some time.

In the vast majority of patients presenting this postoperative clinical picture, inspection of the fenestra region during revisions revealed that bone regeneration was limited to the fenestra rim of the bony labyrinthine capsule. When the newly formed endosteal bony growth was removed from the fenestra rim the hearing, as a rule, immediately improved and when osteogenesis did not recur, this improvement continued indefinitely. If osteogenetic closure of the fenestra took place once again the hearing again receded to the preoperative level.

In some fewer cases belonging to this clinical group I found no bone regeneration in fenestra rim but observed some narrowing of perilymphatic lumen as a result of endosteal osteogenesis. In these cases the hearing showed no improvement following revision and not infrequently the hearing continued to recede still further following the revision.

Clinical Picture Number Two

A patient who had practical hearing restored following the fenestration operation at the end of six months or so begins to lose his hearing improvement and more or less rapidly reaches the preoperative hearing level, but instead of remaining at that level for some time, his hearing continues to deteriorate to a level lower than it was preoperatively.

FIG. 2.

FIG. 4.

FIG. 1.—M. G. 10811. Right. Eight-month fetus. Three layers of bone form the otic capsule. A relatively thin layer of lamellar bone, the endosteal bone, immediately surrounds the membranous labyrinth. Next to this lies the more extensive enchondral layer, consisting of globuli interossei and marrow spaces. Most peripherally lies the periosteal layer of lamellar bone.

FIG. 2.—Osteogenetic closure of fenestra in rhesus monkey by endosteal bone only. The periosteal and enchondral layers are not participating in the process of osteogenesis.

FIG. 3.—Human 41—10811. Left. Eight-month fetus. Perilymphatic trabeculae and blood-vessels within vestibular labyrinth of eight-month-old fetus.

FIG. 4.—Human 35. Left. 254. Perilymphatic trabeculae and blood-vessels within external semi-circular canal of human labyrinth.

The findings grossly observed with the aid of magnification upon revision of the fenestra in such cases were usually of a more serious nature. Here the osteogenetic process was observed to have involved extensively both the fenestra rim and the perilymph space. The hearing in these cases did not improve following revision and continued its downward trend.

but observe that in fracturing and pulverizing the endosteal bony layer of the fenestra region, bone dust and bone splinters unavoidably fell into the perilymph space and frequently disappeared beyond sight and reach.

Lindsay, after having made similar observations following experimental fenestration surgery in the rhesus monkey, stated in the November 1947 issue of the *Arch. Otolaryng.*, 46, 590, as follows:

The histologic examination has demonstrated that although at operation the technique appeared to be carried out faultlessly the complete removal of bone dust and fragments was rarely accomplished.

Attempts at removal of bone splinters from the perilymph space often result in severance of some of the perilymphatic trabeculae with hæmorrhage from the trabecular blood-vessels into the perilymph space.

Figs. 3, 4, 5 and 6 show normally present perilymphatic trabeculae and trabecular blood-vessels in the vestibular labyrinth.

The endolymphatic labyrinth can easily be injured by a bone splinter left within the perilymph space or torn by attempts to remove such a splinter from the perilymph space.

Fig. 7 shows injury to endolymphatic labyrinth sustained as a result of bone splinters lost in the perilymphatic space of experimentally fenestrated rhesus monkey.

As a result of my careful observations in the performance of 450 revisions of fenestrated human ears, and the observations made in my histologic studies of the temporal bones in our experimentally fenestrated rhesus monkeys (*Arch. Otolaryng.* (1947) 46, 512-527), I am convinced that bone dust and bone splinters entering the perilymph space are a much more serious threat to the hope of obtaining and continuously maintaining practical serviceable hearing as a result of fenestration surgery than bone dust and bone splinters resting in the region of the fenestra rim. This is so because bony fragments lost in the perilymph space are often not removable, while bone particles in the region of the fenestra rim can, as a rule, be completely removed.

In my postoperative clinical study of the 3,700 fenestration operations which I performed, I was able to observe two distinct clinical pictures both of which could be indicative and suggestive of an osteogenetic process having taken place post-operatively.

Clinical Picture Number One

A patient who had practical hearing restored and after having maintained this improvement at that high level for six months to a year suddenly begins to lose his hearing again and slowly his hearing acuity returns to the preoperative level and remains more or less at this level for some time.

In the vast majority of patients presenting this postoperative clinical picture, inspection of the fenestra region during revisions revealed that bone regeneration was limited to the fenestra rim of the bony labyrinthine capsule. When the newly formed endosteal bony growth was removed from the fenestra rim the hearing, as a rule, immediately improved and when osteogenesis did not recur, this improvement continued indefinitely. If osteogenetic closure of the fenestra took place once again the hearing again receded to the preoperative level.

In some fewer cases belonging to this clinical group I found no bone regeneration in fenestra rim but observed some narrowing of perilymphatic lumen as a result of endosteal osteogenesis. In these cases the hearing showed no improvement following revision and not infrequently the hearing continued to recede still further following the revision.

basis, since injury to the endosteum-lined perilymphatic space is normally not part of my surgical technique. I therefore reasoned hypothetically that perhaps the perilymphatic endosteal osteogenetic processes which I observed in the human have been initiated by bone fragments having found their way unnoticed into the perilymph space.

Histologic studies of our experimental post-fenestrated rhesus monkeys have confirmed my suspicions that irremovable bone fragments, entering unavoidably and unnoticed and remaining in the perilymph space, do create endosteal osteogenesis in the perilymph space, a non-remediable condition which when occurring following the fenestration operation in the human is most damaging to the expected end-results.

Figs. 9, 10 and 11 show perilymphatic endosteal osteogenesis initiated by bone

FIG. 9.

FIG. 10.

FIG. 11.

FIG. 9.—Monkey 42. Left. Exp. III. 6 months 1 week P.O. Fenestra of fenestrated rhesus monkey has remained patent showing absence of osteogenesis at fenestra rim. However, perilymphatic endosteal osteogenesis stimulated by unavoidably lost bone particles within the perilymph space can be seen.

FIG. 10.—Monkey 46. Right. Exp. III. 3 months 2 weeks P.O. Almost complete obliteration of perilymphatic space of external semicircular canal in fenestrated rhesus monkey by endosteal osteogenesis which was apparently initiated by bone particles unavoidably lost in perilymph space during the process of fenestration. Osteogenesis has also taken place at fenestra rim.

FIG. 11.—Monkey 23. Left. Exp. II. Sec. 500. Complete obliteration of perilymphatic space of external semicircular canal in fenestrated monkey by endosteal osteogenesis which was apparently initiated by bone particles unavoidably lost in perilymph space during the process of fenestration.

fragments lost unavoidably within the perilymph space of the post-fenestrated rhesus monkey.

In view of the clinical and operating-table observations, made in the human following fenestration of the labyrinth for clinical otosclerosis and the histologic observations made in the post-fenestrated labyrinths of rhesus monkeys, it became obvious that just as long as the creation of the fenestra nov-ovalis will involve the

In analysing these findings in the two groups of post-fenestrated patients it became obvious that, since I have always meticulously removed all bone fragments visualized in the region of the fenestra gap, the osteogenetic process observed in the bony fenestra rim evidently was started by the inherently existing tendency for repair within the freshly injured bony histologic layers of the fenestra rim.

FIG. 5.—Human 10942. Right. Three-day infant. Perilymphatic trabeculae and blood-vessels within vestibule of human labyrinth.

FIG. 6.—Monkey L. I. 21. Right. Perilymphatic trabecular blood-vessels within crus commune of fenestrated rhesus monkey.

FIG. 7.—Monkey 24. Right. Exp. II. Injured endolymphatic labyrinth as a result of unavoidably lost bone splinters within the perilymph space of the external semicircular canal of a fenestrated rhesus monkey. Newly created fenestra is completely closed by osteogenesis.

FIG. 8.—Monkey 28. Right. Exp. II. Normally appearing perilymphatic space of fenestrated external semicircular canal in rhesus monkey. The endolymphatic labyrinth is seen in its normal position and uninjured. The perilymphatic trabeculae and blood-vessels remained uninjured and intact. Neither bone-dust nor bone-chips have entered the perilymph space. Bone regeneration has taken place only in the region of the fenestra rim.

Fig. 8 shows osteogenetic process limited to freshly injured bony walls of fenestra rim in post-fenestrated rhesus monkey. The perilymphatic space appears normal with the endolymphatic labyrinth and trabeculae undisturbed.

However, the endosteal osteogenetic processes observed within the perilymphatic space during revisions of post-fenestrated human ears could not be explained on this

the antero-lateral margin of the base of the endosteal bony cupola is engaged, gently lifted and everted in a direction postero-lateral to the fenestra and removed intact. The endolymphatic labyrinth, without having been disturbed from its normal position, is thus exposed to view (figs. 14A, B).

Step IV.—Lead-burnishing of bony fenestra rim. To prevent osteogenesis from

originating within the bone-dust-free freshly cut bony fenestra rim.—Pure lead is applied to the fenestra rim using a specially devised pencil holder. The leaded surface is then highly polished with an electrically driven smooth steel or gold burnishing burr.

ADVANTAGES

(1) By employing this new technique for creating the fenestra nov-ovalis, the endosteal bony layer of the labyrinthine capsule is neither fractured inward nor pulverized. Since no bone particles are formed, none can be lost in the perilymphatic space. Therefore, neither the endolymphatic labyrinth nor the trabecular blood-vessels are ever in danger of being injured by bone splinters.

fracturing inward and pulverization of the endosteal bony layer of the labyrinthine capsule, some of the bone splinters and bone dust thus formed will frequently fall into the perilymph space and unavoidably disappear beyond retrieve within it.

In order to avoid the dire consequences and untoward end-results observed, which were caused apparently by non-retrievable unavoidably lost bone fragments within the labyrinthine perilymph space, I have gradually developed a new technique which I now exclusively employ for fenestrating the surgical dome of the vestibule without creating bone splinters and bone dust.

BONE-DUST-FREE FENESTRA NOV-OVALIS TECHNIQUE

*Step I.—Creation of an endosteal bone cupola on surgical dome of vestibule (fig. 12).—*Employing an electrically driven 1 mm. dental polishing burr the bony capsule of the surgical dome of the vestibule is gradually worn down to the endosteal bony

FIG. 12.—Step I: Creation of an endosteal bone cupola on surgical dome of vestibule.

layer, until it is thinned to a bluish-grey transparency. The bony capsule is then slowly and gradually worn down both antero-lateral and postero-lateral to the bluish-grey transparent area until a bluish-grey cupola of endosteal bone is created upon the surgical dome of the vestibule. The bone dust formed is constantly removed with saline and suction.

Step II.—Base of bony endosteal cupola is circumferentially incised.—In an absolutely blood-free surgical field, free from bone debris, the base of the cupola is incised as follows: The antero-lateral aspect of the base of the cupola is incised with a small sharp perforating knife in the direction of the perilymph space. A linear incision is then carried from the perilymph space outward through the endosteum and endosteal bone along the entire circumference of the base of the cupola (figs. 13A, B, C).

Step III.—Eversion and removal of intact bony cupola to uncap perilymph space and expose to view endolymphatic labyrinth.—With a flat spatula-tipped excavator

percentage of cases to render the surgical treatment of clinical otosclerosis acceptable to both the otologist and his patients.

There exists evidence now which suggests that the percentage of permanent practical hearing improvements is still further increased when the fenestra edges are treated with pure lead.

Also it is logical to assume that the bone-dust-free atraumatic creation of the fenestra will prove to be another great advance towards the final successful solution of the surgical treatment of clinical otosclerosis.

Mr. Terence Cawthorne, after congratulating Dr. Lempert on the brilliant presentation of his subject, went on to say that in the fenestration operation Dr. Lempert had done more than any other single person to help the hard-of-hearing and unlock the door of deafness; but he had done more than this, for not only had he found the key that unlocked the door, but he had given that key to others and taught them how to use it, with the result that there were many men all over the world to-day who had been trained by Dr. Lempert in the technique which he had shown to them this morning.

When he was in America the speaker had had the good fortune to see Dr. Lempert at work. During the all-too-brief week that he spent at Dr. Lempert's Institute he had learnt a great deal, and he wished Dr. Lempert to know how very much he appreciated all that had been shown to him and all that he had learnt, not only from watching operations, but from observing the care with which Dr. Lempert selected the patients and the infinite personal pains that he took over each case.

The demonstration of specimens in the West Hall of the Royal Society of Medicine illustrating temporal bone surgery enabled the details of the technique to be appreciated by anyone who had the time to study the specimens. He thought that they represented a magnificent achievement, not only on Dr. Lempert's part, but also on the part of Mr. Olofson, the technician, who had come over to England with Dr. Lempert and who played an important part in arranging and mounting the specimens.

The film that they had just seen gave a very fine pictorial record of Dr. Lempert's operation, and the speaker felt that it represented a triumph of technique over the innumerable difficulties that beset cinematography of temporal bone surgery.

In his paper Dr. Lempert spoke with the authority of a vast experience, and the new bone-dust-free technique that he had described would, the speaker felt sure, represent a real advance. It had been most stimulating to hear Dr. Lempert's insistence on the principle that technical measures, no matter how refined, should never be allowed to supplant the clinical examination of the patient as a whole. Everyone realized the importance and value of audiometry but the speaker was glad to hear Dr. Lempert say that nothing must be allowed to supplant the examination of the patient by the otologist who might have to do the operation.

The Section was very glad indeed that Dr. Lempert was accompanied by Dr. Kos. Dr. Kos had been doing some very important otological work for the American Air Force during the war, and he came from the University of Iowa, which had always been famed for the part it had played in otology, as it was there that the pure tone audiometer was first developed.

The speaker asked if Dr. Lempert could tell them what was the chance of long-term improvement in hearing that a surgeon well trained in the fenestration technique could conscientiously offer to his patient; and, secondly, what steps Dr. Lempert would advise to combat the infection that so often persisted in the cavity after a fenestration operation.

Finally, Mr. Cawthorne paid a personal tribute to Dr. Lempert whom he was very proud to call his friend and also his colleague, for they both had the honour of being Fellows of the American Laryngological, Rhinological and Otological Society and also the great honour of being Honorary Members of the American Otological Society.

On behalf of the Section of Otology of the Royal Society of Medicine, Mr. Cawthorne moved a very hearty vote of thanks to Dr. Julius Lempert for coming all this way to give them such a magnificent presentation.

Mr. I. Simson Hall, in seconding the vote of thanks, also expressed the great pleasure that it was to have listened to what Dr. Lempert had told them that day. An enormous amount of scientific research and clinical observation had gone to the elaboration of this method. All over the United States there were thousands of people to-day who had the happiness of hearing when previously they could not hear, and this was due, directly or indirectly, to Dr. Lempert's work. He thought that was the thing that must give him the greatest satisfaction.

One of the most important contributions which Dr. Lempert had made to this operation was his demonstration that it was capable of being done safely in one stage.

There was a class of case in which it was very difficult to decide whether or not to advise operation. It was a type of patient who had a reasonably good bone conduction for the speech range but by reason of trauma or of other damage to the cochlea had a sharp drop in hearing at the upper level of speech. In such a border-line case, how did Dr. Lempert assess such a patient?

The President, in associating himself with what Mr. Cawthorne and Mr. Simson Hall had said,

(2) Since there are no bone particles to be lost in the perilymph space, endosteal osteogenetic processes formerly stimulated in the perilymph space by such bone particles are no longer possible.

(3) By employing this technique the endolymphatic labyrinth always maintains its normal position within the perilymph space.

(4) Fenestration surgery can thus be performed without traumatizing the endolymphatic labyrinth, the trabeculae and endosteal perilymphatic membrane.

By employing the bone-dust-free technique for creating the fenestra nov-ovalis the heretofore existing problem of how to best accomplish the removal of bone dust has been disposed.

EVALUATION OF RESULTS FOLLOWING FENESTRA NOV-OVALIS OPERATION

A uniformly agreed upon method of evaluating and reporting results is desirable. Careful postoperative testing with pure tone audiometry and its comparison with the preoperative audiometric reading are to date the most scientific means of evaluating the hearing result obtained.

A patient's postoperative claim of improved hearing acuity following the fenestration operation is acceptable only when his claim can be audiometrically substantiated, just as his preoperative claim of deafness was substantiated audiometrically.

Though it is true that preoperative pure tone air-conduction hearing for the 512, 1,024 and 2,048 frequencies at the 30 decibel level in a deafened ear does not necessarily always represent practical serviceable hearing for the spoken voice, it is only a half-truth, since it is also a fact that in such an ear the cochlear nerve function as represented by the bone conduction hearing is already at a level lower than the air-conduction hearing. However, a postoperative rise in the pure tone air-conduction hearing to the 30 decibel level, from a preoperative lower decibel level, following the fenestration operation is always accompanied by improved intelligibility for the spoken voice and is therefore representative of practical hearing. Such a pure tone decibel improvement and improved intelligibility could not have taken place if the bone conduction hearing representing the cochlear nerve function reservoir was not preoperatively adequate enough to permit the hearing restoration to the 30 decibel level.

Practical hearing improvements obtained following fenestration in clinical otosclerosis with preoperative evidence of unimpaired cochlear nerve function were as a rule permanently maintained at the practical level when the newly created window remained permanently open. There exists no clinical evidence of secondary cochlear nerve changes in these cases. However, since secondary cochlear nerve changes have only rarely been observed in the non-operated ear of such patients, definite conclusions that the fenestration operation prevented secondary cochlear nerve changes in these cases cannot as yet be drawn.

Results following this surgery, when estimated on the basis of written replies to a posted questionnaire, are completely unreliable in a large number of instances. Many deafened people who are socially and economically insecure and do not like to call attention to their infirmity by wearing a hearing-aid, also hesitate to admit their deafened state in writing, though they would gladly admit it in confidential consultation with their physician.

Following a successfully performed fenestration operation in one ear, an improvement of hearing in the non-operated ear which could be audiometrically substantiated in more than one audiometric reading has never been observed.

CONCLUSION

The Lempert fenestra nov-ovalis technique, whereby the fenestra is created in the surgical dome of the vestibule, when carefully performed can result in the restoration and permanent maintenance of practical serviceable unaided hearing in a high enough

percentage of cases to render the surgical treatment of clinical otosclerosis acceptable to both the otologist and his patients.

There exists evidence now which suggests that the percentage of permanent practical hearing improvements is still further increased when the fenestra edges are treated with pure lead.

Also it is logical to assume that the bone-dust-free atraumatic creation of the fenestra will prove to be another great advance towards the final successful solution of the surgical treatment of clinical otosclerosis.

Mr. Terence Cawthorne, after congratulating Dr. Lempert on the brilliant presentation of his subject, went on to say that in the fenestration operation Dr. Lempert had done more than any other single person to help the hard of hearing and unlock the door of deafness; but he had done more than this, for not only had he found the key that unlocked the door, but he had given that key to others and taught them how to use it, with the result that there were many men all over the world to-day who had been trained by Dr. Lempert in the technique which he had shown to them this morning.

The Lempert fenestra nov-ovalis technique, whereby the fenestra is created in the surgical dome of the vestibule, when carefully performed can result in the restoration and permanent maintenance of practical serviceable unaided hearing in a high enough

Section of Surgery

President—Sir MAX PAGE, K.B.E., C.B., D.S.O., M.S.

[April 7, 1945]

DISCUSSION ON PRIMARY TREATMENT OF VARICOSE VEINS

Mr. A. Dickson Wright: Varicose veins have been the despair of surgeons ever since aseptic surgery began. Growing out of patience with a condition which recurs in the face of all treatments, surgeons have at times cast reason to the winds and performed most brutal and illogical operations. Rindfleisch-Friedel went to the extent of cutting the skin spiral wise from the knee to the ankle, and the resulting wound was left to heal by granulation. The healed legs resembled more those of a Chippendale table than a human being and gave endless trouble thereafter. Another vicious method was to circumcise the skin of the leg just below the knee down to the deep fascia, so that every superficial vein was divided. This did not help the varicose veins and sometimes ended in amputation from contraction of the scar. Extensive and laborious dissection of the veins was carried out by others and the results were poor. Mayo invented a ring stripper to strip out lengths of veins, and Babcock passed a long probe down the vein and tied it to the vein lower down, a large length of the vein was then dragged from its bed.

The injection treatment first thought of by Pravaz and elaborated by Sicard and Forestier provided an escape from the disappointing surgery of the day and seemed a subtle way out of the difficulty, but, after an enthusiastic start, the results proved disappointing, because of recurrence. An attempt was made to diminish the recanalization by using different sclerosing agents, but although some were better than others, the treatment proved inadequate, especially in those cases in which, owing to valvular defect, there was a free communication with the deep veins shown by the impulse on coughing, and various filling tests such as those of Trendelenburg, Perthes and Ochsner and Mahorner. It was then felt that a combination of surgery and injection treatment would be made in these advanced cases by ligaturing the saphenous veins at the femoral confluence and injecting sclerosing solution down the divided vein. Results were improved by this plan, but still there were recurrences and further ligatures were carried out just above the knee to cut off a deep communicating branch at this point, and also the short saphenous was tied in the popliteal space and occasionally a gluteal vein was tied. Dodd then suggested ligaturing the internal saphenous in front of the malleolus together with an upward injection of the divided vein. Even with all these ligatures some cases still recurred, because varicose veins, if patent, will draw blood into their commodious interiors from any source available and deep communicating branches, although important, did not provide the answer to all the problems. Once the veins refill, they will grow again and ramify without benefit of communicating veins; after all, they started long years before without this benefit. Driven by these failures to more radical measures, the out-patient treatment of the more severe cases could not be adhered to, and the cases were brought in so that a general anæsthetic could be given, and all the necessary ligatures carried out at one session, and, with the patient unconscious, a very thorough injection of the varicose veins carried out using a total quantity of 100 c.c. of 30% saline. The object of this is to endeavour to get every varix in the legs thrombosed and all deep communicating veins closed at the same time, so that the whole varicose network disappears at once, and the chance of recurrence is reduced to a minimum. Bandaging of the leg with elastoplast after these thorough procedures also helps greatly in reducing the bulk of the clots and helping to secure venous obliteration with the minimum of clot formation. One night in hospital suffices for all this, because it is important to get the patient out of bed as soon as possible. If any veins escape this

added that the operation was a great advance in surgery. This world-wide interest in fenestration was an excellent thing for surgery in general, but he hoped surgeons' researches would include the whole structure and function of the temporal bone.

Careful technique meant so much in this operation and some present, young as well as old, might find that they were not so equipped as to be able to do it. In that case they should be big enough to realize their limitations and not try. Others would fail to obtain results in this operation. They should stop for a while, and go to some of the masters to learn just that little bit more.

Dr. J. Lempert said that perhaps the best way he could answer Mr. Cawthorne's question about results would be as follows: If he were to take 100 patients and examine them and find them most suitable for the operation, if they were the type of patient whose hearing could be restored to the practicable decibel level for the three speech frequencies and higher, he could in this type of case restore practical, serviceable, unaided hearing in about 80 out of the 100. If then he waited two years and examined those 80 successful cases at the end of that time he would find himself left with only 60, the condition having recurred in the other 20. This meant that in 25% of the cases that were successfully operated on and in which hearing was restored, there was no longer practical hearing after two years. The other 75% would keep their hearing permanently. Such were the figures which had been obtained up to the present but with advances in technique, especially the new method of bone-dust-free fenestra technique, there might be an improvement. Only time would show whether this new technique resulted in a larger proportion of cases in which permanent hearing was restored.

He wished to say something about the patient who came to the otologist and wanted to have a fenestration operation and was found suitable for such operation. It was always best on finding such a patient to tell him the facts. He should be told that he was a suitable case for operation and what the chances of success were. It should be explained to him that there was an 80% possibility of restoring his hearing immediately and a 60% possibility of maintaining his hearing permanently. It should also be explained to the patient that there was perhaps one chance in 100 that the hearing would get worse instead of better in the operated ear following the operation. It should also be explained to him that he might well have vertigo for the first few days, that he would have to stay in bed for five days, remain in hospital for ten days and a week later he should be going about his own affairs.

As far as post-operative infection was concerned, he had tried many things to avoid this. The most satisfactory way of avoiding it was to get rapid healing, and to get rapid healing one had to do some skin grafting. With a good skin graft from the thigh, used immediately on the operating table, one should in three or four weeks have a dry and completely healed cavity. But there were cases which would stay dry for a while and then begin to desquamate and some mild staphylococcal infection would make its appearance. There was nothing he could tell them about that which they did not know already. In one case an excellent result would be obtained with sulphathiazole, but when one began to use it for other cases it did not seem to do the same amount of good. Another thing was a solution of gentian violet, and another was sulphadiazine and plain boric acid. In another case one might follow the bold plan of saying to the patient, "Do nothing, and don't see me again for three months", at the end of which time one may find the cavity completely healed. The worst thing one could use was silver nitrate. Some of these wounds continued to discharge for months or even for years. Others dried up perfectly within a relatively short time. He could only suggest that where one thing did not serve another should be tried.

Mr. Simson Hall had spoken of the border-line case. Dr. Lempert had a very strong feeling about these border-line cases. He would not say that they should not operate on them where there were some secondary nerve changes and there was still sufficient cochlear nerve function reservoir for the 512, 1,024 and 2,048 frequencies to improve their hearing, though not to the practical unaided level. However, anybody whose livelihood depended upon their hearing would not be satisfied with such a result. Such a person would still need a hearing-aid. Since an individual with inadequate cochlear nerve function cannot hear efficiently without a hearing-aid following fenestration, then he would suggest that they should keep their hearing-aid and not be operated on at all.

On the other hand, there were people who were economically secure and who refused to wear a hearing-aid for social intercourse and wanted to hear a baby cry or to follow conversation when playing bridge. For them the fenestration operation was justifiable and they could get a good enough result to be satisfied without wearing a hearing-aid. But the fact that they did not wear a hearing-aid should not lead to the supposition that they would not need such an aid to achieve economic and social security if they needed it. Over 80% of the deafened who came to see him wore hearing-aids but they were averse to using hearing-aids because they did not want to proclaim their infirmity. They did not want a "crutch". If they could get their hearing restored with the fenestration operation, that was what they wanted, even if there was inadequate bone conduction hearing in the high frequencies which would make the restoration of practical hearing doubtful. If they still wanted it even after a full explanation of what could be obtained by means of a hearing-aid and by means of operation respectively, there was no reason why they should be denied the operation. But these people could get only a limited improvement in hearing, which was not practical or serviceable enough for them to continue their life's work without the additional use of a hearing-aid.

[April 7, 1948]

DISCUSSION ON PRIMARY TREATMENT OF VARICOSE VEINS

Mr. A. Dickson Wright: Varicose veins have been the despair of surgeons ever since aseptic surgery began. Growing out of patience with a condition which recurs in the face of all treatments, surgeons have at times cast reason to the winds and performed most brutal and illogical operations. Rindfleisch-Friedel went to the extent of cutting the skin spiral wise from the knee to the ankle, and the resulting wound was left to heal by granulation. The healed legs resembled more those of a Chippendale table than a human being and gave endless trouble thereafter. Another vicious method was to circumcise the skin of the leg just below the knee down to the deep fascia, so that every superficial vein was divided. This did not help the varicose veins and sometimes ended in amputation from contraction of the scar. Extensive and laborious dissection of the veins was carried out by others and the results were poor. Mayo invented a ring stripper to strip out lengths of veins, and Babcock passed a long probe down the vein and tied it to the vein lower down, a large length of the vein was then dragged from its bed.

The injection treatment first thought of by Pravaz and elaborated by Sicard and Forestier provided an escape from the disappointing surgery of the day and seemed a subtle way out of the difficulty, but, after an enthusiastic start, the results proved disappointing, because of recurrence. An attempt was made to diminish the recanalization by using different sclerosing agents, but although some were better than others, the treatment proved inadequate, especially in those cases in which, owing to valvular defect, there was a free communication with the deep veins shown by the impulse on coughing, and various filling tests such as those of Trendelenburg, Perthes and Ochsner and Mahorner. It was then felt that a combination of surgery and injection treatment would be made in these advanced cases by ligaturing the saphenous veins at the femoral confluence and injecting sclerosing solution down the divided vein. Results were improved by this plan, but still there were recurrences and further ligatures were carried out just above the knee to cut off a deep communicating branch at this point, and also the short saphenous was tied in the popliteal space and occasionally a gluteal vein was tied. Dodd then suggested ligaturing the internal saphenous in front of the malleolus together with an upward injection of the divided vein. Even with all these ligatures some cases still recurred, because varicose veins, if patent, will draw blood into their commodious interiors from any source available and deep communicating branches, although important, did not provide the answer to all the problems. Once the veins refill, they will grow again and ramify without benefit of communicating veins; after all, they started long years before without this benefit. Driven by these failures to more radical measures, the out-patient treatment of the more severe cases could not be adhered to, and the cases were brought in so that a general anæsthetic could be given, and all the necessary ligatures carried out at one session, and, with the patient unconscious, a very thorough injection of the varicose veins carried out using a total quantity of 100 c.c. of 30% saline. The object of this is to endeavour to get every varix in the legs thrombosed and all deep communicating veins closed at the same time, so that the whole varicose network disappears at once, and the chance of recurrence is reduced to a minimum. Bandaging of the leg with elastoplast after these thorough procedures also helps greatly in reducing the bulk of the clots and helping to secure venous obliteration with the minimum of clot formation. One night in hospital suffices for all this, because it is important to get the patient out of bed as soon as possible. If any veins escape this

onslaught they must be followed up ruthlessly with injections of quinine, salicylate, ethamolin or P.G.3 solution (gelatine 0.5 gramme, dextrose 25 grammes, glycerin 30 grammes, phenol 2 grammes, aq. dest. to 100 c.c.).

There are signs of restiveness even with this treatment and a long blunt needle has been devised by Stevenson, so as to place the injection a long way down from the ligature in the groin; others recommend the ureteric catheter to achieve this. Riddoch goes even further in using a rasper passed down the vein so as to damage the intima at the time of the ligation and injection.

The contra-indications to treatment are old age, obesity, and diabetes. If arterial disease is present, great caution is indicated. If the patient has a history, family or particular, of easily provoked phlebitis, it is wise to abstain from treatment, because dangerous venous and even arterial thrombosis may occur in vital parts of the body if these patients are injected with sclerosing solutions.

The complications of treatment are important. If one has by chance stirred up a thrombophilia, then the case must be taken very seriously and anti-coagulants used to tolerance point, and if minor pulmonary embolism occurs, the femoral vein or veins should be tied.

Allergic manifestations are commoner with the fatty acid sclerosing agents and may be very severe and should be combated with adrenaline, ephedrine and benzedrine. The same agents occasionally produce most violent backaches, and even neck-aches and headaches shortly after injection, sometimes requiring intravenous morphia. Excessive inflammation of the veins is well managed with elastoplast bandage and necrosis is treated the same way. Femoral or posterior tibial thrombosis is generally due to keeping the patient in bed, or to thrombophilia.

The complications of varicose veins, thromboses, eczema, pruritus, and ulceration, are all cured by obliteration of the varicose veins except a hard core of cases with incompetent deep veins or old femoral thrombosis. These are treated by the various forms of compressive bandages and pads which are varied with the type of case and the sensitivity of the patient's skin. The main thing to remember is that every chronic ulcer of the leg will heal with adequate support (or rest in bed) except those due to specific infections such as syphilis, tropical spirochætal ulcer, Ducrey sores, mycosis and malignant disease.

Mr. J. B. Kinmonth: I propose to discuss the treatment of varicose veins in the light of information derived from venographic and histological studies. The X-ray studies comprised about 100 venograms made at operation and also on out-patients. The histological studies were made on portions of veins removed at operation from some 20 patients who had previously had their veins injected. Before dealing further with these investigations it is necessary to consider the theoretical basis of the various therapeutic injection techniques.

In every case a solution is injected which is damaging to living tissues, in order to cause the obliteration of the diseased vein. Inefficient circulatory channels containing stagnant or distal flowing blood are thus eliminated.

Methods fall into two groups according to whether the injected solution is fixed where injected, or passes on to be diluted in the general circulation.

(1) *Immediate clotting and fixation.*—The older method is injection into stationary blood behind a tourniquet which is removed when firm clotting has occurred. The clot is painful and bulky, and may involve deep veins as their blood flow also is impeded by the tourniquet. Lord Lister used this method but abandoned it for these reasons.

(2) *Delayed clotting.*—Here fluid is injected into a vein, injures the lining and then passes on into the general circulation where it is diluted. The damaged vein ultimately becomes filled with clot which in time organizes. If sufficient injury has been done to the vein, obliteration will be permanent; if not, recanalization will take place. It is difficult to believe that any vein which recanalizes in this way with the valves, intima and walls damaged can that remains long enough to produce irretrievable damage and then passes on to be diluted as quickly as possible.

Having dealt with these theoretical considerations, it is now proposed to see what light venographic and histological studies throw upon current practice.

VENOGRAPHY

Injections imitating therapeutic injections were made with radiopaque dyes. Observations of three types were made:

(1) *Retrograde injection at operation.*—The rationale of this type of injection is to obliterate the great saphenous vein and possibly calf varicosities by injecting sclerosing fluid down a catheter passed from an incision in the groin. A series of venograms were made at operations injecting amounts varying from $1\frac{1}{2}$ to 8 c.c. of dye.

The venograms suggest this to be an inefficient method because: (a) Much of the dye goes straight into the deep veins. (b) Spasm of the great saphenous vein occurs due to irritation by the catheter so that little injected fluid stays in the vein. (c) Little fluid goes below the knee—it tends to pass into communicating veins or even normal veins.

With larger quantities of fluid than 8 c.c. the excess goes straight into the deep veins.

(2) *Fluoroscopic screening*.—Dye injected into normal superficial leg veins never passes distally—even if there is a tourniquet above the site of the injection. Dye injected into varicose veins with the patient standing sinks rapidly towards the ankle. Dye injected into a varicose vein with the patient lying remains at the site of injection until the patient moves the limb.

(3) *Serial venograms of direct injections into leg varicosities*.—These show that 1 to 1½ c.c. is the optimum amount for a single injection. Larger amounts tend to spill over into the deep veins. Entry to the deep veins is particularly likely to occur, as would be expected, in tributaries of the small saphenous vein at the back of the calf.

Serial pictures of the same injection confirm what was found on screening, that injections made into a vein with the limb horizontal and at rest remain stationary until the limb is moved.

The serial pictures also show that fluid passing into the deep veins remains there longer than one would expect: it is not swept instantly away but may often be seen still lying in some concentration a minute or more after injection. It remains for a longer time still in the communicating veins and can often be seen to linger in the neighbourhood of valves. As the valves are extremely delicate and vulnerable structures this is a very significant observation.

I do not believe that the fluid which is, as it were, "off the target" often causes extensive deep clotting in ordinary doses, but it does appear extremely likely that damage may occur to valves and intima, particularly in the communicating channels. What is worse, this may occur without permanently obliterating these communicating veins and leave them with incompetent valves.

Histological studies.—Small portions of vein were excised at operation from patients who had had injections of sclerosing fluid a few days beforehand. These injections were often inadequate clinical "takes" followed by no palpable clotting and little or no tenderness. And yet when the vein was removed it was found to show surprising changes both to the naked eye, when oedema of the walls and quite unsuspected clotting was observed, and also on microscopy. These changes were most marked in this region of the valves which were found on microscopy to be damaged and involved in adherent clot even when there had been no clinical "take".

CONCLUSIONS AS TO TREATMENT

(1) For more severe cases with incompetent great saphenous valves requiring operation: High saphenofemoral ligature probably combined with ligature at knee level or in the thigh if a communicating vein "blow-out" is detected. No retrograde injection. Local injection of calf varicosities if necessary at a later date.

(2) For mild cases: Injection of the affected veins using an empty vein technique with the limb horizontal. Not more than 1½ c.c. in each injection. The leg to be kept still for five minutes, then moved vigorously to sweep the fluid away.

I should like to thank Mr. Douglas Robertson for the excellent work he put in on the histological side.

Professor A. M. Boyd: The treatment of varicose veins has provided acrimonious discussion for nearly two thousand five hundred years and has probably been the subject of more papers than any other single disease. It was a problem in the time of Hippocrates, who realized the necessity for the complete obliteration of the varices. Galen in the second century A.D. forestalled the Mayo stripper by tearing the varices out with a hook. Paulus Aegineta in the seventh century preceded Trendelenburg by practising ligation and section of the saphenous vein of the thigh. Davat in the early nineteenth century abandoned the percutaneous ligature he had previously introduced—a method which was reintroduced in 1943. Consideration of the progress made in the treatment of varicosities up to the nineteenth century reveals the interesting fact that the principles underlying all the technical procedures we know to-day have been employed except the following:

(1) *Spiral incision* (Rindfleisch-Friedel) from ankle to groin round and round the limb to the deep fascia in order to interrupt the blood flow from the superficial veins.

(2) *Injection of substances* directly into a vein to produce thrombosis—fortunately delayed until the introduction of the hypodermic syringe by Francis Rynd in 1845.

The first method has been entirely given up and the second will, I think, be shortly abandoned. All the modern methods have been discarded and reintroduced repeatedly

onslaught they must be followed up ruthlessly with injections of quinine, salicylate, ethamolin or P.G.3 solution (gelatine 0.5 gramme, dextrose 25 grammes, glycerin 30 grammes, phenol 2 grammes, aq. dest. to 100 c.c.).

There are signs of restiveness even with this treatment and a long blunt needle has been devised by Stevenson, so as to place the injection a long way down from the ligature in the groin; others recommend the ureteric catheter to achieve this. The damaged vein ultimately becomes filled with clot which in time organizes. If sufficient injury has been done to the vein, obliteration will be permanent; if not, recanalization will take place. It is difficult to believe that any vein which recanalizes in this way with the valves, intima and walls damaged can be anything but less efficient than before the injection. The best injection is obviously one that remains long enough to produce irretrievable damage and then passes on to be diluted as quickly as possible.

Having dealt with these theoretical considerations, it is now proposed to see what light venographic and histological studies throw upon current practice.

VENOGRAPHY

Injections imitating therapeutic injections were made with radiopaque dyes. Observations of three types were made:

(1) *Retrograde injection at operation.*—The rationale of this type of injection is to obliterate the great saphenous vein and possibly calf varicosities by injecting sclerosing fluid down a catheter passed from an incision in the groin. A series of venograms were made at operations injecting amounts varying from 1½ to 8 c.c. of dye.

TREATMENT OF VARICOSE VEINS

The sheet-anchor of treatment is ligation. In addition to proximal ligation where the main superficial vein enters the deep vein, distal ligations at the sites of incompetent perforating veins should be undertaken.

Internal saphenous system.—(1) *Proximal ligation of internal saphenous vein in the groin.*—The technique of the operation is well known. There are, however, a few points which I should like to stress.

(a) *Ligation of all the tributaries of the saphenous vein in the groin:* Reimann *et al.* (1946) have drawn attention to the common variations of the anatomy of the tributaries entering

FIG. 2.

FIG. 3.

FIG. 2.—Venogram showing well-marked deep phlebitis of calf. Patient, who had varices of internal saphenous vein below the knee, complained of aching pain in calf of leg.

FIG. 3.—Venogram of a patient with oedema of leg, showing deep varices affecting the posterior tibial group of veins.

the internal saphenous vein in the groin. Knowledge of these abnormalities is of no great surgical importance because every tributary entering the saphenous vein in the neighbourhood of the fossa ovalis should be ligatured and divided.

There is one, however, to which little attention has been paid and which may be missed. The accessory saphenous vein (either the medial or lateral superficial femoral veins may qualify by their size for assumption of the title of accessory internal saphenous vein) usually joins the internal saphenous vein within two or three inches of the sapheno-femoral junction. Sometimes, however, the accessory saphenous vein pierces the deep fascia 4 or 5 in. (10–12.5 cm.) below the fossa ovalis and runs upwards lying superficial to the femoral vein and joining the internal saphenous *deep* to the fossa ovalis (fig. 4A, B).

FIG. 4.—(A) Accessory saphenous vein joining internal saphenous vein 2 in. distal to fossa ovalis. (B) Accessory saphenous vein piercing the deep fascia 4 or 5 in. below fossa ovalis and joining internal saphenous vein in fossa ovalis.

since the time of Hippocrates. Before Lister's work failure was largely due to sepsis. Since it has been possible to operate aseptically, failure to obtain 100% successful results has led to the introduction of numerous combinations of operative and non-operative methods. One of the great handicaps in the assessment of the best treatment for varicose veins is the paucity of publications of end-results of cases accurately followed up. Ochsner in 1939 reviewed all the end-results published prior to that year. I have examined the follow-up results published since 1939. The recurrence rate after one year varies from 20-98%. Moore and Knapp state that after one year there is little change in the comparative results. That has not been my experience. 60 cases treated in the wards of the Surgical Unit at St. Bartholomew's Hospital were followed up by Alan Walker over a period of eight years. There was a steady increase in the recurrence rate year by year. The reason for these unsatisfactory results lies in the ætiology of varicose veins. I believe that varicose veins are primarily due to a congenital deficiency or weakness of the valves. The condition is progressive. No single operation is likely to cure them.

SYMPTOMS OF VARICOSE VEINS

Causes of pain.—(1) Varices of external saphenous system. (2) Complete dilatation of internal saphenous vein with saphena varix. (3) Involvement of cutaneous nerves in periphlebitis. (4) Deep phlebitis of the calf.

(1) *Varices of external saphenous system.*—Varices on the back of the calf are undoubtedly painful. The superficial and deep veins in the back of the leg do not communicate directly but via the muscular veins. Incompetency of the valves in these veins leads to varices in the calf muscles, the subcutaneous varices appearing later. It is these muscular varices which give rise to the aching pain of which patients complain.

(2) *Complete dilatation of the internal saphenous vein with saphena varix.*—This condition is due to deficiency or even absence of the femoral valve. Back pressure soon overcomes the resistance of the valves in the internal saphenous vein. Hence there is an unbroken column of blood from the right atrium to the ankle. This condition undoubtedly gives rise to discomfort—aching and a "heavy" feeling in the leg on prolonged standing (fig. 1A, B).

FIG. 1A.

FIG. 1B.

FIG. 1.—(A) Diagram of valves, groin region. (B) Illustrates effect of back pressure on saphenous vein when femoral valve is weak or absent.

(3) *Involvement of cutaneous nerves in periphlebitis*—usually the saphenous—by inflammatory changes round varices, particularly "blow-outs", gives rise to paroxysms of intense burning pain.

(4) *Deep phlebitis of the calf.*—Dr. R. N. Tattersall drew my attention to the frequency of deep phlebitis in patients with varicose veins who complain of calf pain. I fully concur with his view. Venograms of patients with internal saphenous varices below the knee who have genuine pain in the leg show varying degrees of deep phlebitis. The presence of deep phlebitis should always be suspected if a patient with incomplete internal saphenous varices complains of aching pain in the calf on standing, especially if there is any œdema of the ankle (fig. 2).

Deep phlebitis is *not* a contra-indication to ablation of the superficial varices; it is in fact an indication for operative treatment.

œdema due to chronic venous insufficiency.—Venographic examination of chronic œdematous legs with or without superficial varices has occasionally shown gross varicosities of the deep veins. This seems to me to be of great importance explaining chronic swelling of a leg in which there is no history of phlebitis. Moreover it explains the success of ligation of the femoral vein in occasional cases diagnosed as thrombophlebitis (fig. 3).

were carried out at both groin and knee levels. In every case where injection was given in the groin, the solution passed into the femoral vein through the perforating vein in the

FIG. 7.—Ven ogram showing filling of femoral and upper third of popliteal vein following injection of pyelectan into distal end of divided saphenous vein.

FIG. 8.—Saphenous vein divided just below the knee. Pyelectan injected into distal end. Some opaque solution has passed through a perforating vein just below the knee filling the popliteal vein.

lower third of the thigh. Plates exposed one minute later showed the opaque solution in the femoral vein. A further skiagram ten minutes after injection, when the superficial veins were firmly sclerosed, showed the radiopaque sclerosant still present in the femoral vein (figs. 9 and 10).

FIG. 9.—Venogram showing radiopaque sclerosing solution in femoral vein following injection of the solution into distal end of divided saphenous vein.

FIG. 10.—Venogram of same patient taken ten minutes later showing radiopaque sclerosant still in femoral vein. Superficial veins were firmly sclerosed.

Injection from knee level produced results similar to those obtained from pyelectan. Unless there happens to be a perforating vein of unusual size very little of the sclerosant will enter the deep vein.

These observations prove beyond doubt that retrograde injection of sclerosing solutions are unsafe, at all events if the injection is given at groin level. Probably small injections of

It is extremely easy to mistake the accessory saphenous for the femoral vein, ligating the saphenous vein *distal* to the entrance of this large tributary instead of at the sapheno-femoral junction. The result is *complete* failure to prevent filling of the varicosities. Fig. 5 shows a venogram of a case in which this error has been made.

(b) *Ligation of saphenous veins flush with the femoral vein*: Much unnecessary emphasis is, in my opinion, placed on the necessity of ligating the saphenous vein flush with the femoral vein. The concept of clot forming in the stump of the vein and giving rise to pulmonary embolism seems to me highly theoretical. The necessity for a similar procedure has never been stressed in ligation of large tributaries of other main veins—for example, ligation of the distal end of the internal jugular in block dissection of the neck, or the external jugular in other incisions in the cervical region, or the subscapular vein in radical mastectomy.

FIG. 5.—Venogram of patient after ligation in groin in which ligature was placed distal to entrance of accessory saphenous vein instead of at the sapheno-femoral junction.

FIG. 6.—Method of injury of femoral vein in flush ligation at sapheno-femoral junction.

These observations have been criticized on the grounds that, while a non-irritant solution entered the deep veins, a sclerosing solution would either thrombose the perforating veins so rapidly or cause such spasm that leakage into the deep vein was improbable. Alternatively, if any did reach the deep veins it would be diluted and swept away so rapidly that no damage to the deep veins was likely to occur.

My Lecturer, Mr. John Loewenthal, suggested to me that these points could be cleared up by using a radiopaque sclerosant. All the common sclerosing solutions were mixed with the various radiopaque organic iodine solutions in varying proportions without success. Mr. J. B. Lloyd, M.P.S., Chief Pharmacist to the Manchester Royal Infirmary, solved this problem for us with the following solution: Sodium ortho-iodohippurate 75%; mono-ethanolamine oleate 5%; benzyl alcohol 2%. This is both an excellent sclerosant and of adequate radiopacity. The iodine is absorbed within an hour.

Retrograde injection with radiopaque solution.—Retrograde injections of this solution

I would go further—I believe it is undesirable. It is extremely easy to injure the femoral vein in a similar way to the classic injury of the common bile duct, by deforming the sapheno-femoral junction by traction on the proximal end of the saphenous vein in an attempt to define the exact point of union (fig. 6).

(2) *Distal ligation.*—(a) *Lower third of thigh*: A short segment of the internal saphenous vein including the perforating vein should be excised. The exact site can be found by means of the tourniquet test of Mahorner.

(b) The communicating vein often found behind the knee between the external and internal saphenous veins should be ligated if present. This is best carried out through a vertical incision in the popliteal fossa, so that proximal ligation of the external saphenous vein can be done at the same time if required.

Injection of sclerosing substances.—*Dangers of retrograde injection*: Deep phlebitis occasionally follows retrograde injection of sclerosing solutions. Retrograde injection of pylectan into the distal end of the saphenous vein divided in the groin has been shown by X-ray to enter the femoral vein via the perforating veins in every case in which it was used (fig. 7).

If the retrograde injection is carried out from knee level, the radiopaque solution could only occasionally be seen in any quantity in the popliteal vein.

As a rule the capacity of the superficial varicosities was so great that all the solution was taken up by them, negligible quantities leaking into the deep veins through the perforating branches. Occasionally, however, the perforating veins, especially the highest situated at the level of the lower border of the head of the tibia, are very large, allowing most of the solution to enter the popliteal vein (fig. 8).

sclerosants, as Mr. Kinmonth had shown, provided the answer to the disrepute of such varicose vein therapy; the patient was often saddled with the added serious disability of deep vein damage.

Mr. A. S. Till asked whether the ligation of painful varicose veins was countenanced during pregnancy.

In these days it was generally not possible for pregnant women to rest for long periods and in several such cases in second or subsequent pregnancies ligation had been carried out with marked relief.

Mr. R. H. Gardiner asked if the hæmaturia which occasionally occurred after the injection of sclerosing agents into the internal saphenous veins in the groin might be explained by the rapid absorption of these agents into the general circulation, in view of what had been shown by the venograms seen earlier in the discussion. He thought it possible that certain agents might have a toxic effect on the parenchymatous organs, particularly the kidneys. In his experience, injection of sclerosing agents at the groin level was not necessary, as adequate clotting appeared to take place in the internal saphenous veins in the thighs if the veins were ligated in the groin and again just above the level of the knee-joint.

Professor Boyd (in reply) agreed with Mr. Cohen that deep phlebitis was not necessarily a contra-indication to treatment of the superficial varices. Chronic venous insufficiency of the superficial veins required treatment on its own merits and should be considered separately from deep venous insufficiency. The view that superficial varicosities are "compensatory" due to deep obstruction is erroneous. As Turner Warwick has shown, deep obstruction will not cause reversal of flow in the deep perforating veins unless there is a congenital weakness or deficiency of the valves in the perforating veins, i.e. unless the patient is of a varicose tendency and would have developed them anyhow. Dilatation of superficial veins in obstruction of the femoral veins or even of the inferior vena cava are the exception rather than the rule. He did not feel, however, so certain about the value of high femoral ligation in deep phlebitis. Femoral ligation only occasionally results in dramatic relief of oedema in "deep phlebitis". It is probable that in the successful cases of femoral ligation the oedema was, in fact, due to varices of the deep veins (see fig. 3) rather than to deep phlebitis.

Professor Boyd was extremely interested in Mr. A. S. Till's question about the desirability of ligation of varicose veins during pregnancy. He had had no experience in the treatment of varicose veins during pregnancy but saw no contra-indication to ligation, should the veins be a source of discomfort.

He agreed with Mr. Gardiner that hæmaturia following injection of varicose veins was probably due to rapid absorption into the general circulation and renal damage. He recalled seeing hæmaturia following injection of sclerosants on several occasions during the war but could not remember whether quinine-urethane or sodium morrhuate had been used as the sclerosing agent. He was inclined to think that the quinine solution had been used.

[May 5, 1948]

DISCUSSION ON VAGAL RESECTION FOR PEPTIC ULCER

Mr. Ian Orr: It would be impossible, in this brief Address, to refer in detail to the rapidly accumulating literature on vagal resection, or to describe the results of numerous animal experiments designed to determine the secretory changes found in vagotomized animals.

I shall confine my remarks to describing the rationale, the mode of investigation and findings in a series of 115 vagal resection operations performed by Mr. H. D. Johnson and myself at Hammersmith and other hospitals.

Rationale.—The rationale is based on the present medical conception of ulcer therapy; namely, that in the control of acid secretion continuously throughout the twenty-four hours lies the key to healing.

When the physician treats a patient with duodenal ulcer, he aims at providing mental as well as physical rest by withdrawing the patient from his environment, excluding him from domestic and business worries, and thereby reducing the intensity of the cephalic stimuli travelling to the stomach by way of the vagi. He supplements this mental rest by large doses of atropine, which, acting on the endings of the vagus, relaxes the pylorospasm commonly found in the duodenal ulcer patient, and inhibits both the motility and secretory activity of the stomach. According to Douthwaite the dose of atropine requisite for this purpose has to be sufficient to produce toxic manifestations. Even this is insufficient to cut down the acid in the vagotonic patient to a level compatible with healing of the ulcer, and the residue of acid has to be buffered by a continuous milk drip. The importance of continuing this buffering effect throughout the twenty-four hours is now fully appreciated. That medical

not more than 3 to 5 c.c. at knee level are in most cases quite safe. How frequently the highest calf perforating vein is large enough to allow the solution to enter the popliteal vein has yet to be determined. The saphenous vein should be exposed and the retrograde injection given about 1 in. (2.5 cm.) below the head of the tibia in order to be certain of being below the highest perforator.

CONCLUSION

I wish to stress the congenital basis and progressive nature of varicose veins. Operation should only be advised if there is definite evidence of chronic venous insufficiency or for genuine pain or discomfort. Operation for purely cosmetic reasons should be discouraged. Treatment should consist of ligation of the internal saphenous vein in the groin; excision of a segment including the perforating vein in the lower third of the thigh; excision of another segment including the perforating vein immediately below the knee if this is found to be large; retrograde injection from knee level of 3 to 5 c.c. of sclerosant solution. The communicating vein behind the knee, if present, and sometimes the external saphenous vein, should be ligated if there is valvular incompetence.

Compression of the vein walls to avoid painful and unsightly thrombosed veins is secured by an elastoplast bandage applied firmly and evenly from *above downward* beginning a few inches above the point of injection and continued as far as the metatarsophalangeal joints. The patient is confined to bed, the foot of which is raised on 5-in. blocks, for one week.

I have only seen one example of pulmonary embolism following operation for varicose veins. This was in a woman of 50 who had a small pulmonary infarction; she had been operated upon as an out-patient under local anaesthesia and treated by immediate ambulation.

In my opinion the groin wound heals better and the cosmetic result is improved by confining the patient to bed.

Finally I should like to pay a tribute to the pioneer work of Turner Warwick, whose delightful monograph published in 1931 contains almost all the observations which have since been made.

Mr. Peter Martin advocated the importance of constant and firm pressure on long-standing varicose ulcers and said that in his experience the best method of applying this pressure was by a two-way stretch non-adhesive bandage.

Mr. Sol. M. Cohen questioned whether deep venous thrombosis should be regarded as a complete contra-indication to any form of operation. These were the patients particularly liable to serious limb sequelae, and surgery had hitherto but little to offer. The clot and phlebitis fixed and impeded vein valve action, and as the lumen was only partially filled by clot, blood "snaked down" from the vena cava, subjecting the distal venous tree to the full gravitational force of a long column of blood. High femoral vein interruption was thus a rational procedure, and he had practised such deliberate ligation in some of these cases, with beneficial result. He was opposed to sclerosant injection coincident with the operation; the rapidity with which such injected material entered the deep circulation could be demonstrated readily by injecting pentothal into a varicosity—the onset of general anaesthesia being found to be very little delayed. The *fons et origo* of the post-operative embolus was the thrombosis in the deep veins secondary to sclerosant diffusion, and not, as commonly taught, clot formation clinging perilously to the saphenous vein stump. Sclerosant injection was particularly hazardous under general anaesthesia; for with flaccid limb there was pooling and stagnation within the deep veins. Multiple vein resection operations, although tedious, yielded gratifying results. Professor Boyd had explained in lucid fashion the probable mechanism of pain with such varices, and provided an explanation for the completely symptom-free clinical picture, in spite of the presence of gross varicosities. The latter were not, however, to be regarded as benign and inconsequential for, besides the remote effects on the general circulation, there was as yet no true explanation of the factors underlying the development of varicose ulceration. Varices were a frequently associated feature, but the lesion was ischaemic on microscopy; the arterioles in the area were found to be compressed or strangled by the fibrous tissue reaction secondary to lymph fluid seepage and stagnation. The frail nature of the vein valves and their ready damage by

Polya type of anastomosis. This antrectomy, plus vagotomy, has resulted in the most marked fall in acid, as the hormone as well as the nervous secreted acid has been dealt with and gastric drainage has been adequate. Some of our most spectacular results have been in this antrectomy plus vagotomy group.

Methods of investigation.—For the proper selection of cases a routine investigation is essential. The barium meal study, in addition to determining the existence of an ulcer, should indicate the rate of emptying, the possibility of minor degrees of stenosis and the absence of other pathology such as duodenal diverticula or gastric ulcers which might confuse the result.

The acid secretion tests are of great importance and though the standard fractional test meals are carried out in many of the cases, the finding of greatest importance is the quantity and acid level of night secretion entirely unstimulated by food, or drugs. This entails continuous gastric suction throughout the night, titration of hourly samples and estimation of the total quantity of free acid secreted. It is on the basis of this estimation that the decision to resect the vagus is made.

The insulin test meal is also employed both before, and on several occasions following, operation. Its main value lies in providing an indication whether or not the vagotomy has been complete. Sufficient insulin is given intravenously to produce a fall in the blood-sugar level to 50 mg. per 100 c.c., or lower. This degree of hypoglycæmia leads to a stimulation of the hypothalamus which, acting through the vagus nerves, results in a marked outpouring of gastric juice. If even one fibre of the vagus is left intact this response may be obtained. A comparison of the insulin response before and after operation therefore provides a reliable, but not infallible, indication of the completeness of the operation.

The operative technique was then demonstrated by means of coloured illustrations.

Post-operative régime.—Even the best vagal resection may lead to the most unfortunate results if the importance of the early post-operative management is left to the discretion of ward sisters and house surgeons. It is essential to decompress the stomach completely for five days after the vagotomy. This was not appreciated in our earlier cases and some of those who had troublesome retention might have enjoyed a much greater benefit by an earlier application of this principle. Some of the very unsatisfactory cases recently reported in American literature also appear to have been due to neglect in this respect. The patient is given only intravenous feeding for five days, and food and water by the mouth are entirely withheld. When the tube is removed the patient is given fluids, one ounce per hour, and the stomach tube is passed in the evening and the gastric contents aspirated. If the day's ration of fluid appears to have passed successfully, two ounces hourly are allowed the next day. If this passes successfully he is placed on a liquid diet with instructions to cease drinking if he feels distended. A few days later, if the liquid diet is passing the pylorus, semi-solid food is added and gradually the diet is built up. It should be possible to allow a full normal meal in a month from the date of the operation. Given rest, Auerbach's plexus establishes an autonomous motility which may reach a degree of activity equal to normal.

These cases are allowed to sit and stand up forty-eight hours after operation, unless there is some other counter-indication, and by the end of a week they are surprisingly active.

Results.—Post-operative follow-up is made of all cases. They are readmitted as bed space permits for a repeat of their night secretion tests, and barium meal studies, after three months have elapsed. Tests performed soon after the operation may be misleading due to delayed emptying of the stomach and other factors. The patients are seen again at six-monthly intervals for two years, and then once a year with instructions to report immediately any untoward event. 115 operations have been performed (Tables I and II).

SEPT.—SURG. 2.

therapy heals a high proportion of duodenal ulcers there is no doubt whatever. Unfortunately when these people return to their normal activities the cephalic stimuli return with their former intensity and it is no longer possible to anchor the patient to his milk drip or continue to push atropine to the limits of tolerance, and within two years a regrettably high percentage of these ulcers recur.

Present-day surgical therapy also depends for its success on the control of acid, and it has been found necessary to remove the greater part of the acid-secreting portion of the stomach to protect the jejunum used in the anastomosis. Both physician and surgeon aim at the control of acid, one by the exhibition of therapeutic measures over a limited period, the other by ablating the organ which secretes the acid. Much confusion of thought would be avoided if it were clearly recognized that acid may be secreted in response to two entirely different types of stimuli. One is due to a hormone, believed to be formed in the first part of the duodenum and the pyloric antrum. In normal people this is the predominant factor in acid secretion, and as it occurs only when there is food in the stomach to buffer it, its action is entirely beneficial. On the other hand recent work by Johnson has shown that a large and unfortunately growing class of people secrete acid in response to nervous stimuli. This secretion is not limited to psychic stimuli such as the sight, smell and taste of food, but is continuous throughout the hours of sleep; and in fact it may reach higher levels while the stomach is empty than it does following a test meal. If we remember this we see how important it is for the physician to treat the patient by a continuous milk drip during the hours of sleep, and how essential it is for the surgeon to remove all the secreting part of the stomach if he is to avoid the danger of a stomal ulcer. But if this acid, secreted in response to nervous stimuli, is as important as recent investigation would suggest, it is at least rational to attempt to eliminate it by interrupting the nerve pathways. This, then, is the rationale of vagus resection. If it can be shown that the quantity of acid secreted during the hours of sleep is appreciably reduced, that the hypermotility and pylorospasm are abolished, that pain is relieved and the ulcer shown to heal, then, indeed, we have a humane experiment worth following up in all its aspects. If, in addition, our follow-up shows a persistence of the benefits and a lack of disabling side-effects, we have contributed something of permanent value in the therapy of duodenal ulcer. Even though it is unlikely to supplant medical treatment or gastrectomy entirely, a place may be found for it among the accepted procedures of our time.

Anatomical considerations.—The right and left vagus nerves distribute themselves in the form of a plexus around the œsophagus below the hila of the lungs. On the lower two inches of the œsophagus, however, the multiple branches group themselves into two to four main trunks, related to the anterior and posterior aspects of the œsophagus, and it is at this point that they are most easily located and followed through the hiatus and a segment resected. The approach favoured by Allen is transthoracic, on the assumption that only by this route can the vagotomy be made complete. Dragstedt, who has performed four hundred vagal resection operations in the past five years, began with the thoracic approach but of recent years has adopted the transabdominal route. At Hammersmith we have employed a trans-abdominal, trans-hiatal approach in all but four of our cases, and with growing experience complete vagotomy has been achieved, though in many of the early cases fibres were missed and the results were disappointing. The advantage of the transabdominal approach is that the ulcer can be seen and verified, other pathology detected, and additional operative procedures carried out if thought necessary.

Selection of cases.—The ideal case for vagal resection alone is the patient with a duodenal ulcer with a rapidly emptying stomach and a highly acid night secretion. Gastric ulcers are, in our experience, unsuitable for treatment by vagal resection alone, though Dragstedt finds it beneficial; and Professor Beattie, in his recent Hunterian lecture, looks upon it as an indication. We have rarely found the gastric ulcer case with a night secretion sufficiently high to justify a vagotomy, and we agree with Allen that in view of the risks of malignancy, if surgery is indicated at all, such ulcers are better resected.

Stomal ulcers following gastrectomy provide a first-class indication for vagotomy. Indeed, it may be the only surgical procedure practicable. Stomal ulcers following gastro-enterostomy appear to do well on vagal resection alone, but on theoretical grounds it seems rational to remove the pyloric antrum at the same time, thereby eliminating hormone-secreted acid as well as the acid under nervous control.

Ulcers complicated by stenosis, even relative stenosis, do badly with vagotomy alone in view of the fact that gastric motility is reduced and gross gastric retention is likely to follow. In the earlier cases in the series, we performed a posterior gastro-enterostomy at the same time as the vagotomy, or as a secondary procedure if gastric retention became manifest later. The results (some of them three years old) have remained good to date, but during the past year we have resected the pyloric antrum at the time of the vagotomy operation, employing a

Polya type of anastomosis. This antrectomy, plus vagotomy, has resulted in the most marked fall in acid, as the hormone as well as the nervous secreted acid has been dealt with and gastric drainage has been adequate. Some of our most spectacular results have been in this antrectomy plus vagotomy group.

Methods of investigation.—For the proper selection of cases a routine investigation is essential. The barium meal study, in addition to determining the existence of an ulcer, should indicate the rate of emptying, the possibility of minor degrees of stenosis and the absence of other pathology such as duodenal diverticula or gastric ulcers which might confuse the result.

The acid secretion tests are of great importance and though the standard fractional test meals are carried out in many of the cases, the finding of greatest importance is the quantity and acid level of night secretion entirely unstimulated by food, or drugs. This entails continuous gastric suction throughout the night, titration of hourly samples and estimation of the total quantity of free acid secreted. It is on the basis of this estimation that the decision to resect the vagus is made.

The insulin test meal is also employed both before, and on several occasions following, operation. Its main value lies in providing an indication whether or not the vagotomy has been complete. Sufficient insulin is given intravenously to produce a fall in the blood-sugar level to 50 mg. per 100 c.c., or lower. This degree of hypoglycemia leads to a stimulation of the hypothalamus which, acting through the vagus nerves, results in a marked outpouring of gastric juice. If even one fibre of the vagus is left intact this response may be obtained. A comparison of the insulin response before and after operation therefore provides a reliable, but not infallible, indication of the completeness of the operation.

The operative technique was then demonstrated by means of coloured illustrations.

Post-operative régime.—Even the best vagal resection may lead to the most unfortunate results if the importance of the early post-operative management is left to the discretion of ward sisters and house surgeons. It is essential to decompress the stomach completely for five days after the vagotomy. This was not appreciated in our earlier cases and some of those who had troublesome retention might have enjoyed a much greater benefit by an earlier application of this principle. Some of the very unsatisfactory cases recently reported in American literature also appear to have been due to neglect in this respect. The patient is given only intravenous feeding for five days, and food and water by the mouth are entirely withheld. When the tube is removed the patient is given fluids, one ounce per hour, and the stomach tube is passed in the evening and the gastric contents aspirated. If the day's ration of fluid appears to have passed successfully, two ounces hourly are allowed the next day. If this passes successfully he is placed on a liquid diet with instructions to cease drinking if he feels distended. A few days later, if the liquid diet is passing the pylorus, semi-solid food is added and gradually the diet is built up. It should be possible to allow a full normal meal in a month from the date of the operation. Given rest, Auerbach's plexus establishes an autonomous motility which may reach a degree of activity equal to normal.

These cases are allowed to sit and stand up forty-eight hours after operation, unless there is some other counter-indication, and by the end of a week they are surprisingly active.

Results.—Post-operative follow-up is made of all cases. They are readmitted as bed space permits for a repeat of their night secretion tests, and barium meal studies, after three months have elapsed. Tests performed soon after the operation may be misleading due to delayed emptying of the stomach and other factors. The patients are seen again at six-monthly intervals for two years, and then once a year with instructions to report immediately any untoward event. 115 operations have been performed (Tables I and II).

72 patients have expressed themselves well satisfied with the operation.

15 are partially satisfied.

Only 2 patients out of 69 in whom vagal resection has been shown to be complete have had a continuation or recurrence of symptoms.

To date there have been no deaths due to vagotomy, though one of our early incomplete cases sustained a severe hæmorrhage three months after vagotomy, from which he died; and another had a duodenal fistula due to the resection of a penetrating ulcer, following an uneventful vagotomy. He subsequently died from an attempt to close the fistula.

One patient who had been symptom-free for a year with a negative insulin response and persisting low acid, had a hæmatemesis. Complete investigation failed to detect a recurrence of the ulcer, and the final conclusion was that he bled from œsophageal varices.

One patient with both gastric and duodenal ulcer at the time of the original operation continued to suffer from pain, due to the gastric ulcer. This experience has tended to damp our enthusiasm for vagal resection in the treatment of gastric ulcer.

The earlier attempts to resect the vagus nearly always resulted in missing an important branch, with the result that the effect was transient. One fibre appears to be capable of transmitting the total vagal impulse and considerable experience is necessary before the operator can be sure of the completeness of his operation. Most of the unsatisfactory results in this series have been found in the incomplete group.

Complications.—Of the immediate post-operative complications, basal collapse has been the most frequent, and occurred in 50% of the cases. In no case did it give rise to anxiety. Two patients had burst abdomens due to post-operative coughing. No case of pulmonary embolism has been noted and, due to the post-operative decompression of the stomach, there has been no case of acute dilatation of the stomach or complete gastric retention, though these disasters have featured in at least one of the series reported from America (Tables III and IV).

TABLE III.—IMMEDIATE POST-OPERATIVE COMPLICATIONS

Respiratory, not serious	56
Empyema following transthoracic operation	1
Acute dilatation of stomach	0
Burst abdomen	2

TABLE IV.—LATE POST-OPERATIVE COMPLICATIONS

Gastric retention, not associated with stenosis, requiring surgery for relief	0
Gastric retention, associated with organic stenosis, requiring surgery for relief	6
Gastric retention relieved by aspiration or recovering spontaneously	5
Diarrhœa: Transient and not incapacitating	56
Persistent	1
Dysphagia: Transient	8
Persistent	1
Attacks of weakness and giddiness	28

The late complications have, for the most part, been transient and tended to rectify themselves spontaneously. A feeling of fullness after meals and belching is common in the first six months. Diarrhœa has been troublesome in 50% of cases. This tends to clear up, but may recur from time to time following chills, indiscretions in diet, &c. Two complaints are of interest, not so much from their disabling effects as from the questions they raise regarding their cause. Slight difficulty in swallowing has been noted in 9 patients, and 28 have admitted on questioning to experiencing transient attacks of weakness and sweating, passing off when something is eaten. Most of those 28 patients volunteered the statement that such sweating attacks closely resembled the upset they experienced after intravenous insulin.

Conclusion.—No attempt will be made at this stage to compare the results of vagotomy with gastrectomy. The operation of vagal resection alone carries no mortality other than the risk of an odd fatality which is bound to occur in any large series of operations. Where it is combined with a gastrectomy or gastro-enterostomy, of course, it carries the risk of the major procedure. The economic factor in time lost from work weighs heavily in favour of the vagal resection, and the post-operative complications and disabilities, whilst by no means negligible, are not of an incapacitating order.

The follow-up statistics present a more gloomy picture than the faces of the patients who attend the follow-up clinic. The symptoms recorded are mostly obtained by close questioning; and the voluntary statements of the vast majority of those in whom the vagotomy has been complete are emphatic in their gratitude for the relief afforded after years of invalidism and repeated courses of medical treatment.

We know now that vagal resection is capable of lowering free acid levels to a marked degree, and that pain is relieved, and ulcers heal. Its final usefulness may be as an adjuvant to other

gastric procedures. We may find ways and means of avoiding the unpleasant side-effects and rendering the completeness more certain.

To be worth doing at all vagal resection must be complete, the patients must be carefully chosen and the post-operative régime must be strict.

There are precise indications for the operation and it should not be resorted to as a way out when one is doubtful about the diagnosis or apprehensive about more radical procedures.

This report on the first hundred and fifteen cases has dealt mainly with vagal resection alone, but the excellent results obtained when vagal resection has been combined with other operations such as gastro-enterostomy, or antrectomy, have prompted us to combine antrectomy with vagal resection in the next hundred cases, and in due time I trust we may have the opportunity to present the results of two parallel series; one showing the late results of vagal resection alone, and the other the results of the combined operation.

Dr. F. Avery Jones: Section of the vagus nerve is a logical sequence to the advances in our knowledge of the natural history of duodenal ulcer. It has been clearly recognized that disharmony with the environment plays an important rôle in the development, persistence or recurrence of duodenal ulcer.

Nervous tension is undoubtedly transmitted to the stomach via the vagus nerve and will stimulate particularly the inter-digestive secretion of acid and cause increased motility of the stomach. After cutting the nerve there is diminution of motility and of secretion, particularly between meals, and the volume and acidity of the nocturnal gastric secretion is reduced. The stomach will still respond to food and histamine stimulation, i.e. to hormonal and chemical stimulation, and the patients therefore still need proper diet. There is no longer an acid secretory response to hypoglycæmia from insulin and this enables us to test for completeness of the nerve section.

The development of a new surgical treatment at once raises the question of the scope for surgery in the management of duodenal ulcer. To what extent is medical treatment unsuccessful? My colleague, Dr. R. Doll, has been engaged in a field survey of peptic ulcer in different occupations and in interviewing 4,871 men in industry and transport or agriculture. The survey mainly covered London but was also conducted in a rural district and a small town. He found 148 who had, or had had, duodenal ulcer and they have been classified according to the present state of their dyspepsia and according to the type of treatment they had received. Some, indeed, had had no treatment and they were not diagnosed until X-rayed as a result of the survey.

	Total	Present ulcer symptoms			Number finally receiving surgical treatment
		None	Relapsing	Refractory	
<i>Medical treatment:</i>					
None	24	2	22	—	—
Home	58	15	36	7	(1)
Hospital	57	14	23	20	(12)
<i>Initial surgical treatment</i>	9	5	1	3	(2)

The intermediate group with amelioration of symptoms were men with recurring attacks of dyspepsia, often at fairly long intervals, and who were not losing much time from work. Many undoubtedly had recurrent ulceration. The refractory groups were men losing more than a month a year from work and subject to prolonged and severe bouts of dyspepsia.

Of those receiving medical treatment at home or in hospital, approximately 25% were entirely free from symptoms, 50% were having recurring attacks of mild or moderate severity and 25% were by all standards failures of whom half had a subsequent surgical operation with resulting cure in all but two cases.

The incidence of complications is another indication of the present inadequacy of medical control. In the survey, no less than 10% of the duodenal ulcers had perforated and 20% of them had bled, and this is the recognized incidence. Many of these complications had occurred while the patient was under medical supervision and even sometimes while in hospital. Illingworth *et al.* (1946) noted that 20% of their cases had re-perforated or bled within five years of the first perforation. It does seem that even with the best medical attention failure is to be expected in over a quarter of cases and there is therefore considerable scope for surgery. Even under ideal conditions at New Lodge and under the supervision of the late Sir Arthur Hurst, the final results were unsatisfactory and Barford (1928) reported 25% failures and 36% cures in a one to four years' follow-up of 90 cases.

Although the final results of medical treatment are unsatisfactory, nevertheless the initial response is excellent and in spite of a long history of dyspepsia, patients may obtain long-continued relief after a spell of medical care. Every case of uncomplicated duodenal ulcer is initially a medical problem and surgery is indicated only when the ulcer has become refractory or causes acute perforation or pyloric stenosis.

The rôle of a new surgical procedure must be considered in relation to the mortality of ulcer. Death occurs mainly from hæmorrhage or perforation and I have put together the deaths from these two causes at my hospital, 1945-6-7.

Age	No. admitted with hæmatemesis or perforation, 1945-6-7	Deaths	Percentage
20-29	22	—	—
30-39	41	3	4
40-49	72	2	
50-59	55	5	9
60-69	33	3	
70-79	25	8	32
80-	9	6	67

With modern treatment the mortality of major complications is low under 50 years of age and the need for elective surgery is much more to save the man's job than to save his life. Over 60, the need is certainly to save life in the face of possible complications. Although it is possible to achieve a mortality of 2 to 3% for partial gastrectomy, there are comparatively few surgeons in this class and 5% at least must represent the figures of the majority of surgeons. This is a high price for job-saving operations. As the operation is a major strain on the patient, there are many older patients who are not thought fit for it. Nevertheless, partial gastrectomy is a tremendous help in many cases but there is a great need for an operation with a low mortality and which imposes less strain on the elderly. Vagus nerve resection has a mortality of under 1% and in this respect meets our requirements.

Does vagotomy influence the disease process and improve the patient's prospect of full work? The results with duodenal and jejunal ulcer so far seem highly promising. My series, with my surgical colleagues, Mr. Ilyd James and Mr. J. D. Fergusson, is at present small. 48 cases have been done without a death but a number are too recent for any real assessment. Of these, 33 were done last year and 3 were for post-operative dyspepsias. They have since been reviewed. 30 were performed for duodenal ulcer. In the duodenal ulcer group, 2 cases have been unsuccessful; one has had a subsequent gastro-enterostomy for stenosis and the other has had continued pain but the insulin test showed an incomplete section of the nerve. 21 patients are perfectly well, their weight has increased, they are free from pain and have had no symptoms at all. The remaining 7 cases of duodenal ulcer have had varying degrees of discomfort, diarrhoea (7), which has persisted in 3 cases, occasional attacks which sound like hypoglycæmia (3), heartburn (1) and slight transient dysphagia (1). In spite of these symptoms, these patients, all with a long history of ulcer, profess themselves satisfied with the operation. The 3 cases with previous partial gastrectomy (2) or gastro-enterostomy (1) have not been satisfactory but all have a considerable functional overlay.

The unsatisfactory side-effects of the operation are undue gastric stasis, causing the halitosis and sense of fullness, diarrhoea, which usually clears up in a short time but may be quite severe and may occasionally persist, slight dysphagia with failure of relaxation of the lower end of the œsophagus and attacks which resemble hypoglycæmia. There may be persistence of ulcer pain if the nerve section is incomplete and pyloric stenosis may develop with the scarring of the healing ulcer. Finally, there may be persistence of symptoms from an associated psychoneurotic state. It seems probable that satisfactory results are obtained in 85-90% of cases, a proportion similar to the results after partial gastrectomy but achieved with a lower mortality.

Although the initial results are impressive these untoward effects are particularly disturbing because the intimate mechanism of the diarrhoea and of the "hypoglycæmic attacks" is at present unknown. It must be remembered that the intestine and pancreas are denervated by the operation. The question of gastric stasis is a further problem which needs study. It is possible that freer use of gastro-enterostomy will be needed, particularly when there is any indication of narrowing at the time of operation. Some are also advocating a limited gastrectomy plus vagotomy.

The position in this country to-day is that a number of surgeons have now had a limited experience of the operation. What we need is a really careful, well organized, well coordinated study in a number of centres. We need a central committee which can draw up a simple plan for routine recording of cases and of the follow-up. This needs to be done with the assistance of a statistician well versed in the modern methods of mechanical tabulation of results. With the taking over of hospitals, almoners should be able to undertake more follow-up studies and really careful proleptic series are urgently needed.

The careful planning and length of history and enable comparisons to be made between them down into age-groups and length of history and enable comparisons to be made between those with and those without gastro-enterostomy or antrectomy. The details of insulin tests and night-secretion tests could be standardized and would be a great help to busy

surgeons in other centres. Let us see that the appalling conflict of opinion over the results of gastric surgery in the past is not repeated over vagotomy. By good planning and team work, the treatment of bacterial endocarditis with penicillin was quickly worked out. It is just such a study that is urgently needed for vagotomy. Peptic ulcer is an important disease of modern life. Over 6% of men in industrial life have, or have had, ulceration and many continue to have recurring attacks. About 10% of the adult general medical or surgical beds in this country are occupied by patients with peptic ulcer.

Mr. Rodney Maingot: After much investigation into the subject of vagotomy, I decided to apply the method to certain types of peptic ulcer which were recalcitrant to medical therapy and which, in my experience, yielded poor results with gastrojejunostomy or gastrectomy.

In spite of the flattering reception accorded by surgeons throughout the world to this newly resurrected operation, and the pleasing facility with which it can be accomplished with negligible mortality, it is my opinion that this procedure is being carried out at the present time too frequently and too light-heartedly.

If the experiment is worth while—and I am convinced that it is—then it should be undertaken only by those experienced in gastric surgery and who in addition hold responsible posts where every facility exists for research work.

Gastric ulcer.—Vagotomy should not be performed for chronic gastric ulcer. It is generally agreed that the correct treatment for a patient with a callous gastric ulcer is partial or subtotal gastrectomy; as the operative mortality is low, 3% or under, the subsequent onset of gastrojejunal ulceration is an extremely rare event, and the immediate and late results are excellent in every respect.

From every point of view the results of gastrectomy for gastric ulcer are superior to those which follow gastroduodenal resection for duodenal ulcer.

If a patient with a gastric ulcer cannot withstand resection, it is on the whole better to resort to medical therapy than to perform local excision of the ulcer alone or V-excision combined with gastrojejunostomy. Such operations not infrequently yield results as poor as those of medical treatment.

Although gastric ulcer is essentially a surgical condition, *medical in-patient treatment* for a period of one month is warranted if: (1) the patient is young; (2) there is a short history of indigestion; and (3) the ulcer is in the vertical part of the lesser curvature and is small. Healing should be demonstrated in one month and be confirmed at subsequent intervals varying according to the progress of the case.

A patient with a gastric ulcer has a cancer in his stomach until it has been proved otherwise. The ulcer is innocent if it heals staunchly as shown by gastroscopy and by radiology, and displays no signs of recurrence.

The recommendation has been made that vagotomy should be used as a therapeutic test for gastric ulcer—more especially the high cardinal ulcers, and for combined ulcers, the idea being that if the ulcer heals after vagotomy the lesion must be benign.

Then if it fails to heal, it is malignant and should be resected. "One may also agree that the patient is hardly to be blamed if after one major operation to deal with a gastric ulcer he refuses further surgery when told that his lack of response indicates that his stomach should have been taken out in the first place" (F. D. Moore, 1947, *Surg. Clin. N. Amer.*, 1078).

The most cogent reason for *not* employing vagotomy for cases of gastric ulcer is the fact that gastric ulcer is a recognized complication of this operation, especially when it is carried out as a primary procedure for uncomplicated duodenal ulcer.

To date I have had to perform subtotal gastrectomy on two occasions for simple penetrating gastric lesions which followed speedily in the wake of vagotomy for duodenal ulcer.

Duodenal ulcer.—My experience of vagotomy in this disease is limited to 46 cases during the last twenty-two months. All except two of the operations were for duodenal ulcer. There were: 23 simple vagotomies; 10 gastrojejunostomies combined with vagotomy; 11 gastrectomies combined with vagotomy; and 2 vagotomies for stomal ulcer following gastroduodenal resection for duodenal ulcer. There was one death in this small series.

Ogilvie once said that every operation upon the stomach is a success until it is found out.

At the Mayo Clinic in 1934 fully one-third of all cases of duodenal ulcer submitted to operation were pyloroplasties.

Now, fourteen years later, less than 1% of these cases are subjected to Judd's operation.

The rôle of a new surgical procedure must be considered in relation to the mortality of ulcer. Death occurs mainly from hæmorrhage or perforation and I have put together the deaths from these two causes at my hospital, 1945-6-7.

Age	No. admitted with hæmatemesis or perforation, 1945-6-7	Deaths	Percentage

With modern treatment the mortality of major complications is low under 50 years of age and the need for elective surgery is much more to save the man's job than to save his life. Over 60, the need is certainly to save life in the face of possible complications. Although it is possible to achieve a mortality of 2 to 3% for partial gastrectomy, there are comparatively few surgeons in this class and 5% at least must represent the figures of the majority of surgeons. This is a high price for job-saving operations. As the operation is a major strain on the patient, there are many older patients who are not thought fit for it. Nevertheless, partial gastrectomy is a tremendous help in many cases but there is a great need for an operation with a low mortality and which imposes less strain on the elderly. Vagus nerve resection has a mortality of under 1% and in this respect meets our requirements.

Does vagotomy influence the disease process and improve the patient's prospect of full work? The results with duodenal and jejunal ulcer so far seem highly promising. My series, with my surgical colleagues, Mr. Iltyd James and Mr. J. D. Fergusson, is at present small. 48 cases have been done without a death but a number are too recent for any real assessment. Of these, 33 were done last year and 3 were for post-operative dyspepsias. They have since been reviewed. 30 were performed for duodenal ulcer. In the duodenal ulcer group, 2 cases have been unsuccessful; one has had a subsequent gastro-enterostomy for stenosis and the other has had continued pain but the insulin test showed an incomplete section of the nerve. 21 patients are perfectly well, their weight has increased, they are free from pain and have had no symptoms at all. The remaining 7 cases of duodenal ulcer have had varying degrees of discomfort, diarrhoea (7), which has persisted in 3 cases, occasional attacks which sound like hypoglycæmia (3), heartburn (1) and slight transient dysphagia (1). In spite of these symptoms, these patients, all with a long history of ulcer, profess themselves satisfied with the operation. The 3 cases with previous partial gastrectomy (2) or gastro-enterostomy (1) have not been satisfactory but all have a considerable functional overlay.

The unsatisfactory side-effects of the operation are undue gastric stasis, causing the halitosis and sense of fullness, diarrhoea, which usually clears up in a short time but may be quite severe and may occasionally persist, slight dysphagia with failure of relaxation of the lower end of the œsophagus and attacks which resemble hypoglycæmia. There may be persistence of ulcer pain if the nerve section is incomplete and pyloric stenosis may develop with the scarring of the healing ulcer. Finally, there may be persistence of symptoms from an associated psychoneurotic state. It seems probable that satisfactory results are obtained in 85-90% of cases, a proportion similar to the results after partial gastrectomy but achieved with a lower mortality.

Although the initial results are impressive these untoward effects are particularly disturbing because the intimate mechanism of the diarrhoea and of the 'hypoglycæmic attacks' is at present unknown. It must be remembered that the intestine and pancreas are denervated by the operation. The question of gastric stasis is a further problem which needs study. It is possible that freer use of gastro-enterostomy will be needed, particularly when there is any indication of narrowing at the time of operation. Some are also advocating a limited gastrectomy plus vagotomy.

The position in this country to-day is that a number of surgeons have now had a limited experience of the operation. What we need is a really careful, well organized, well co-ordinated study in a number of centres. We need a central committee which can draw up a simple plan for routine recording of cases and of the follow-up. This needs to be done with the assistance of a statistician well versed in the modern methods of mechanical tabulation of results. With the taking over of hospitals, almoners should be able to undertake more follow-up studies and really careful proleptic series are urgently needed.

The careful planning and central collection of 500-1,000 cases would enable us to break them down into age-groups and length of history and enable comparisons to be made between those with and those without gastro-enterostomy or antrectomy. The details of insulin tests and night-secretion tests could be standardized and would be a great help to busy

There were 37 such cases reported by Waltman Walters (personal communication, January 1948) with good results in 31, fair results in 5, and poor results in 1.

I do not advise transthoracic vagotomy for the last-mentioned type of case, as I believe that by the abdominal route large segments of the right and left vagus nerves can be resected after the surgeon has assured himself that the amount of stomach removed is adequate, that no pyloric stump with its baneful mucous lining is left behind, and that the stoma is adequate and well placed, that there is no obstruction of the proximal or distal jejunal limbs, and that a gastro-jejuno-colic fistula can be excluded with safety.

I would not recommend vagotomy for anastomotic ulcer following gastrojejunostomy, because the mechanics of this procedure are so often at fault, and even if healing of the lesion does eventuate this is often followed by excessive and progressive scar formation at the site of the all-too-frequently contracted stoma. The healing of the ulcer, the tardy emptying of the stomach, and the added pyloric spasm may precipitate a condition of malnutrition complicated by a low-grade small-gut obstruction.

Technique of vagotomy.—The operation may be performed through the chest or through the abdomen. If the operator is a thoracic surgeon or one interested in thoracic surgery, he will perform the operation through the chest; if, on the other hand, he has specialized in abdominal surgery, and more particularly if he is a general surgeon, he will select the epigastric route.

I would criticize the transthoracic approach on these grounds: (1) The lesion cannot be examined (possibly malignant). (2) Pyloric obstruction cannot be corrected. (3) Post-operative pain in the incision and costo-vertebral joint may result. (4) Gastrojejunostomy is a difficult and unsatisfactory procedure when performed as a secondary operation on a dilated, oedematous and atonic stomach. (5) Intrathoracic complications (empyema) may result.

Mr. David H. Patey: Though Dragstedt in 1943 with his paper on vagotomy in the treatment of peptic ulcer reopened the whole question of the surgical treatment of peptic ulcer, it is still too soon for any final conclusions on the position of vagotomy in the treatment of peptic ulcer. My own experience is of 31 cases the first of which was operated on in November 1945. I have regarded them as research cases, and have carried out full pre- and post-operative tests. As a result of my experiences I should like to make a few brief observations under three headings: Surgical anatomy, complications, and results.

Surgical anatomy.—The abdominal route is, with the possible exception of certain cases of gastrojejunal ulcer, better than the thoracic for the main reason that it enables the condition of the ulcer to be examined, and if necessary additional operative procedures to be performed to deal with the mechanical sequelæ of peptic ulceration. A minor additional reason in favour of the abdominal route is that sometimes following the thoracic approach the patient has temporary neuritic pains in the epigastrium from trauma to intercostal nerves which is of little significance in itself but which he may interpret as a persistence of his visceral troubles. When I have used the thoracic route, I have preferred a right-sided approach to a left-sided. I have found touch as well as sight valuable for identification of the vagus with the intra-abdominal approach, since this nerve may lie in the cellular tissue quite a distance from the œsophagus. The nerves offer a resistance to touch quite different from that of the cellular tissue.

Complications, or perhaps, more accurately, sequelæ: I have had cases with temporary trouble from diarrhœa, duodenal ileus, cardiospasm, attacks of giddiness due to transient hypoglycæmia, and foul eructations. These sequelæ are usually only temporary, cause only a minor degree of disability, can in part be alleviated by correct post-operative treatment, and in no way should condemn the operation or lead to its abandonment if the results on the ulcer itself should prove satisfactory.

Results.—In 5 cases where the operation was performed for gastrojejunal ulcer, the results have so far been good. 2 cases bear on the problem of gastric ulcer: one was that of a combined gastric and duodenal ulcer. Following vagotomy the duodenal ulcer healed but the gastric ulcer got progressively larger and was eventually excised by a partial gastrectomy. The other case was that of a vagotomy for duodenal ulcer in which a gastric ulcer developed subsequent to the operation. From these two experiences, and in view of the general good results of gastrectomy in gastric ulcer, I decided not to do any more vagotomies for gastric ulcer. Of the remaining 24 cases, which were of duodenal ulcer, 4 cases were failures in that symptoms persisted and X-rays still showed active duodenal ulcers. In 2 of these cases there was evidence that vagotomy was not in fact achieved, so that they must be

It has taken nearly fifty years to appreciate the fact that in duodenal ulcer *gastrojejunostomy* is a damning procedure when carried out in young patients, in those with uncomplicated lesions associated with marked hyperchlorhydria, in those with recurrent hæmorrhages, in psychoneurotics, and in patients with intractable ulcers.

Gastrojejunostomy should be reserved for aged and feeble patients with obstructive symptoms or severe pain due to a deeply penetrating duodenal ulcer, and for those who are in a poor general state of health due to some concomitant lesion which would render gastric resection too hazardous (R. S. Boles, 1948, *J. Amer. med. Ass.*, 136, 764).

I do not therefore advise vagotomy combined with gastrojejunostomy for the unresponsive duodenal ulcer, as the post-operative convalescence in my series of cases has been prolonged and stormy, and it takes weeks or long months for the flabby, distended, atonic stomach to empty its decomposing contents into the patulous unreceptive jejunal stoma.

Diarrhœa, ileus, colic, dysphagia, and the belching of malodorous gases have been troublesome sequelæ in the majority of cases. I agree with Lewishon that pronounced atony is one of the most dangerous complications following abdominal operations. Four of my patients developed well-marked cardiospasm within one week following vagotomy for duodenal ulcer, which, however, responded to dilatation with œsophageal bougies or treatment with octyl nitrite.

I do not believe that the new physiologic operation of pyloro-duodenectomy or antrectomy followed by the Polya type of anastomosis combined with vagotomy will improve the late results, since we are as yet ignorant of the exact anatomical distribution of the "humoral" elements in the stomach, and gastric neurectomy leaves the large residual gastric pouch sullen and toneless.

Subtotal gastrectomy—the removal of at least five-sixths of the stomach together with the ulcer in the duodenum, adopting the antecolic Polya-Hoffmeister procedure, is a seasoned, highly perfected and gratifying procedure when performed for duodenal ulcer, yielding a high percentage of lasting cures.

The higher the resection, the fewer are the number of subsequent secondary ulcers. In expert hands the incidence of gastrojejunal ulcer is about 3%. This figure may be lowered by a complementary vagotomy, and more especially in that treacherous type of case associated with recurrent hæmorrhages and markedly raised acid values in the gastric juice.

The higher the resection, the greater is the loss of weight. Following subtotal gastrectomy patients are slow to gain in weight.

Insulin test.—All authorities are agreed that Hollander's insulin test is a reliable one in ascertaining post-operatively whether all the vagal branches to the stomach have been well and truly resected.

The test in its present form is not free from the danger of insulin shock and other alarming phenomena. There were cases in which I was certain I had sectioned all the nerves, and yet the test was positive; in others again I performed what I considered to be an unsatisfactory and incomplete gastric neurectomy, and to my surprise the test was negative.

I have had patients who after simple vagotomy for duodenal ulcer gave a negative response shortly after operation and in whom six months later the test was positive. Although the insulin test revealed that in the majority of my patients the nerves had been completely sectioned, nevertheless there did not appear to be any relationship between the completeness and incompleteness of the vagotomy and the relief of pain, the acidity figures, the motor disturbances and the other complications.

Indications for vagotomy.—Because the results are so unpredictable and variable, I would now advise vagotomy for the following types of cases: (1) Nervous patients under the age of 45 with uncomplicated duodenal ulcer (no history of recurrent hæmorrhages and no evidence of obstruction), in whom repeated courses of treatment in hospital have failed to effect a cure. Here the lesion is often puny and out of all proportion to the symptoms and may rightly be deemed to be unworthy of a pyloroplasty or a grandiose gastroduodenal resection.

(2) Cases of chronic duodenal ulcer which give a history of repeated bleedings. Here vagotomy is combined with subtotal gastrectomy to safeguard the patient against the real danger of stomal ulceration or recurrent hæmorrhages.

(3) Cases of gastrojejunal ulcer which have followed a well-performed gastroduodenal resection. This is the prime indication for vagotomy.

The immediate and interim results following vagotomy for an anastomotic ulcer after gastroduodenal resection are excellent in every respect. Pain is instantly relieved, the ulcer heals with dramatic rapidity, and the longing for food is restored.

There were 37 such cases reported by Waltman Walters (personal communication, January 1948) with good results in 31, fair results in 5, and poor results in 1.

I do not advise transthoracic vagotomy for the last-mentioned type of case, as I believe that by the abdominal route large segments of the right and left vagus nerves can be resected after the surgeon has assured himself that the amount of stomach removed is adequate, that no pyloric stump with its baneful mucous lining is left behind, and that the stoma is adequate and well placed, that there is no obstruction of the proximal or distal jejunal limbs, and that a gastro-jejuno-colic fistula can be excluded with safety.

I would not recommend vagotomy for anastomotic ulcer following gastrojejunostomy, because the mechanics of this procedure are so often at fault, and even if healing of the lesion does eventuate this is often followed by excessive and progressive scar formation at the site of the all-too-frequently contracted stoma. The healing of the ulcer, the tardy emptying of the stomach, and the added pyloric spasm may precipitate a condition of malnutrition complicated by a low-grade small-gut obstruction.

Technique of vagotomy.—The operation may be performed through the chest or through the abdomen. If the operator is a thoracic surgeon or one interested in thoracic surgery, he will perform the operation through the chest; if, on the other hand, he has specialized in abdominal surgery, and more particularly if he is a general surgeon, he will select the epigastric route.

I would criticize the transthoracic approach on these grounds: (1) The lesion cannot be examined (possibly malignant). (2) Pyloric obstruction cannot be corrected. (3) Post-operative pain in the incision and costo-vertebral joint may result. (4) Gastrojejunostomy is a difficult and unsatisfactory procedure when performed as a secondary operation on a dilated, œdematous and atonic stomach. (5) Intrathoracic complications (empyema) may result.

Mr. David H. Patey: Though Dragstedt in 1943 with his paper on vagotomy in the treatment of peptic ulcer reopened the whole question of the surgical treatment of peptic ulcer, it is still too soon for any final conclusions on the position of vagotomy in the treatment of peptic ulcer. My own experience is of 31 cases the first of which was operated on in November 1945. I have regarded them as research cases, and have carried out full pre- and post-operative tests. As a result of my experiences I should like to make a few brief observations under three headings: Surgical anatomy, complications, and results.

Surgical anatomy.—The abdominal route is, with the possible exception of certain cases of gastrojejunal ulcer, better than the thoracic for the main reason that it enables the condition of the ulcer to be examined, and if necessary additional operative procedures to be performed to deal with the mechanical sequelæ of peptic ulceration. A minor additional reason in favour of the abdominal route is that sometimes following the thoracic approach the patient has temporary neuritic pains in the epigastrium from trauma to intercostal nerves which is of little significance in itself but which he may interpret as a persistence of his visceral troubles. When I have used the thoracic route, I have preferred a right-sided approach to a left-sided. I have found touch as well as sight valuable for identification of the vagus with the intra-abdominal approach, since this nerve may lie in the cellular tissue quite a distance from the œsophagus. The nerves offer a resistance to touch quite different from that of the cellular tissue.

Complications, or perhaps, more accurately, *sequelæ*: I have had cases with temporary trouble from diarrhoea, duodenal ileus, cardiospasm, attacks of giddiness due to transient hypoglycæmia, and foul eructations. These sequelæ are usually only temporary, cause only a minor degree of disability, can in part be alleviated by correct post-operative treatment, and in no way should condemn the operation or lead to its abandonment if the results on the ulcer itself should prove satisfactory.

Results.—In 5 cases where the operation was performed for gastrojejunal ulcer, the results have so far been good. 2 cases bear on the problem of gastric ulcer: one was that of a combined gastric and duodenal ulcer. Following vagotomy the duodenal ulcer healed but the gastric ulcer got progressively larger and was eventually excised by a partial gastrectomy. The other case was that of a vagotomy for duodenal ulcer in which a gastric ulcer developed subsequent to the operation. From these two experiences, and in view of the general good results of gastrectomy in gastric ulcer, I decided not to do any more vagotomies for gastric ulcer. Of the remaining 24 cases, which were of duodenal ulcer, 4 cases were failures in that symptoms persisted and X-rays still showed active duodenal ulcers. In 2 of these cases there was evidence that vagotomy was not in fact achieved, so that they must be

regarded as technical failures. In the other 2 cases, however, the ulcers persisted in spite of technically successful vagotomies.

At subsequent operations for excision of the ulcers, in one case an adherent callous ulcer 2 cm. in diameter was found and in the other a similar ulcer 1.3 cm. in diameter. From this experience I concluded that vagotomy alone was not sufficient in large callous ulcers. In the remaining 20 cases of duodenal ulcer, the results up to the present are satisfactory although it should be emphasized once again that in no case has the follow-up been very long and that some of the cases are very recent. These 20 cases fall into two approximately equal groups. In the first, the ulcers were small—either no induration was present or the induration was less than 1 cm. in diameter—and there was no cicatricial narrowing of the duodenal lumen. In this group vagotomy only was performed. In the second, there was either a large callous ulcer of the duodenum or cicatricial narrowing of the lumen. In this group in addition to the vagotomy a duodeno-pylorotomy with end-to-end anastomosis has been the standard operation performed. The amount of tissue excised has been small, on the stomach side the section running immediately proximal to the pyloric sphincter and on the duodenal side the section being made immediately beyond the ulcer after the duodenum had been sufficiently freed to enable a direct end-to-end anastomosis to be made after resection. The tissue excised has been about 21 to 42 grammes, so that any good results that may be obtained cannot be attributed to a gastrectomy effect. While local conditions may exceptionally indicate gastro-enterostomy rather than pyloro-duodenectomy, I feel that wholesale gastro-enterostomies would be unwise, particularly as my experience has been (and I know it is the exact reverse of what is generally taught) that, in cases of pyloric stenosis especially, gastro-enterostomy is liable to be followed by anastomotic ulceration. The counter-argument might rightly be made of the generally good results so far from vagotomy in gastrojejunal ulcers but I think it would be wrong to revive as a standard procedure an operation like gastro-enterostomy, the complications of which have proved such a trial to surgery for so many years, without strong proof of the long-term value of vagotomy.

My tentative conclusions are that vagotomy has no place in the treatment of gastric ulcer; it may have an important place in gastrojejunal ulcer, and its possible place in duodenal ulcer is worthy of further exploration. But alone it is not sufficient to cure large callous duodenal ulcers and it is clearly inadequate alone in the presence of mechanical complications such as stenosis.

Mr. Bryan N. Brooke: In the first 50 cases of a series of vagal sections performed by the Surgical Unit at the Queen Elizabeth Hospital, Birmingham, there were 51 lesions including 43 duodenal, 5 gastric, 2 anastomotic ulcers, and 1 gastro-jejuno-colic fistula. The operations performed were:

Thoracic	Abdominal
28	9
	+ Gastro-enterostomy
	11
	+ Pyloroplasty
	2

The "drainage" operations were all premeditated and performed at the time of the nerve section; gastro-enterostomy has never had to be performed as an emergency to relieve retention.

The gruel test meal, night resting juice and insulin test are performed, repeated immediately post-operatively, and again at a six-month follow-up when the patient is readmitted for three nights. The insulin test is not regarded as entirely satisfactory, for there is no certain indication that the full vagal reflex has been brought into play in the post-operative case with a negative response, unless the hypoglycæmia symptom of sweating can be accepted as a signal of this. Hollander's figure of a blood-sugar level of 50 mg. is arbitrary and unacceptable, particularly when judged against sweating (figures were presented to illustrate this argument). The dose of 0.1 unit per kilo body-weight has been found satisfactory, when judged either by sweating or by Hollander's standard, except immediately post-operatively when more insulin appears to be required to lower the blood sugar to the same extent (examples were given).

The usual arguments regarding approach prevail with us, the balance having to be struck between the advantage of the less uncertain section by the thoracic approach, and the diagnostic advantages of the abdominal approach together with assessment of stenosis which the laparotomy permits. Pleural adhesions do not cause insuperable difficulty, but hiatus hernia, encountered three times and not displayed by previous X-ray, is disconcerting from the abdominal approach.

No deaths have occurred. Chest complications were as follows:

Approach	Cases	Pul. collapse	Effusion
Thoracic ..	28	12	16 (4 required aspiration. No empyema)
Abdominal	22	7	0

There were no cases of persistent gastric retention and only 2 patients vomited in the immediate post-operative period. Persistent diarrhoea occurred in 5 cases. This is in clear contrast to the American reports, for in their series gastric retention and diarrhoea are notably higher. Perhaps this is the result of the higher fat content of their diet, for a recent report shows that the diarrhoea may be a steatorrhoea; the fat may further slow down the emptying of an atonic stomach. Nine patients experienced a sense of obstruction to swallowing, one returning to hospital two weeks after discharge with this complaint. Barium swallow showed no achalasia, nor any "hold-up". This symptom corrects itself without treatment. Likewise foul eructation has corrected itself in three to six months in the eight patients who have complained of it.

One possible autonomic complication has been encountered. In view of the imbalance in favour of the sympathetic system brought about by cutting the vagus, the blood-pressure has been recorded at follow-up in all cases. One patient of 50 had a blood-pressure of 130/90, before operation; three months later it was 198/120, and after six months, when the patient was admitted for three days, it was persistently 210/130. This patient had no headaches and no albuminuria.¹

With 35 cases followed up and only 18 seen at six months, too little evidence has yet been collected to judge the effects of section on peptic ulcer.

Mr. H. Daintree Johnson (*Précis*): Of the 115 patients operated on by Mr. Orr and myself I have submitted 52 to intensive investigation and personal follow-up.

Investigation of spontaneous night secretion, as well as insulin test, is carried out before and after operation in all cases. Some have half-hourly gastric aspirations for twenty-four hours while on a normal diet and the H ion concentration of the samples is measured electrically. This investigation has confirmed that it is during the night, when the buffering action of food is absent, that gastric acidity reaches its highest levels.

After vagotomy there is a reduction by 77% of the average free acidity in the night secretion. Volumes are probably at least as important as acid levels and these are reduced on the average by 74%.

The reduction in H ion concentration averages 99.8%, represented by a rise in pH from 2 to 4.7. The amount of free HCl in grammes in the whole of the night secretion is probably the most valuable figure and this is reduced by 96% on the average (Table I).

TABLE I.—SPONTANEOUS NIGHT SECRETION IN 40 CASES OF DUODENAL ULCER, BEFORE AND TWO TO THREE WEEKS AFTER VAGOTOMY

	Before operation	After vagotomy
Average free HCl, ml. N/10 ..	53	12
range	10-91	0-32
Average peak free HCl	80	31
range	26-116	0-74
Average total volume, mls. ..	522	137
range	187-1,115	23-290
Average pH	2.0	4.7
range	1.1-3.2	1.9-8.0
Average free HCl in grammes in whole night secretion ..	1.01	0.05
range	0.11-2.47	0.0-0.14

Out of 95 patients with peptic ulcer submitted to insulin test before operation 9 failed to respond, though 5 reacted normally when tested again with the same dose of insulin. A single negative insulin test is therefore not a proof of complete vagotomy. Some have

¹Bilateral hydronephrosis has since been demonstrated in this case. The time of onset of the hypertension may be coincidental, or the hypertension may have been precipitated by vagal section in a patient previously disposed towards it.

attempted to employ the insulin test before operation as an index of "vagotonia". It is true that the gastric insulin response is typically high in duodenal ulcer patients, but if indeed neurogenic secretion is an important factor in the aetiology of duodenal ulcer, as I believe it to be, then I would suggest that it is the amount of vagal activity that is likely to be at fault, rather than the secretory response to a single and, in a sense, unphysiological stimulation of the vagus. The estimation of the spontaneous night secretion of acid is probably a better index of spontaneous vagal activity.

To employ the histamine test, as some have done, to assess the effects of vagotomy would seem quite irrational. It is one of the virtues of vagotomy that, unlike gastrectomy, it reduces the dangerous resting secretion without having any direct effect on hormonal secretion produced in response to the taking of food and essential to its proper digestion.

Motor effects.—It has been shown by many workers from Pavlov to Teorrel that acid which remains in the stomach is slowly eliminated, probably by a variety of mechanisms. The rapidly emptying stomach in duodenal ulcer hurries acid on into the duodenum before these mechanisms have had time to operate. For this reason the delay in gastric emptying which results from vagotomy is probably one of its most important curative effects. Also the protective buffering action of food is prolonged.

Diarrhœa.—The incidence of diarrhœa can be correlated with the degree of hypochlorhydria. It has not occurred in any patient whose insulin test was still positive or equivocal after operation, but transitory diarrhœa has occurred in one in three of those whose vagotomy appeared to be complete. Large doses of hydrochloric acid have failed to relieve the condition, but in two cases precipitated ulcer pain. Sulphasuxidine is more successful but not consistently so. There is no relation between the incidence of diarrhœa and the rate of gastric emptying.

Dysphagia.—"Slow swallowing" is a common complaint for a short time after operation and may be traumatic. One patient had dysphagia which took three months to clear up. X-ray showed the appearance of achalasia of the cardia and relief was obtained from octyl nitrite inhalation.

Persistent deformity of the duodenal bulb.—Deformity may be due to either spasm or scarring. The former disappears after vagotomy. The latter is part of the healing process and may increase. 8 patients showing increasing X-ray deformity are all symptom free. 2 of these still have the appearance of a crater.

Hypoglycæmia.—About one-third of the patients have attacks of weakness, sweating and faintness which often pass off in a few weeks. Two patients investigated had hypoglycæmia during an attack.

Body-weight.—Weight gain was considerably superior to that of a group of gastrectomized patients followed during the same period (Table II).

TABLE II.—BODY-WEIGHT

	18 vagotomy patients st. lb.	21 gastrectomy patients st. lb.
Average "normal" weight	10 1	10 2
Average pre-operative weight	9 0	9 0
Average weight six months after operation ..	9 11	8 12
Average weight one year after operation ..	9 13	8 13

Almost without exception the complications of vagotomy in our series have been transitory. I am still of the opinion that pure vagotomy is a more justifiable operation for uncomplicated but recalcitrant duodenal ulcer than pure gastrectomy.

To perform gastrectomy and reserve vagotomy for the anastomotic recurrences seems to me less rational than to try vagotomy first and keep gastrectomy for those in whom vagotomy fails to give permanent relief. In this way the more dangerous operation is used less often and the overall mortality should be reduced.

With deeply penetrating or stenosing ulcers my experience with combined vagotomy, antrectomy and removal of the ulcer is so far most encouraging.

Dr. J. Jacques Spira: Vagal resection for peptic ulcer.—Criticism of vagal resection for peptic ulcer cannot be attempted without reference to the physiological principles which regulate gastric function; the misinterpretation of the role played by hydrochloric acid in the pathogenesis of ulcer is, in my opinion, mainly responsible for the present confusion and the consequent failure to find a solution of the problem.

A review of the literature reveals that treatment is solely concerned with the elimination of the acid factor held to be responsible for the causation of the ulcer. In view of the important role which hydrochloric acid plays in the metabolism of the body, it is questionable whether the establishment of a permanent achlorhydria, which is difficult to achieve in practice, is at all desirable.

While ulcer does not occur in the absence of acid, chronic ulcer is invariably associated with an excess of gastric secretion. Hydrochloric acid, however, cannot by itself produce the ulcer, the gastric mucosa must first be damaged before the acid can have its destructive effect but the presence of acid does not delay healing (Bolton, 1913). Prolonged night secretion which has been blamed for ulcer causation can be controlled medically by the continuous drip method without alkalis (Winkelstein, 1932) but is tedious and does not prevent recurrence; according to Sandweiss (1946) and Voegtlin (1947) normal and ulcer patients have similar nocturnal secretions. Surgery now advocates a drastic "measured radical gastrectomy" which leaves only a small devascularized remnant (Visick, 1948).

Dragstedt and Owens (1943) introduced vagotomy because Hartzell's (1929) experiments suggested a neurogenic origin for the excessive gastric secretions, but Vanzant (1931) found that two years later the gastric secretions of Hartzell's dogs had returned to normal. In the human, gastric secretions return to normal six to twelve months after vagotomy (Moore *et al.*, 1947); if not, the patient requires parasympathomimetic drugs to counteract the gastric atony (Stein *et al.*, 1947).

It should be remembered that the secretory and motor functions of the stomach cannot be dissociated and that they respond simultaneously to stimulation or to inhibition.

Normally, mechanical trauma alone fails to produce ulcer. The maintenance of continuous hypermotility and hypersecretion does not produce chronic ulcer (Orndorff *et al.*, 1935) neither does anastomosis of the oesophagus to the duodenum after total gastrectomy (Ivy *et al.*, 1931) while a rough diet after bilateral vagotomy produces ulceration (Beazell and Ivy, 1936). Vagotomy shortens the survival period of Mann-Williamson dogs (Saltzstein, 1948) and does not prevent the occurrence of ulcer (Beaver and Mann, 1931) which it may produce experimentally (Greggio, 1916).

The role of hydrochloric acid as a basis for the classification of peptic ulcer.—The association of hydrochloric acid with gastroduodenal ulcer provides the basis of a classification of peptic ulcers:

(1) It distinguishes between the acute and chronic lesions: (i) Acute ulcer occurs in the presence of normal or diminished acid values: hydrochloric acid takes no part in its production; (ii) chronic ulcer is invariably associated with high acid values: hydrochloric acid is an essential element in its production.

These two varieties of ulcer are aetiologically unrelated to each other.

(2) It subdivides chronic ulcers into two categories according to whether they are situated in (i) an acid milieu, or (ii) an alkaline milieu.

These two varieties of ulcer are aetiologically unrelated to each other.

The former is strictly limited to the stomach and the first part of the duodenum while the latter affects the rest of the intestinal tract. Hydrochloric acid has no injurious effect on the normal mucous membrane of the "ulcer-bearing" area in the acid milieu and *a priori* cannot be the only factor concerned in ulcer formation. It is, however, strongly destructive of the mucous membrane of the alkaline milieu outside the "ulcer-bearing" area, its effect varying directly as the distance from the pylorus (McMaster, 1934); it is the only factor responsible for the production of the oesophageal ulcer, Meckel's diverticulum ulcer and the gastrojejunal ulcer. Ulceration does not take place in the aberrant gastric mucosa but in the tissue immediately adjacent to it.

With the exception of the gastrojejunal ulcer, true chronic ulcer as seen in man has not been reproduced experimentally (Ivy, 1946). Dragstedt (Dragstedt and Schafer, 1945) commits his initial error by assuming that the gastrojejunal ulcer artificially produced in the alkaline milieu is analogous to the ulcer which occurs spontaneously in the acid milieu and he applies his observations on experimental ulcer to all other types of peptic ulcer. He argues from the particular to the general and is led to postulate untenable premises from which he deduces inadmissible conclusions.

To summarize.—A procedure which is fraught with grave operative risks and is based on the erroneous interpretation of observed facts, which abolishes the nervous control of the gut and its sphincters and completely disorganizes its natural reactions and which, in addition, interferes with the normal responses of the gall-bladder, pancreas and kidneys, cannot claim the support of physiological principles in justification of a surgical experiment on the human.

The suggestion (Boles, 1948) that surgeons should declare a moratorium for vagotomy for five years should be imposed forthwith.

Mr. Eric M. Nanson for Mr. Norman C. Tanner: In 24 cases of peptic ulcer, mainly duodenal in site, we have employed vagal resection; the follow-up period ranged from one month to fourteen months. The ages ranged from 19 years to 65 years, the larger number being in the 30–40 age-group. Males predominated over females by 19–5. The duration of symptoms previous to operation varied from one year to thirty years, the average duration being five to ten years. The mortality rate was nil.

Post-operative follow-up showed 10 cases satisfactory in all respects. The most serious and frequent complication was diarrhoea which persisted in one case up to six months, and, characteristically, occurred in the early mornings.

The selection of cases suitable for operation is essentially clinical—the insulin test meal is not a test used in selection. Insulin test meal was used in all cases post-operatively to test the completeness of the operation. We used 15 units of insulin intravenously in all cases and always got a satisfactory hypoglycæmia.

Other post-operative complications noted were tachycardia within twelve to twenty-four hours, and evidence of peripheral circulatory failure. Distension and ileus coming on after thirty-six hours was also noted in a few cases.

The operation of vagotomy for peptic ulcer is still an experimental procedure. If there is an obstructive element present, it would be more effective to do a pyloroplasty rather than a gastrojejunostomy in order to limit the introduction of complicating factors.

Clinical Section

President—G. E. VILVANDRÉ

[April 9, 1948]

MEETING HELD AT ST. JAMES' HOSPITAL, BALHAM, LONDON, S.W.12

Chronic Cyclical Granulopenia.—B. BARLING, M.D.

E. R., female aged 32. This case was reported to the Clinical Section in November 1943 (*Proc. R. Soc. Med.*, 1944, 37, 86).

Since the age of 12 she has complained of ulcers of the mouth recurring at irregular intervals of three to four weeks. The ulcers are shallow and painful. Situated on the tongue, under the tongue, on the mucous membrane of the cheek and also at the angles of the mouth. The average duration of the ulcers is about two weeks, but when they become deep and widespread they may take months to heal. Ulcers at the corners of the mouth involve all tissues and have the appearance of a bloodless excision of tissue about the size of a half-penny. The healing is slow with marked scarring.

In 1944 she became pregnant and during this period the ulceration of the mouth became more persistent and for the first and only time she had vulval ulcers.

The delivery was normal and the child is well. On and off since then she has had ulcers of the mouth and tongue of varying severity. Nine months ago she developed two large painful ulcers on the back of the right leg just above the heel. They have resisted all attempts at healing.

Past history.—Tonsillitis frequently until 1940, when tonsillectomy was performed; no infection since then. No other illnesses.

Family history.—No relevant facts.

Physical examination reveals no abnormalities except the scarring at the corners of the mouth and the apparently healing leg ulcers.

No splenic or hepatic enlargement, no palpable glands.

Blood examination has shown a variable but persistent low level of the cells of the granular series. No anaemia or abnormality of red cells. It has been noted, however, that when the total white cells fall, which is due to a reduction in the granulocytes, the ulcers appear.

The sternal marrow is normal.

Section of a fragment of one of the ulcers of the leg shows fibrous pyogenic granulomatous inflammation of the skin of leg. A blood-count was done after an injection of adrenaline with no change in the count. She is well except for the troublesome recurrent ulcers of the mouth and the ulcers of the leg which do not heal.

She has been treated with liver, hog's stomach, nicotinic acid, pyridoxin, pentnucleotide, nucleic acid, yellow bone-marrow extract and iron, but has failed to show any response.

Blood-counts were as follows:

		W.B.C.	Polymorphs. %	Eosinos. %	Lymphos. %	Monos. %
18.4.41	..	6,800	52	—	36	12
29.5.42	..	1,300	26.5	0.5	60	13.5
3.11.43	..	3,600	25	4	59	11.5
29.3.44	..	2,760	15	3	57	24
28.8.47	..	3,800	31	10	35	24
24.3.48	..	4,800	60	—	30	9

The advisability of splenectomy was discussed.

OCT.—CLIN. 1

The suggestion (Boles, 1948) that surgeons should declare a moratorium for vagotomy for five years should be imposed forthwith.

Mr. Eric M. Nanson for Mr. Norman C. Tanner: In 24 cases of peptic ulcer, mainly duodenal in site, we have employed vagal resection; the follow-up period ranged from one month to fourteen months. The ages ranged from 19 years to 65 years, the larger number being in the 30–40 age-group. Males predominated over females by 19–5. The duration of symptoms previous to operation varied from one year to thirty years, the average duration being five to ten years. The mortality rate was nil.

Post-operative follow-up showed 10 cases satisfactory in all respects. The most serious and frequent complication was diarrhoea which persisted in one case up to six months, and, characteristically, occurred in the early mornings.

The selection of cases suitable for operation is essentially clinical—the insulin test meal is not a test used in selection. Insulin test meal was used in all cases post-operatively to test the completeness of the operation. We used 15 units of insulin intravenously in all cases and always got a satisfactory hypoglycaemia.

Other post-operative complications noted were tachycardia within twelve to twenty-four hours, and evidence of peripheral circulatory failure. Distension and ileus coming on after thirty-six hours was also noted in a few cases.

The operation of vagotomy for peptic ulcer is still an experimental procedure. If there is an obstructive element present, it would be more effective to do a pyloroplasty rather than a gastrojejunostomy in order to limit the introduction of complicating factors.

The test was carried out in order to ascertain whether the spleen was storing and then destroying the granulocytes, the so-called "cannibal spleen". Had this been established benefit might have accrued from splenectomy, which we have been reluctant to consider because of her excellent health and complete absence of symptoms.

Dr. F. Parkes Weber considered that in both cases splenectomy would be unwise and a "jump in the dark".

Acromegaly and Pluriglandular Dysfunction showing Calcification of Pituitary.—A. G. LEISHMAN, M.B. (for A. KAHAN, M.D.).

Mrs. S. P., aged 46.

History of present condition.—1931: Became anxious after death of child in accident. 1932: Onset of symptoms of thyrotoxicosis and tracheal pressure. 1939: Early acromegaly, recognizable in photograph. 1940: Removal of cystic adenoma of thyroid (? partial thyroidectomy) followed by rapid development of florid acromegaly. 1941: Diabetes mellitus discovered.

One week before admission she developed sudden loss of speech, asymmetry of face and became confused.

Family history.—Father subject to gout. Sister had fits in childhood. Married, with two sons.

On examination.—Typical acromegalic facies. Slight proptosis on left. Fundi: Veins full, no other abnormality. Left fundus partly obscured by immature cataract. Visual fields: Right normal. Left, gross temporal and upper nasal quadrantic defect.

Abdominal reflex absent, and plantar response extensor, on right side.

Urine: Severe glycosuria and ketonuria. (She had discontinued taking insulin one year previously, because of abscesses.)

FIG. 1.—Pituitary fossa showing enlargement and central calcification.

Z.P.I. 32, Soluble Insulin 44, o.m. (180 grammes carbohydrate).

Comment.—The association of acromegaly with outspoken evidence of pluriglandular dysfunction as shown by this case is well recognized. The correlation of an only moderately enlarged sella with Jacksonian seizures and evidence of intrasellar calcification is less easy. No record was found of even large acidophil adenomas causing fits nor of undergoing calcification. The family history suggests that this patient may have a congenital low cerebral "threshold" for epilepsy.

Calcification, and osseous metaplasia occur frequently in slowly growing squamous-cell carcinomata of the craniopharyngeal tract (squamous adamantinoma, &c.), but no record was found of such tumours producing an acromegalic syndrome. Whatever the pathology the presence of calcification in association with a clinical picture of continued anterior lobe hypersecretion is of interest.

POSTSCRIPT (September 1948).—This patient has now completed a course of deep X-irradiation of the pituitary fossa with striking symptomatic improvement and some increase of the visual fields.—A. G. L.

Investigations.—Blood-count normal. Blood urea 53 mg. %. Plasma cholesterol 218 mg. %. C.S.F. (two examinations): Protein 50 mg. %, pressure normal. W.R. negative in blood and C.S.F. X-ray: Sella moderately enlarged, posterior clinoid processes thinned and rarefied. Rounded opacity in sella approximately 1.0×0.8 cm. demonstrated stereoscopically (fig. 1). Pineal body in normal position. Moderate bony changes of face. Phalanges thickened and characteristically "tufted".

Progress.—She had frequent Jacksonian convulsions involving right side of face for periods of four days during two admissions and associated with aphasia, Todd's paralysis and transient hemiplegic signs. All resolved except minimal right facial weakness on discharge. Diabetes moderately well stabilized on

Dr. F. Parkes Weber referred to Dr. Dennis Embleton's case (which he remembered) of "Rhythmic Neutropenia with Recurrent Buccal Ulceration" (*Proc. Roy. Soc. Med.*, 1937, 30, 980). He also referred to "Behcet's Syndrome"—recurrent ulceration of the oral and genital mucosæ, sometimes associated with recurrent iritis and hypopyon (I. Katzenellenbogen, *Brit. J. Derm.*, 1946, 58, 161).

Chronic Granulopenia.—B. BARLING, M.D.

M. W., female aged 17. This girl was admitted to the Grove Hospital in June 1945 as a case of gastro-enteritis. She had marked pallor and a temperature range of 98–103° F.

Investigation.—Fæces: No pathogenic bacteria. Urine: Some epithelial cells, sterile, acid, trace of protein, no sugar. Blood: Culture gave no growth; agglutinations negative for enteric group, dysentery group, abortus, non-specific salmonella. Sputum: No tubercle bacilli seen.

Blood-count.—22.6.45: R.B.C. 1,460,000; Hb 32%; C.I. 1.1; W.B.C. 6,400 (polys. 5%, lymphos. 92%, monos. 3%). Platelets: normal number, cell diameter 7.5 μ . Some anisocytosis and slight poikilocytosis.

Sternal puncture showed normal cell content.

29.6.45: She was transferred to St. James' Hospital. Apart from the history above, the mother stated that the girl had not been well for a year and that during that time she had complained of tiredness, lack of energy and more recently her mother had noticed pallor, anorexia and shortness of breath.

The mother also stated that the child had had tonsillectomy performed four times.

On examination.—She was pale with a temperature of 102.4° and pulse-rate of 124. The liver was just palpable and the spleen was easily palpable. There were no enlarged glands, no purpura. Fundi were normal. No other physical signs.

The blood-count was as follows.—R.B.C. 1,540,000; Hb 25%; C.I. 0.8; W.B.C. 3,200 (polys. 10%, lymphos. 89%, monos. 1%). Anisocytosis, poikilocytosis, slight polychromasia, platelets 231,100 per c.mm. Red cells: fragility normal.

She was given a blood transfusion of 3 pints which brought her blood up to: R.B.C. 2,690,000; Hb 58%; C.I. 1.1, W.B.C. 3,200 (polys. 11%, lymphos. 88%, monos. 1%). Bleeding time and coagulation time normal.

The blood culture was sterile. Van den Bergh 0.4 unit; Kahn negative. The temperature continued to be raised and her blood had to be kept up by transfusions from which at times she had reactions.

E.N.T. report: Some post-tonsillectomy scarrings and pharyngitis sicca. Nose and ears: N.A.D.

She was treated in addition to the transfusions with iron, intramuscular injections of liver and pentnucleotide 10 c.c. b.d. but with no obvious improvement.

4.8.45: She developed pneumonia consolidation at the right base, but her white cells remained at 4,500 and polys. 12%.

She was treated with penicillin but the condition showed no change and she appeared to be rapidly losing ground. However, as she is an only child, on 10.8.45 her mother decided to take her home which she did by ambulance.

Three weeks later she was readmitted for a blood transfusion—on admission the count was: R.B.C. 1,580,000; Hb 37%; C.I. 1.15; W.B.C. 4,600 (polys. 16%).

Since then she has been on large doses of proteolysed liver and iron and her hæmoglobin and red cells have been kept at approximately normal levels. Although the total white cells have occasionally exceeded 10,000 the percentage of granulocytes has rarely reached 10% of the total.

Throughout the past two and a half years she has kept in good health and developed normally. There are no physical signs except for a steady increase in the size of the spleen. She was given an injection of adrenaline and white cell counts were taken before and after. There was a rise in the total leucocytes, but the percentage of granulocytes did not increase.

Mr. A. M. Desmond: It is important to determine what relationship multiple carcinomata, presenting as in this case, bear to polyposis of the colon. It is advised that in polyposis, as malignancy usually occurs in the distal bowel, this event should be awaited and an abdomino-perineal resection then performed. The distal bowel is then observed by sigmoidoscopy through the terminal inguinal colostomy, subsequent resections being carried out if indicated. In this case, the first malignant growth occurred in the caecum and later two others in the pelvic colon; in other words a reversal of the sequence of events stated to occur in polyposis. I therefore feel that as in 25% or more of patients suffering from polyposis, malignant change takes place, more radical measures should be adopted.

Mr. Norman C. Tanner: In this case we performed a Mikulicz type of colonic resection, though our usual procedure is to make a defunctioning proximal colostomy, followed by a radical resection of the colon and end-to-end anastomosis. This has proved to be very suitable, even for aged people, for two nonagenarians and several octogenarians have survived it without difficulty. At one time I used aseptic anastomoses, but stenosis of the anastomosis complicated one or two cases and so I changed to open end-to-end suture with good mucosal apposition. We have never had a general or local peritonitis following this procedure and I do not believe that the slight, almost theoretical soiling at the time of operation makes much difference—it is a continuous leak from the anastomosis which kills and this does not occur in well-prepared defunctioned bowel. If resection and immediate anastomosis is made without a proximal colostomy then a leak would probably be fatal, whether there is an intestinal antiseptic in the faeces or no. Therefore, we rarely omit the temporary colostomy except in a few palliative resections of hopeless cases.

Cirrhosis of Liver. End-in-side Spleno-Renal Venous Anastomosis.—NORMAN C. TANNER, F.R.C.S.

C. G., male aged 61, a labourer.

History.—Heavy beer drinker in youth. Had pneumonia and malaria. In 1933 he had infective hepatitis. Since October 1947 he has suffered from central abdominal aching pain and the abdomen was getting bigger. In January 1948 the feet began to swell.

On examination.—A slender man, looking fairly well. Distended veins were seen coursing over the upper abdomen and round the umbilicus. There was marked ascites, and the liver was felt to be hard and knobbly.

Investigations.—X-rays of barium swallow and meal, and enema were normal. Blood: W.R. negative. Count normal. Blood proteins normal. Liver function tests: Blood alkaline phosphatase 10 units %. Takata-Ara reaction positive. Colloidal gold reaction negative. Thymol turbidity test negative (3 units).

The ascites made repeated paracentesis necessary.

Operation.—On March 10, 1948, under cyclopropane and curare. The patient was placed on his right side and a left transverse abdominal incision made, extending into the flank. There was some ascites, the liver was coarsely cirrhotic, the spleen hard and small. There was gross hypertension in all the branches of the portal vein. The spleen was removed, the splenic vein mobilized, and an end-in-side anastomosis made between the splenic and left renal veins, using a Blakemore vitallium tube. The tension was removed from the anastomosis by suturing pancreas to kidney.

Post-operative course.—The patient was treated post-operatively with heparin and had a quiet convalescence, but still has some ascites.

Comment.—There are obvious advantages in the end-in-side operation in that nephrectomy is avoided and experimentally there is some evidence that the tendency to thrombosis is less. Technically this is more difficult than end-to-end union. The problem here is, has the anastomosis remained patent? X-ray shows the tube in position. There has been no hæmaturia, an intravenous pyelogram is normal, and there is no left varicocele.

Perineal Urethrostomy Preliminary to Retropubic Prostatectomy.—H. K. VERNON, M.S.

Patient aged 82. Admitted with retention of urine and intermittent fever.

12.3.48: Perineal urethrostomy.

31.3.48: Retropubic prostatectomy.

8.4.48: Both wounds healed and patient voiding urine easily.

The advantage of this method of preliminary drainage of the bladder, suggested by J. G. Sandrey,¹ is that it leaves the abdominal wall undisturbed for a rapid retropubic prostatectomy later. The retropubic is the operation of choice in the aged prostatic with a large adenoma, because healing is quicker and the patient can be sat out of bed immediately.

¹See Sect. Urol., *Proceedings*, November 1948.

Multiple Primary Colonic Malignancy.—E. NANSON, F.R.C.S.

Mrs. E. T., aged 56.

History.—Fifteen years ago resection of right side of colon with ileo-transverse colostomy, followed by deep X-ray therapy for carcinoma of caecum. Three months ago malaise, lassitude, loss of weight. Admitted to St. James' Hospital 14.2.47 complaining of diarrhoea for three days, with three stools per day containing bright red blood. On night of admission had a severe hæmorrhage *per rectum* of about half a pint of bright red blood.

On examination.—A pale cachectic and very ill-looking woman. T. 100.8°. P. 100/min. R. 22/min. Tongue pale and atrophic. Abdomen: Two right mid-paramedian scars, and an area of radiation pigmentation in right lower abdomen. A firm mobile, nodular, slightly tender mass in left iliac fossa. Sigmoidoscopy normal. Barium enema showed a filling defect in pelvic colon 3 in. long, consistent with neo plasm (see fig. 1).

FIG. 1.—Mrs. E. T. Barium enema showing double lesion, sigmoid colon. (Arrow, top left, indicates ileo-transverse colostomy.)

FIG. 2.—Mrs. E. T. Operation specimen of sigmoid colon showing two carcinomata.

Blood-count.—R.B.C. 2,900,000; Hb 44%; C.I. 0.75; W.B.C. 8,800 (polys. 60%, lymphos. 25%, monos. 15%).

Patient was prepared for operation with a high protein diet, transfusions and sulphasuxidine.

4.3.48: Operation by Mr. Tanner. Through an oblique left inguinal muscle-cutting incision the pelvic colon containing two separate stenosing carcinomata, each with its own group of lymphatic metastases, was resected by the Mikulicz technique. In order to improve the artery bare. The liver and pelvis were free of metastases.

11.3.48: A clamp to crush the spur of the colostomy was applied.

30.3.48: Colostomy closed by extraperitoneal method.

Following the resection of the growths the patient's general condition has remarkably improved, and she has made an uninterrupted convalescence.

Pathological findings.—The pelvic colon contained two ulcerating carcinomata, approximately 3 in. apart, each with its own group of metastases (see fig. 2). Histological report not yet available.

Points of special interest.—(1) The patient was not suffering from multiple polyposis yet she developed three distinct primary neoplasms of the colon—one singly and two synchronously. (2) There was no evidence of distant metastases. (3) A profuse hæmorrhage of half a pint *per rectum* is a relatively uncommon event in neoplasm of the large bowel. (4) Having had a previous ileo-transverse colostomy it was not possible to make a defunctioning transverse colostomy as is our usual practice preliminary to doing an excision of pelvic colon and end-to-end anastomosis. Therefore the Mikulicz technique had to be resorted to.

POSTSCRIPT.—Histological report: Two separate adenocarcinomata of colon, with normal intervening mucosa.—E. N.

Physical examination.—Very ill, apathetic and drowsy. Skin showed reddish brown isolated papules, linear lesions and almost black indurated areas.

Blood-pressure 120/65.

Blood: Hypochromic anaemia. Hb 46%; R.B.C. 2,630,000. Urine: Spec. gravity 1.006 (fixed), alb. +, sugar 0.

Blood chemistry: Calcium 9.8 mg. %; plasma phosphorus 8.4 mg. %; plasma phosphatase

FIG. 1.

17.2 units; plasma proteins total 6.17%; fibrin 0.6%; albumin 2.94; globulin 2.63, blood urea 304 mg. %.

Radiological findings.—(1) Generalized osteoporosis. (2) Cortical thinning particularly of long bones, disintegration in the phalanges and especially in os pubis (fig. 1). (3) Widespread calcifications in the subcutaneous tissues (cf. fig. 3, p. 140¹). (4) Extensive arteriosclerosis of the arteries in hands and feet (fig. 2).

The patient died on November 22, 1944.

Post-mortem examination.—Chronic nephritis, marked enlargement of the parathyroids (only hypertrophy) (cf. fig. 2, p. 140²).

Comment.—The differential diagnosis between primary and secondary hyperparathyroidism in a patient with renal insufficiency may sometimes be difficult. Renal damage in primary hyperparathyroidism may be caused by precipitation of calcium in the renal pelvis, leading to calculus formation and pyelonephritis or by deposit of calcium within the kidney parenchyma. These calcifications can usually be recognized on X-ray examination and represent an important radiological sign for the diagnosis of primary hyperparathyroidism. The characteristic bone changes of osteitis fibrosa cystica are usually present, and examination of the blood chemistry revealing raised serum calcium and low phosphorus will in the majority of cases lead to a correct diagnosis.

[May 12, 1948]

Calcified Intrathoracic Cyst (Old Interlobular Empyema).—IVOR LEWIS, M.S.

Mrs. V. K., aged 26, married. She was referred by the Tuberculosis Officer. There was little in the past history except measles as a child. A healthy-looking, cheerful young woman; no clubbing of the fingers and no abnormal physical signs in the lung.

B.S.R. 6 mm. in one hour.

Sputum: A few c.c. per day, yellow, showed no tubercle bacilli.

X-rays showed a calcified cyst of ovoid shape in the right lung field, rather posteriorly.

FIG. 1.—P.A. view.

FIG. 2.—R. lateral view.

FIG. 3.—Photograph of the calcified shell. Note the hole, where it communicated with a bronchus.

There were one or two cavities the size of marbles to be seen in some of the X-rays just below this cyst (figs. 1 and 2).

Casoni test negative.

W.B.C. 13,200. 53% polymorphs., 2% eosinophils.

(It transpired that her chest had been X-rayed by "mass radiography" two years ago, apparently without comment. The film, however, cannot be found.)

Subsequent operation revealed a calcified shell of an old interlobular empyema, with a hole from it into the lower lobe bronchus, near which there were two small cavities.

The specimen was dissected free (fig. 3).

Convalescence was uneventful.

Chronic Renal Insufficiency with Secondary Hyperparathyroidism.—A. ELKELES, M.D.

Female, aged 21, admitted to Ashridge E.M.S. Hospital, August 1944. Within the last two years became increasingly pale and breathless and lost 2 st. in weight; amenorrhœa, irritating skin conditions in axillæ, cubital fossæ, under the breasts, groins, anogenital region and upper thighs. (Case was shown by J. E. M. Wigley and D. Hunter at Dermatological Section on November 16, 1944.¹)

[April 28, 1948]

The Hypothalamus and Water Metabolism

By G. W. HARRIS, M.A., M.D. Cantab.

Lecturer in Physiology, Cambridge University

THE hypothalamus can influence water metabolism in several ways: by influencing sweating, vascular tone, respiration and by other means. Only the control exerted through the mediation of the pituitary gland will be considered. The terminology for the various divisions of the pituitary gland has been standardized by the "Association for Research in Nervous and Mental Diseases", and the nomenclature they suggested is given below and will be adopted here (*see also fig. 1*).

Adenohypophysis—Lobus glandularis—	{ Pars distalis (anterior lobe)	
	{ Pars tuberalis	
	{ Pars intermedia	} posterior lobe
Neurohypophysis—Lobus nervosus—	{ Infundibular process	
(neural lobe)		
Infundibulum	{ Infundibular stem	Neural stalk together with sheath of portions of lobus glandularis designated as hypophyseal stalk
(neural stalk)	{ Median eminence of tuber cinereum	

FIG. 1.—Diagram of a sagittal section through the hypothalamus and pituitary gland to illustrate the terminology used, and the nerve supply of the gland. The three parts of the neurohypophysis include the bulbous median eminence (M.E.), the constricted infundibular stem (I.S.) and the swollen infundibular process (I.P.). The adenohypophysis also consists of three divisions, the pars distalis (P.D.), the pars intermedia (P.I.) and the pars tuberalis (P.T.). It is established that the neurohypophysis is innervated by the supraoptic nucleus (S.O.N.) situated above the commencement of the optic tract (O.T.), and the paraventricular nucleus (P.V.N.) which is in intimate relationship with the third ventricle (III.V.). Other fibres constituting the tuberohypophyseal tract (T.H.) also run to the hypophysis, but their origin is unknown.

Anatomical connections between the hypothalamus and hypophysis.—There are two anatomical links between the hypothalamus and hypophysis; first a prominent nervous pathway, the hypothalamo-hypophyseal tract, which ends mainly in the neurohypophysis, and secondly a vascular connexion, the hypophyseal portal vessels, which connect with the adenohypophysis.

The case presented here shows the characteristic features of primary renal insufficiency with subsequent secondary hyperparathyroidism. In spite of advanced renal failure no metastatic calcium deposits in the kidneys are present, whereas calcification in the subcutaneous tissues and peripheral arteries is very pronounced. There is widespread osteoporosis and even some bone resorption with concomitant deposition of amorphous calcium; the bony changes, however, are in no way characteristic of osteitis fibrosa cystica. Furthermore the investigation of the blood chemistry reveals a considerable retention of non-protein nitrogen, a normal serum calcium and a much raised plasma phosphorus. Thus renal insufficiency with retention of urea was associated with a rise of phosphorus in the blood. Since renal excretion of phosphorus is related to the

FIG. 2.

activity of the parathyroid gland, it may be assumed that prolonged retention of phosphorus causes hyperactivity of the parathyroid in an attempt to eliminate the excess of phosphorus by an intensified phosphaturia. Not only is this compensatory hyperactivity of the parathyroid without lasting effect in cases in which renal damage is permanent and even progressive, but is responsible, in addition, for the mobilization of calcium from the skeletal system, resulting in general osteoporosis and precipitation of calcium in the subcutaneous tissues and arteries.

years that clinical diabetes insipidus may be controlled by the administration of posterior pituitary extract. Fisher, Ingram and Ranson (1938) have shown that the essential lesion in experimentally produced diabetes insipidus is one that interrupts bilaterally the supraoptico-hypophysial (S.O.H.) tracts. This is followed by atrophy of the neurohypophysis, failure in production of the antidiuretic hormone and diminished reabsorption of water by the tubules of the kidney. The converse experiment of stimulating the S.O.H. tracts with consequent liberation of the antidiuretic hormone and inhibition of a water diuresis requires a specialized technique for anaesthesia itself inhibits a water diuresis.

In order to stimulate the hypothalamus and pituitary gland in the unanaesthetized rabbit the remote control method has been used (Harris, 1947a). A small (secondary) coil is buried beneath the scalp and from this coil an insulated electrode passes through a small trephine hole in the skull to the desired region. (Such preparations may remain in a satisfactory condition for several years.) Stimulation is produced by placing the animal's head in the electromagnetic field of an external (primary) coil, the desired voltage being induced through the healed skin. Spread of the stimulus is not more than 0.5 mm. for the fibres in the neural stalk. In order to study the effects of stimuli administered to various parts of the hypothalamus and pituitary gland on a water diuresis the routine procedure is as follows:

Water is administered by stomach tube to a rabbit bearing an implanted coil, and the urine collected and measured every 15 minutes. When the urine flow has increased to 10 c.c./15 min. or more, the animal is stimulated, usually for a period of 1 minute. If the electrode tip is in, or in contact with, the S.O.H. tract in the median eminence, infundibular stem or infundibular process, a marked antidiuresis follows stimulation. The strength of the stimulus can be varied by varying the distance between the primary coil, held over the animal's head, and the implanted secondary coil. The amount of antidiuretic hormone liberated varies directly with the strength of the stimulus as shown by the extent and duration of the antidiuresis elicited. With strong stimuli the urine flow may be depressed to very low levels for several hours, though it rises eventually as the effect of the post-pituitary secretion wears off and the high water load is excreted. All intermediate grades of response may be obtained at will by varying the strength of the stimulus. In any one animal the antidiuresis evoked by a given stimulus remains constant over a series of days or weeks. The antidiuretic response following stimulation of the S.O.H. tract is similar qualitatively and quantitatively to that following the intravenous injection of an appropriate dose of post-pituitary extract. Control experiments have shown that if the electrode is within 0.5 mm. of the S.O.H. tract but not in contact with it, stimulation elicits a lessened antidiuretic response, but if the electrode is farther from the tract than 0.5 mm. (either above, below or lateral) then the diuresis continues unabated in spite of stimulation. These, and other, facts show that the stimulus used is very localized, and that the response is due to liberation of the antidiuretic hormone from the neurohypophysis by stimulation of the S.O.H. tract.

It is impossible to measure directly the amount of antidiuretic hormone liberated from the neurohypophysis by maximal stimuli, for the antidiuresis so produced is outside the range which can be assayed with any degree of accuracy. It has been found, however, that small amounts of antidiuretic substance are excreted in the urine following stimulation of the S.O.H. tract (Harris, 1948a). By comparing these amounts with those excreted after the intravenous injection of different doses of post-pituitary extract, and assuming that the secretion liberated from the neurohypophysis behaves in the same way in the blood stream as injected extract, the approximate figure has been obtained that stimulation of the S.O.H. tract for 1 minute liberates less than 50 mU. of antidiuretic hormone. This figure is in rough agreement with those obtained by entirely different methods, described below.

Post-pituitary extracts have many pharmacological activities and investigations have been made to see which of these activities follow stimulation of the S.O.H. tract. It has been found that such stimulation causes the secretion of substances which raise the relative (and sometimes absolute) chloride excretion in the urine, causes contraction of the oestrous or oestrogenized uterus, produces an increase in intestinal peristalsis, but has no effect on blood sugar and causes only slight rises in blood-pressure (Harris, 1947a, 1948b).

It is well known that posterior pituitary extracts may be separated into two fractions, a pressor and an oxytocic fraction. In the rabbit the pressor substance is responsible for the rise in blood-pressure, the antidiuresis and chloruresis, the increase in intestinal peristalsis and the hyperglycemia that follow injection of post-pituitary extracts, and the oxytocic substance for any uterine contraction which may follow such injection. In most whole extracts these activities are present in a constant proportion, that is, the ratio of oxytocic to pressor substance is constant. It seemed of interest then to see whether the

The hypothalamo-hypophysial tract starts in various hypothalamic nuclei. The origin of fibres in the supraoptic and paraventricular nuclei is established, but which of the other hypothalamic nuclei contribute fibres to the tract is doubtful though the anterior hypothalamic, ventromedial hypothalamic and more caudal nuclei have been suggested. The similar connexion of the supraoptic and paraventricular nuclei is of interest in view of their common phylogenetic origin and cytological and vascular architecture. The normal appearance of cells in these nuclei is similar to that of cells in other parts of the nervous system undergoing chromatolysis, that is, they have a peripheral distribution of Nissl substance, a clear perinuclear zone and an eccentric nucleus. Also both nuclei are exceedingly vascular. The number of cells in each supraoptic nucleus has been estimated at 7,000 (rat) and 60,000 (man), and the number of fibres in the supraoptico-hypophysial tract at 10,000 (rat) and 100,000 (man) (Rasmussen, 1940). The great majority of fibres of the hypothalamo-hypophysial tract end in the three subdivisions of the neurohypophysis, only a very few passing forwards into the pars intermedia. The exact mode of termination is doubtful, though most workers agree that a large number of fibres terminate as perivascular endings especially in the region of the median eminence. It is not possible at the moment to describe a secreto-motor ending for these fibres.

The hypophysial portal vessels were first described by Popa and Fielding (1930, 1933), and later by Wislocki and King (1936), and by Green and Harris (1947). The anatomy of these structures is now fairly clear (fig. 2). Small twigs of the internal carotid arteries supply a vascular plexus situated between the pars tuberalis and the median eminence, and from this plexus "vascular tufts" or "sinusoidal loops" penetrate the tissue of the median eminence. These loops are then in intimate contact with the wealth of nerve fibres in this situation. From these vessels the blood is drained into large portal trunks which pass to the pars distalis where they break up into the sinusoids of this part of the gland. Therefore at one end the wide trunks are continuous with the loops in the median eminence and at the other end with the sinusoids of the pars distalis, that is they are truly portal vessels. This system of vessels, with minor variations in pattern, has been found in all vertebrates so far examined from amphibians to man (Green, 1948*a*). Even in the porpoise, where the infundibular process is separated from the pars distalis by a thick dural septum, a typical and well-marked portal system exists (Harris, 1947*b*). The direction of blood-flow in these vessels has been the subject of much controversy, but has now been directly observed (under the microscope) in anaesthetized frogs (Green, 1947) and rats (Green and Harris, 1948) as being from the median eminence to the pars distalis. The exact vascular pattern varies amongst different mammals and seems to depend largely on the length of the pituitary stalk, for in dogs (with a very short stalk) the intermediate trunks of the vessels are abbreviated and the terminal capillaries and sinusoids approximated, whereas in man (with a long stalk) the vessels are elongated and very easily observed. Since the pars tuberalis has no proven endocrine function and since it bears a constant relationship to the sinusoidal vessels which penetrate the median eminence it has been suggested (Harris, 1947*c*) that the

FIG. 2.—Diagram of a sagittal section through the hypothalamus and pituitary gland to illustrate the hypophysial vascular system. The details are more in accord with the organs of a rabbit, but the general plan is typical for mammals as a whole. Small twigs (T.) from the internal carotid arteries supply a vascular plexus situated between the pars tuberalis (P.T.) and the median eminence. From this plexus sinusoidal loops (L.), in large numbers, penetrate the tissue of the median eminence the blood from these loops being drained by the large portal trunks (T.P.) which eventually break up into the sinusoids of the pars distalis (S.). The pars distalis also receives a systemic arterial supply (A.H.) from the internal carotid artery, and the infundibular process a similar supply (P.H.) from the same source. The short veins into the surrounding venous sinuses

significance of the pars tuberalis lies in the fact that it forms a bed for the vascular pathway between the hypothalamus and pars distalis. (It may be mentioned that the two lobes of the pituitary also receive a systemic arterial supply from the internal carotid artery directly, and that their venous drainage passes by short wide veins to the adjacent venous sinuses—see fig. 2.)

The hypothalamus, neurohypophysis and water metabolism.—It has been known for many

abolishing the influence of the nervous system over the anterior pituitary. In keeping with these observations is the paucity of nerve fibres in this part of the gland.

There is, however, another anatomical pathway between the hypothalamus and anterior lobe of the pituitary gland, namely the hypophysial portal vessels described above. The hypothesis that the nervous system, and in particular the hypothalamus, controls the activity of the pars distalis (and so most of the other endocrine glands) through the mediation of the hypophysial portal vessels was suggested by Harris (1944) and restated with further anatomical data by Green and Harris (1947). It is possible that hypothalamic nerve fibres, ending on the upper set of capillaries in the median eminence, liberate some chemo-transmitter into the portal vessels which is carried humorally to the anterior pituitary and there controls or modifies the activity of this gland. Since this mode of control would involve a nervous and vascular link, it has been referred to as "neuro-vascular" control of the anterior pituitary. Evidence in favour of this view may be summarized as follows:

(1) Under normal conditions ovulation in the rabbit only occurs ten hours after coitus. This reaction has been analysed and found to involve reflex nervous stimulation of the anterior pituitary to liberate gonadotrophic hormone which acts on the ovaries to produce follicular rupture. The pituitary secretion occupies the first hour following coitus, but since the nervous stimulus of mating takes only a few minutes, it may be that one phase in the reaction is a slow humoral excitation of the anterior pituitary.

(2) It has been shown that electrical stimulation of the tuber cinereum in the unanaesthetized rabbit, for as short a period as 3 minutes, may be followed by a full ovulatory response (Harris, 1948c). Direct stimulation of the pars distalis, pars intermedia or infundibular stem for periods up to $7\frac{1}{2}$ hours was not followed by ovulation. If the anterior pituitary is under humoral control via the portal vessels, and is devoid of a secretomotor nerve supply, it is possibly not excitable by electrical stimulation applied directly to the gland.

(3) Very varied results have been obtained by different workers after sectioning the pituitary stalk. The discordant nature of these results may be due to varying degrees of regeneration of the portal vessels. Such regeneration does occur in the rat (Harris, 1948f). Work in progress indicates that if this regeneration is prevented from occurring female rats enter into permanent anæstrum, which suggests cessation of pituitary gonadotrophic function.

(4) Dempsey (1939), Dey (1943) and Leininger and Ranson (1943) found that a greater disturbance of the œstrous cycle of guinea-pigs followed a lesion in the median eminence than after section of the pituitary stalk. A possible explanation is that the former lesion produces a complete irreparable denervation of the portal vessels, whilst the stalk section allows the possibility of vascular repair.

There is as yet little convincing evidence regarding the mechanism by which the portal vessels may regulate the activity of the adenohypophysis. Dr. J. D. Green has made the suggestion (private communication) that the influence of these vessels may be exerted by a simple vasodilatation or vasoconstriction, thus increasing or decreasing the total blood supply of the anterior pituitary gland. Regarding the possibility of a specific chemotransmitter passing via the portal vessels from the median eminence to the pars distalis, two suggestions have been put forward. Taubenhaus and Soskin (1941) suggested a cholinergic transmission, as they obtained a pseudopregnancy response in rats in which a prostigmine-acetylcholine mixture had been directly applied to the rats' pituitary glands. Markee, Sawyer and Hollinshead (1947) obtained ovulation in rabbits after injecting dilute adrenaline directly into their pituitary glands and also showed that dibenamine (a sympatholytic drug) was effective in blocking ovulation following coitus in the rabbit (Sawyer, Markee and Hollinshead, 1947). They suggested, therefore, that the anterior pituitary is stimulated by an adrenaline-like substance which is humorally conducted to the gland.

Clinical observations correlated with post-mortem examination of the hypophysial vessels in patients with lesions involving these structures would be of great value. For example, it would be of interest to know the state of the portal vessels in a case such as that of Dandy's (1940) in which the pituitary stalk of a young woman was sectioned. This patient subsequently showed a mild diabetes insipidus together with normal menstrual cycles, pregnancy and lactation. The diabetes insipidus was doubtless due to atrophy of the neurohypophysis, but it is important to know whether, in such cases, the normally functioning anterior pituitary gland can be correlated with regeneration of the portal vessels. For a description of the hypophysial stalk in man, see Green (1948b).

secretion of the gland, elicited by stimulation of the S.O.H. tracts, had the same ratio of oxytocic to pressor activity as the extracts. This problem was investigated by the following methods.

(1) Simultaneous measurement of pressor (antidiuretic) and oxytocic activities. A weak stimulus was administered to the S.O.H. tract in a rabbit in which a uterine fistula had been prepared some time previously. The antidiuretic and oxytocic responses to this stimulus were measured and compared quantitatively with similar responses following intravenous injection of post-pituitary extract. Only one experiment was performed on any one day, but over a series of days a series of responses were obtained for comparison. It was found that stimulation caused a secretion which possessed less antidiuretic, in proportion to oxytocic activity, as compared with various post-pituitary extracts (Harris, 1947a).

(2) Concurrent measurement of pressor and oxytocic activities. Stimulation of the S.O.H. tract for 1 minute, has been shown to produce an oxytocic effect equivalent to 200–500 mU. of whole posterior lobe extract. Similar stimulation of the same animals, on a different day, was found to produce an effect on intestinal peristalsis and on the blood-pressure less than that elicited by 100 mU. of posterior lobe extract. Thus similar stimuli cause the secretion of more oxytocic substance than pressor (Harris, 1948b).

(3) The qualitative response of the uterus. The uterine movements of the conscious rabbit were recorded by means of a fistula through the abdominal wall. Intravenous injection of whole posterior lobe extract produces a marked uterine contraction (proportional to the oxytocic content of the extract) followed by an inhibitory phase (related to the pressor content). Thus the single uterine recording gives an approximate measure of both oxytocic and pressor activity of an extract or secretion. On this basis it has been shown that stimulation of the S.O.H. tract for 1 minute produces a secretion equivalent (in action on the uterus) to a mixture of, approximately, 250 mU. oxytocic substance and 50–100 mU. of pressor substance (Harris, 1948b).

Thus all the evidence obtained from experiments on unanaesthetized rabbits indicates that the secretion of the gland contains less pressor activity, relative to oxytocic, than is present in various standard extracts. For this reason it has been suggested (Harris, 1948d) "... that in replacement therapy during labour the purified oxytocic fraction be used instead of whole posterior-lobe extracts. However, more direct evidence on the reactions of the human uterus *in situ* to such extracts is desirable".

The hypothalamus, adenohypophysis and water metabolism.—The von Hann-Richter hypothesis states that a maximum diabetes insipidus only occurs in the presence of some normally functioning anterior pituitary tissue. It would seem that there is normally a balance between the specific antidiuretic action of the neurohypophysis and a diuretic influence of the adenohypophysis. It is possible that the pars distalis stimulates water excretion by an action on general metabolism, or indirectly through the thyroid or adrenal cortex, or by some unknown means. The above hypothesis offers an explanation for the clinical cases where a progressive lesion destroys first the neurohypophysis with the onset of diabetes insipidus, whilst further increase in the lesion with destruction of the adenohypophysis leads to regression of the diabetes insipidus.

There is much evidence (Harris, 1948e) that the secretion of the anterior lobe is under the control of the nervous system. As examples of such an influence may be quoted the cases of sexual precocity in young children associated with small localized hypothalamic tumours, the effect of light on the sexual rhythm of many mammals, the disturbances of the menstrual rhythm and lactation caused by emotional upsets, and the histological changes that are known to occur in the thyroid and adrenal cortex in association with changes in environmental temperature. All these reactions, and many others, are most easily explained on the assumption that the nervous system controls the output of the eutrophic pituitary hormones and thus indirectly the activity of the thyroid, adrenal cortex, gonads and breasts. It would appear teleologically probable then that the diuretic processes of the adenohypophysis are integrated with the antidiuretic processes of the neurohypophysis and the hypothalamus.

The question of nervous control of the anterior lobe of the pituitary (and so indirectly the thyroid, adrenal cortex and gonads) is one of the fundamental problems of endocrinology to-day. There is no sound evidence that this gland possesses a secreto-motor nerve supply. Three nervous pathways to the anterior pituitary have been described—hypothalamic via the pituitary stalk, sympathetic via the cervical sympathetic and carotid plexus, and a supply via the petrosal nerves. Each of these pathways, however, has been cut without

Recently I have been investigating the effect of infusion of extract of the posterior lobe when the urine secretion has been increased by the administration of sodium chloride by stomach tube to the conscious dog. Following the administration of sodium chloride in solution hypertonic to the body fluids, the kidney secretes urine rich in chloride (usually about 0.28 molar) but neither the composition nor the volume of the urine is affected by the infusion of extract of the posterior lobe at rates up to 15 micro-units per second. But after the administration of sodium chloride in solution approximately isotonic with the body fluids, the urine flow is usually about 2 ml. per minute, the concentration of chloride in the urine about 0.14 molar and the rate of excretion of chloride about 0.28 mg. equivs. per min. Now, an intravenous infusion of extract of the posterior lobe at about 4 micro-units per second reduces the urine volume to about 1 ml. per min., and increases the concentration of chloride in the urine to 0.28 molar; but the rate of elimination of chloride is unchanged during the period of the infusion. Even with faster rates of infusion of pituitary extract or following the administration of high concentrations of sodium chloride, the concentration of chloride in the urine of the dog under these conditions does not rise higher than 0.28 to 0.3 molar, so that the maximal physiological response of the kidney is produced by the infusion of extract of the posterior lobe at the slow rate of 4 micro-units per second. In this instance, as in the inhibition of water diuresis, the action of the extract is to cause decreased excretion of water, without great change in the excretion of other urinary constituents; and it has already been stated that in these small doses the extract has no effect on the blood flow through the kidney. It is now accepted that the action of the extract on the kidney is to stimulate the reabsorption of water by the tubules, and, indeed, this is probably the only effect on the kidney of the active principle of the posterior lobe in amounts ordinarily liberated in life.

Diabetes insipidus.—The polyuria of diabetes insipidus, associated by pathologists with lesions in the region of the pituitary and hypothalamus, has been regarded as produced by diminished function of the neural lobe since the demonstration independently in 1913 by von den Velden and Farini that the polyuria can be controlled by the subcutaneous injection of extracts of the posterior lobe. For many years attempts to produce diabetes insipidus by operative lesions in experimental animals produced very doubtful results. This may be exemplified by the effect, now well established, of removal of the posterior lobe of the pituitary in dogs by an approach through the soft palate and sphenoid bone. On the days immediately following the operation the dogs drink freely, and the daily urine volume increases from the normal figure of about 200 ml. per day to about 2 litres per day; but then the daily urine volume falls and 2 to 3 weeks after operation is about 300 ml. per day, at which level the fluid exchange persists indefinitely. However, in 1935, Fisher, Ingram and Ranson described an operation which produced persistent diabetes insipidus in cats, consisting of the section of the supraoptico-hypophyseal tracts by electrolytic lesions placed in the hypothalamus by means of a stereotaxic instrument. Subsequent post-mortem examination showed that when the lesions failed to interrupt the supraoptico-hypophyseal tracts no persistent polyuria followed; but in animals in which the tracts were sectioned, the daily urine volume for many months after operation was 300 to 400 ml. per day and the specific gravity of the urine 1.006 to 1.008, instead of the 100 ml. per day (sp. gr. 1.028 or more) of normal cats. Injection of extract of the posterior lobe reduced the daily urine volume of the diabetic cats to 100-170 ml. (sp. gr. 1.015 to 1.027). Despite differences in the configuration of the pituitary stalk, section of the supraoptico-hypophyseal tracts has also been shown to produce diabetes insipidus in the rat and the monkey; and in common with many others, I have observed diabetes insipidus in dogs in which the tracts have been cut by a stab wound in the floor of the hypothalamus between the optic chiasma and the pituitary. At post-mortem, there is always degeneration of the neurohypophysis. The pars nervosa and pituitary stalk distal to the lesion are found to be devoid of nerve fibres and shrunken, while extracts of the posterior lobe lack antidiuretic activity (Fisher and Ingram, 1936). Thus, the diabetes insipidus produced by the procedure of Fisher, Ingram and Ranson (1935, 1938) is adequately explained by the loss of function of the neurohypophysis, absence of the antidiuretic hormone from the circulating blood, and consequent reduced reabsorption of water in the renal tubules. Explanation may also be offered for the failure of other operative procedures to produce permanent diabetes insipidus. In the procedure of Fisher, Ingram and Ranson both the neural lobe and the pituitary stalk, which has many anatomical similarities to the neural lobe, are caused to degenerate; whereas after removal of the posterior lobe the pituitary stalk is left intact to form a possible source of the small amounts of antidiuretic hormone needed to restrain the urine flow to almost normal volume. Other operative procedures, despite adequate destruction of the neurohypophysis, cause extensive damage to the glandular parts of the pituitary, and polyuria may fail to appear because of loss of function of the anterior lobe. Of all operations described, that of section of the supraoptico-hypophyseal tract ensures the best conditions

In summary then it may be stated that the hypothalamus controls the neurohypophysis by means of the supraoptico-hypophysial tract, and that stimulation of this tract results in release of the antidiuretic hormone and inhibition of a water diuresis. As a working hypothesis it is suggested that the hypothalamus controls the adenohypophysis, and so various diuretic processes, by neuro-vascular transmission of stimuli through the hypophysial portal vessels.

The Hypothalamus and Urine Secretion

By W. J. O'CONNOR

From The Department of Pharmacology, Cambridge University

Action on the kidney of extract of the posterior lobe of the pituitary.—Since the release of hormone from the neural lobe of the pituitary constitutes the only mechanism as yet established by which the hypothalamus can influence kidney function, special consideration must be given to the action of extract of the posterior lobe. One effect of the extract is well known: injected intravenously, it causes inhibition of water diuresis; or injected subcutaneously at the time of administration of water, it causes delay of the diuresis for several hours. Inhibition of water diuresis is brought about without change in the blood flow through the kidney (Cowan, Verney and Vogt, quoted by Verney, 1946). The amount of extract of the posterior lobe which need be injected is very small; in the dog, with which species most experimental work has been done, the intravenous injection of 1 milli-unit (0.0005 mg. of the standard powder) usually produces inhibition of water diuresis lasting five minutes; the intravenous infusion of the extract at a rate of 1 micro-unit per second (0.0000005 mg. of the standard powder) maintains the rate of urine secretion at resting level despite the previous administration of a diuretic dose of water. Emphasis has been placed on the minute amounts of the extract needed to inhibit water diuresis in the conscious animal because of the evidence to be presented later that such small amounts only are involved in the regulation of the activity of the kidneys, and also in order to avoid confusion with early experimental work with anaesthetized animals and using much larger doses of extract from which a diuretic action of extract of the posterior lobe was described. The antidiuretic action of extract of the posterior lobe is also exerted in diabetes insipidus in which condition, as in diuresis following the ingestion of water, there is a large volume of dilute urine.

Recently I have been investigating the effect of infusion of extract of the posterior lobe when the urine secretion has been increased by the administration of sodium chloride by stomach tube to the conscious dog. Following the administration of sodium chloride in solution hypertonic to the body fluids, the kidney secretes urine rich in chloride (usually about 0.28 molar) but neither the composition nor the volume of the urine is affected by the infusion of extract of the posterior lobe at rates up to 15 micro-units per second. But after the administration of sodium chloride in solution approximately isotonic with the body fluids, the urine flow is usually about 2 ml. per minute, the concentration of chloride in the urine about 0.14 molar and the rate of excretion of chloride about 0.28 mg. equivs. per min. Now, an intravenous infusion of extract of the posterior lobe at about 4 micro-units per second reduces the urine volume to about 1 ml. per min., and increases the concentration of chloride in the urine to 0.28 molar; but the rate of elimination of chloride is unchanged during the period of the infusion. Even with faster rates of infusion of pituitary extract or following the administration of high concentrations of sodium chloride, the concentration of chloride in the urine of the dog under these conditions does not rise higher than 0.28 to 0.3 molar, so that the maximal physiological response of the kidney is produced by the infusion of extract of the posterior lobe at the slow rate of 4 micro-units per second. In this instance, as in the inhibition of water diuresis, the action of the extract is to cause decreased excretion of water, without great change in the excretion of other urinary constituents; and it has already been stated that in these small doses the extract has no effect on the blood flow through the kidney. It is now accepted that the action of the extract on the kidney is to stimulate the reabsorption of water by the tubules, and, indeed, this is probably the only effect on the kidney of the active principle of the posterior lobe in amounts ordinarily liberated in life.

Diabetes insipidus.—The polyuria of diabetes insipidus, associated by pathologists with lesions in the region of the pituitary and hypothalamus, has been regarded as produced by diminished function of the neural lobe since the demonstration independently in 1913 by von den Velden and Farini that the polyuria can be controlled by the subcutaneous injection of extracts of the posterior lobe. For many years attempts to produce diabetes insipidus by operative lesions in experimental animals produced very doubtful results. This may be exemplified by the effect, now well established, of removal of the posterior lobe of the pituitary in dogs by an approach through the soft palate and sphenoid bone. On the days immediately following the operation the dogs drink freely, and the daily urine volume increases from the normal figure of about 200 ml. per day to about 2 litres per day; but then the daily urine volume falls and 2 to 3 weeks after operation is about 300 ml. per day, at which level the fluid exchange persists indefinitely. However, in 1935, Fisher, Ingram and Ranson described an operation which produced persistent diabetes insipidus in cats, consisting of the section of the supraoptico-hypophyseal tracts by electrolytic lesions placed in the hypothalamus by means of a stereotaxic instrument. Subsequent post-mortem examination showed that when the lesions failed to interrupt the supraoptico-hypophyseal tracts no persistent polyuria followed; but in animals in which the tracts were sectioned, the daily urine volume for many months after operation was 300 to 400 ml. per day and the specific gravity of the urine 1.006 to 1.008, instead of the 100 ml. per day (sp. gr. 1.028 or more) of normal cats. Injection of extract of the posterior lobe reduced the daily urine volume of the diabetic cats to 100-170 ml. (sp. gr. 1.015 to 1.027). Despite differences in the configuration of the pituitary stalk, section of the supraoptico-hypophyseal tracts has also been shown to produce diabetes insipidus in the rat and the monkey; and in common with many others, I have observed diabetes insipidus in dogs in which the tracts have been cut by a stab wound in the floor of the hypothalamus between the optic chiasma and the pituitary. At post-mortem, there is always degeneration of the neurohypophysis. The pars nervosa and pituitary stalk distal to the lesion are found to be devoid of nerve fibres and shrunken, while extracts of the posterior lobe lack antidiuretic activity (Fisher and Ingram, 1936). Thus, the diabetes insipidus produced by the procedure of Fisher, Ingram and Ranson (1935, 1938) is adequately explained by the loss of function of the neurohypophysis, absence of the antidiuretic hormone from the circulating blood, and consequent reduced reabsorption of water in the renal tubules. Explanation may also be offered for the failure of other operative procedures to produce permanent diabetes insipidus. In the procedure of Fisher, Ingram and Ranson both the neural lobe and the pituitary stalk, which has many anatomical similarities to the neural lobe, are caused to degenerate; whereas after removal of the posterior lobe the pituitary stalk is left intact to form a possible source of the small amounts of antidiuretic hormone needed to restrain the urine flow to almost normal volume. Other operative procedures, despite adequate destruction of the neurohypophysis, cause extensive damage to the glandular parts of the pituitary, and polyuria may fail to appear because of loss of function of the anterior lobe. Of all operations described, that of section of the supraoptico-hypophyseal tract ensures the best conditions

In summary then it may be stated that the hypothalamus controls the neurohypophysis by means of the supraoptico-hypophysial tract, and that stimulation of this tract results in release of the antidiuretic hormone and inhibition of a water diuresis. As a working hypothesis it is suggested that the hypothalamus controls the adenohypophysis, and so various diuretic processes, by neuro-vascular transmission of stimuli through the hypophysial portal vessels.

The Hypothalamus and Urine Secretion

By W. J. O'CONNOR

From The Department of Pharmacology, Cambridge University

Action on the kidney of extract of the posterior lobe of the pituitary.—Since the release of hormone from the neural lobe of the pituitary constitutes the only mechanism as yet established by which the hypothalamus can influence kidney function, special consideration must be given to the action of extract of the posterior lobe. One effect of the extract is well known: injected intravenously, it causes inhibition of water diuresis; or injected subcutaneously at the time of administration of water, it causes delay of the diuresis for several hours. Inhibition of water diuresis is brought about without change in the blood flow through the kidney (Cowan, Verney and Vogt, quoted by Verney, 1946). The amount of extract of the posterior lobe which need be injected is very small; in the dog, with which species most experimental work has been done, the intravenous injection of 1 milli-unit (0.0005 mg. of the standard powder) usually produces inhibition of water diuresis lasting five minutes; the intravenous infusion of the extract at a rate of 1 micro-unit per second (0.0000005 mg. of the standard powder) maintains the rate of urine secretion at resting level despite the previous administration of a diuretic dose of water. Emphasis has been placed on the minute amounts of the extract needed to inhibit water diuresis in the conscious animal because of the evidence to be presented later that such small amounts only are involved in the regulation of the activity of the kidneys, and also in order to avoid confusion with early experimental work with anesthetized animals and using much larger doses of extract from which a diuretic action of extract of the posterior lobe was described. The antidiuretic action of extract of the posterior lobe is also exerted in diabetes insipidus in which condition, as in diuresis following the ingestion of water, there is a large volume of dilute urine.

Firstly, whether the salt be given in solution isotonic with or hypertonic to the body fluids, in normal animals or in animals diabetic after section of the supraoptico-hypophyseal tracts, administration of sodium chloride by stomach tube or by intravenous infusion causes increased rate of excretion of chloride in the urine. Thus the actual elimination of the salt is independent of the neurohypophysis; and, as already stated, is not altered by the intravenous infusion of extract of the posterior lobe of the pituitary. Secondly, when salt is given in hypertonic solution, but not when given in isotonic solution, the urine excreted is concentrated in respect of chloride; less water is lost from the body in the process of excretion of salt administered in hypertonic solution than when the same amount of salt is given in isotonic solution. But the chloride concentration of the urine remains low when salt is given in hypertonic solution to dogs diabetic following section of the supraoptico-hypophyseal tract. The experiments of Verney, together with the actions of the extract of the posterior lobe described at the beginning of this paper, provide the explanation. Salt in hypertonic solution causes an increase in osmotic pressure of the blood; which evokes from the neurohypophysis an increased output of hormone; which, reaching the kidney, stimulates the reabsorption of water in the renal tubules. Thus the urine is concentrated in respect of chloride and the salt is excreted with minimum loss of water, when given in hypertonic solution.

In the experiments of Verney (1947) not all crystalloids were equally effective in evoking the release of antidiuretic hormone, when injected into the common carotid artery in amounts calculated to give equal increases in osmotic pressure of the blood in that artery. Sodium chloride, sodium sulphate, and sucrose appeared to be equally effective; urea was without effect; and dextrose had intermediate activity, causing a release of antidiuretic hormone in the experiments first described using a rapid injection of high concentration, but not in the experiments with the slow infusion of lower concentrations. By demonstrating that previous ligation of the internal carotid artery greatly diminished the inhibition of water diuresis by the intracarotid injection of hypertonic solutions, Verney has established that the area sensitive to changes in osmotic pressure lies in the vascular bed of the internal carotid artery; and although no other proof is available, the peculiar anatomical features of the cells of the supraoptic nuclei, together with the large blood supply of the nuclei, suggest that these cells may themselves be the "osmoreceptors".

So we may picture "osmoreceptors" probably situated in the hypothalamus continually responding to the osmotic pressure of the circulating blood and causing in the dog the release of about 1 micro-unit per second of hormone from the neurohypophysis; if the osmotic pressure of the circulating blood decreases by 1% to 2%, stimulation of the "osmoreceptors", and so production of hormone by the neurohypophysis ceases, and water diuresis ensues; if the osmotic pressure rises, more hormone is released from the neurohypophysis and causes the kidney to secrete urine of maximum concentration. The mechanism is peculiarly adapted to maintain the osmotic pressure of the body fluids within narrow limits, and is comparable in its physiological aptness with the control of respiration by the action of carbon dioxide on the respiratory centre.

An output of hormone from the neurohypophysis can be excited by procedures other than changes in osmotic pressure. Emotional stress, induced in a dog during water diuresis, may cause inhibition of the urine flow; this inhibition is observed consistently with animals in which the kidneys and suprarenals have been denervated; resembles closely the inhibition by the intravenous injection of post-pituitary extract; and is practically abolished after removal of the posterior lobe of the pituitary (Rydin and Verney, 1938; O'Connor and Verney, 1942). The inhibition by emotional stress is thus due to release of antidiuretic hormone from the neurohypophysis during the emotion. Emotion produced by a variety of procedures is effective—the sounding of a motor horn, electrical stimulation to the flanks, running on a moving table, even the entry of a strange person into the room may evoke antidiuretic hormone and cause inhibition of water diuresis. Others have shown that acetyl-choline in the atropinized dog and nicotine injected intravenously may also cause inhibition of water diuresis due to release of antidiuretic substance from the neurohypophysis (Pickford, 1939; Burn, Truelove and Burn, 1945). O'Connor and Verney (1945), working with dogs with normal innervation of the kidneys and suprarenals, found that inhibition of water diuresis by emotional stress was by no means the rule. Of 21 normal bitches, the typical inhibition appeared consistently in only 3 and was not produced in any tests on 7; with the remaining 11 animals the typical inhibition appeared in some but not all tests of the effect of emotional stress. Most of these animals were then submitted to denervation of the kidneys and suprarenals, the operation consisting of the division of all visible nerve fibres in the renal pedicle, section of the splanchnic nerves, and removal of the second, third and fourth lumbar ganglia with the sympathetic chain between them. After this operation inhibition of water diuresis occurred with all animals in all tests of the effect of

for the production of polyuria of diabetes insipidus:—total loss of function of the neurohypophysis, without damage to the glandular parts of the pituitary.

The degeneration of the nerve fibres in the neurohypophysis distal to the site of section is accompanied by retrograde degeneration and ultimate disappearance of the cells of the supraoptic nucleus of the hypothalamus and so confirms that these are the cells of origin of non-medullated fibres of pituitary stalk. Similar degeneration occurs in the cells of the paraventricular nuclei (O'Connor, 1947a), indicating that some of the fibres of the stalk, perhaps one-sixth, arise from these cells. However, the peculiar features of the cells of the supraoptic nuclei are observed equally in the paraventricular nuclei, so that there appears to be no need to postulate separate functions for the two groups of cells and their axons in the neurohypophysis. Other neurones in the hypothalamus are not arranged in such compact cell masses as are the cells of the supraoptic and paraventricular nuclei, and so their degeneration following section of the stalk, even if it did occur, would be difficult to recognize; but only a few fibres other than those arising from the paraventricular and supraoptic nuclei pass down the pituitary stalk to the pars nervosa. In all probability, it is the processes of the cells of the supraoptic and paraventricular nuclei which form the link between the hypothalamus and the neural lobe of the pituitary. They probably determine the release of the antidiuretic hormone, and so provide the means by which the hypothalamus can influence the reabsorption of water in the renal tubules.

Factors determining the release of hormone from the neurohypophysis.—The recent work of Verney (1947) has developed experimentally the conception that the output of hormone from the neurohypophysis is determined by the osmotic pressure of the circulating blood. For these experiments, at preliminary aseptic operations, the common carotid arteries of dogs were enclosed in loops of skin so that, when the skin loops had healed, injections could be made into the circulation to the head repeatedly and without disturbance to the animal. The injection of hypertonic solutions of sodium chloride into one carotid artery during water-diuresis resulted in inhibition of urine flow: the inhibition followed a time course identical with that of the inhibition produced by the intravenous injection of a small dose of extract of the posterior lobe of the pituitary, and was reduced to about one-tenth in experiments after removal of the posterior lobe of the pituitary. Thus, a brief but large increase in the sodium chloride content of the blood reaching the head caused liberation of antidiuretic hormone from the neurohypophysis.

In further experiments (Verney, 1947) hypertonic solutions of sodium chloride were infused into one carotid artery at a rate chosen to cause an increase of about 2% in the osmotic pressure of the blood in that artery. The infusion was maintained for 40 minutes and during the infusion the rate of excretion of urine fell from the diuretic level of about 6 ml. per min. to 0.5 ml. per min., and slowly recovered when the infusion was stopped. Infusion of sodium chloride into a vein at the same rate did not inhibit the water-diuresis; but the fall in the rate of urine secretion during the intracarotid infusion could be matched by the inclusion in the intravenous infusion of sufficient extract of the posterior lobe of the pituitary to give a rate of infusion of 1 micro-unit per second. An increase of 2% in osmotic pressure of the blood in one carotid, then, caused the release of 1 micro-unit per second of antidiuretic hormone, and this sufficed to restrain the urine flow from diuretic to resting level.

These experiments enable explanation to be made of some features of the response of the dog to ingested water. Klisiecki, Pickford, Rothschild and Verney (1933) showed that when water was given by stomach tube to dogs, the water load of the tissues—that is the difference at any time between the volume of water absorbed from the intestine and the amount excreted in the urine—rose to a maximum 35 minutes after the administration of the water; but the rate of flow of urine reached its maximum 15 minutes later. The ingestion of 250–300 ml. of water in the dog causes a fall in osmotic pressure of the arterial blood of 1% to 2% and so (from the work of Verney just described) may be presumed to cause a fall of 1 micro-unit per second in the output of hormone from the neurohypophysis. In fact production of the hormone probably ceases, and as the hormone already in circulation is removed from the blood stream the urine flow increases to diuretic level; the lag between water load and rate of flow of urine is accounted for by the time needed to remove the hormone already in the circulation. Water diuresis, the response appropriate to a fall in osmotic pressure of the body fluids, appears to be determined by decreased activity of the neurohypophysis.

The neurohypophysis also determines an appropriate renal response to increased osmotic pressure of the circulating blood. In my own experiments it has become necessary to consider the changes in urine volume and composition which follow the administration of sodium chloride to dogs as composed of two independent responses of the kidney.

DISCUSSION ON STREPTOMYCIN

Professor Clifford Wilson discussed clinical trials of streptomycin in non-tuberculous infections: During the past twelve months these trials have been carried on at five London hospitals and eleven provincial centres. Owing to the comparative rarity of suitable cases, the wide range of conditions treated and the small quantities of streptomycin available, the investigation is still in the preliminary stage. The main effort has been directed against *H. influenzae* meningitis and has confirmed American experience that streptomycin is probably the most effective single therapeutic agent in this disease and that failures are almost entirely due to the rapid development of resistance to streptomycin. Encouraging results have been obtained with other forms of meningitis, and with septicæmia, urinary tract infections and local sepsis where these conditions are due to penicillin-resistant organisms, particularly *B. coli*, *Ps. pyocyanea* and *Proteus* (see also Wilson, C. (1948) *Lancet*, ii, 445).

Dr. Trevor P. Mann: *Streptomycin in treatment of tuberculous meningitis.*—During the last fourteen months we have studied and treated 33 cases of tuberculous meningitis at Hammersmith Hospital. In 32 the diagnosis was bacteriologically proven, and in the one remaining child the presumptive diagnosis was very strong.

Formerly, little was to be gained from the early recognition of the disease for there was no specific treatment and the patient was sure to die. To-day its detection in the prodromal stage, before the onset of neurological signs, has become an urgent necessity, for on the whole it is the early cases which derive most benefit from treatment. The possibility of meningeal involvement must always be considered in the known tuberculous child with unexplained symptoms. This group could in future provide a good source of early cases.

Diagnosis.—In hospital a positive or strongly presumptive diagnosis should be attained within twenty-four hours with prompt and unremitting investigation of a suspicious case. Full examination of the spinal fluid, radiography of the chest and a Mantoux test are part of an immediate and indispensable routine. A careful history is often a valuable guide in assessing the doubtful case. In half our patients there was evidence of close contact with tuberculosis. In all the children the Mantoux test was positive where this was carried out to a dilution of 1 : 100, and in just over half the cases the chest X-ray revealed pulmonary disease of a definite or suspicious nature. In 6 out of 7 cases showing milary infiltration of the lungs, choroidal tubercles were seen at the first examination and in one case tubercles were found in the absence of radiographic changes in the chest. The eye-grounds, therefore, must not be neglected.

The diagnostic importance of a low spinal fluid sugar content needs emphasis. In all except 3 cases the level was significantly lowered in the lumbar fluid at the first puncture, and in 3 patients with a high initial reading, serial punctures showed a progressively falling value. The chloride levels, on the other hand, were not significantly lowered in 13 of our 33 cases at the first examination. As far as the differential diagnosis is concerned, in children with a lymphocytic spinal fluid the possibilities usually rest between the several forms of meningitis of virus origin, tuberculous meningitis and possibly the serous tuberculous meningitis described recently by Lincoln (1947). Here, the chemistry of the fluid is of differential value. Serous meningitis, according to Lincoln, occurs not infrequently in children with active primary tuberculosis and clinically may closely simulate tuberculous meningitis. Spinal fluid examination offers the best means of differential diagnosis. In serous meningitis the pressure and number of cells may be increased but the chemistry of the fluid remains normal. Complete recovery is possible. MacGregor and Green, as long ago as 1937, reported 2 cases showing a similar syndrome where both cases recovered, their spinal fluid returning to normal. We have recently had a case which may be explained on this basis. A child of eighteen months was admitted in November 1947 with a tuberculous abscess of the left chest wall, and a provisional diagnosis of tuberculous meningitis. On admission there were no abnormal signs apart from irritability and the chest-wall swelling. Lumbar puncture showed a pleocytosis and fig. 1 portrays the C.S.F. findings over a period of three to four weeks. Because of the normal chemical values of her fluid on repeated

emotional stress. The explanation of this difference between normal and partially sympathectomized dogs was found to lie in an action of adrenaline on the neurohypophyseal mechanism. If, in a dog with kidneys and suprarenals denervated and so in which emotional stress always produced inhibition of water diuresis, emotion was induced immediately following an intravenous injection of a small dose of adrenaline, no inhibition of water diuresis ensued. Adrenaline did not modify the inhibition of water diuresis by injections of the extract of the posterior lobe of the pituitary, and so the conclusion was drawn that adrenaline, introduced by intravenous injection or set free from the animal's own suprarenals, may block the liberation of antidiuretic hormone from the neurohypophysis during emotional stress. The irregular appearance of inhibition by emotional stress in normal dogs thus found its explanation in the release of adrenaline from the suprarenals during the emotion.

The aspects of the relationship between the hypothalamus and urine secretion discussed in this communication have been dealt with at greater length in two lectures by Verney (1946, 1947) and in a review (O'Connor, 1947*b*), to which reference is recommended for further detail.

DISCUSSION ON STREPTOMYCIN

Professor Clifford Wilson discussed clinical trials of streptomycin in non-tuberculous infections: During the past twelve months these trials have been carried on at five London hospitals and eleven provincial centres. Owing to the comparative rarity of suitable cases, the wide range of conditions treated and the small quantities of streptomycin available, the investigation is still in the preliminary stage. The main effort has been directed against *H. influenzae meningitis* and has confirmed American experience that streptomycin is probably the most effective single therapeutic agent in this disease and that failures are almost entirely due to the rapid development of resistance to streptomycin. Encouraging results have been obtained with other forms of meningitis, and with septicæmia, urinary tract infections and local sepsis where these conditions are due to penicillin-resistant organisms, particularly *B. coli*, *Ps. pyocyanea* and *Proteus* (see also Wilson, C. (1948) *Lancet*, ii, 445).

Dr. Trevor P. Mann: *Streptomycin in treatment of tuberculous meningitis*.—During the last fourteen months we have studied and treated 33 cases of tuberculous meningitis at Hammersmith Hospital. In 32 the diagnosis was bacteriologically proven, and in the one remaining child the presumptive diagnosis was very strong.

Formerly, little was to be gained from the early recognition of the disease for there was no specific treatment and the patient was sure to die. To-day its detection in the prodromal stage, before the onset of neurological signs, has become an urgent necessity, for on the whole it is the early cases which derive most benefit from treatment. The possibility of meningeal involvement must always be considered in the known tuberculous child with unexplained symptoms. This group could in future provide a good source of early cases.

Diagnosis.—In hospital a positive or strongly presumptive diagnosis should be attained within twenty-four hours with prompt and unremitting investigation of a suspicious case. Full examination of the spinal fluid, radiography of the chest and a Mantoux test are part of an immediate and indispensable routine. A careful history is often a valuable guide in assessing the doubtful case. In half our patients there was evidence of close contact with tuberculosis. In all the children the Mantoux test was positive where this was carried out to a dilution of 1 : 100, and in just over half the cases the chest X-ray revealed pulmonary disease of a definite or suspicious nature. In 6 out of 7 cases showing miliary infiltration of the lungs, choroidal tubercles were seen at the first examination and in one case tubercles were found in the absence of radiographic changes in the chest. The eye-grounds, therefore, must not be neglected.

The diagnostic importance of a low spinal fluid sugar content needs emphasis. In all except 3 cases the level was significantly lowered in the lumbar fluid at the first puncture, and in 3 patients with a high initial reading, serial punctures showed a progressively falling value. The chloride levels, on the other hand, were not significantly lowered in 13 of our 33 cases at the first examination. As far as the differential diagnosis is concerned, in children with a lymphocytic spinal fluid the possibilities usually rest between the several forms of meningitis of virus origin, tuberculous meningitis and possibly the serous tuberculous meningitis described recently by Lincoln (1947). Here, the chemistry of the fluid is of differential value. Serous meningitis, according to Lincoln, occurs not infrequently in children with active primary tuberculosis and clinically may closely simulate tuberculous meningitis. Spinal fluid examination offers the best means of differential diagnosis. In serous meningitis the pressure and number of cells may be increased but the chemistry of the fluid remains normal. Complete recovery is possible. MacGregor and Green, as long ago as 1937, reported 2 cases showing a similar syndrome where both cases recovered, their spinal fluid returning to normal. We have recently had a case which may be explained on this basis. A child of eighteen months was admitted in November 1947 with a tuberculous abscess of the left chest wall, and a provisional diagnosis of tuberculous meningitis. On admission there were no abnormal signs apart from irritability and the chest-wall swelling. Lumbar puncture showed a pleocytosis and fig. 1 portrays the C.S.F. findings over a period of three to four weeks. Because of the normal chemical values of her fluid on repeated

punctures and the absence of neurological signs, streptomycin treatment was withheld. Her fluid returned to normal and she was discharged home in January of this year. She is well to-day. Culture and guinea-pig inoculation of the spinal fluid were negative.

The absence of tubercle bacilli in the stained smear does not exclude the diagnosis. Streptomycin must not be withheld for more than twenty-four hours when the other diagnostic elements provide strong presumptive evidence of tuberculous meningitis. However, adequate cultural and biological tests on pre-treatment specimens of the fluid are essential for later bacterial confirmation.

Treatment.—At first continuous intramuscular and intrathecal therapy was employed for long periods but it was soon noted that many patients derived benefit from interrupted treatment. In cases which were going to respond to streptomycin there was frequently a marked improvement in the mental state and general well-being during the rest periods, and where anorexia and vomiting, attributable to streptomycin, had been troublesome, this would usually cease. The trend of the C.S.F. elements during the rest period was often a useful prognostic guide when correlated with the clinical condition. For a short period the intramuscular route alone was used, but as our results were uniformly bad the method was soon abandoned. High streptomycin levels are obtained in the spinal fluid following intrathecal treatment (fig. 2) and concentrations of the order of 500 $\mu\text{g}/\text{ml}$. have been

found in the ventricles several hours after an intraspinal injection. Garrod (1948) has recently shown that high concentrations of streptomycin are rapidly bactericidal to the Oxford strain of *Staphylococcus aureus* if the size of the inoculum is not too large. His findings, if applicable to the tubercle bacillus, may afford a ready explanation for the undoubted benefit accruing from intrathecal injection.

Table I shows the scheme of treatment favoured at the moment. This is the least amount

of treatment that should be given and in the presence of miliary tuberculosis or obvious active primary chest lesions intramuscular therapy should be continued for a further period of at least three months. Each case must be treated on its merits and at any time it may be necessary to modify the basic scheme to suit the needs of a particular patient. Until

recently the drug has been given six-hourly intramuscularly but there is experimental evidence to show that twelve-hourly administration is equally effective. If twelve-hourly injections are used we believe that treatment should be so spaced that the intrathecal injection is given approximately midway between the intramuscular injections, for we have found that after an intrathecal injection in several children off all treatment, streptomycin blood levels in the region of 4-8 $\mu\text{g/ml}$. are obtained in the six-hour period that follows. Giving the intramuscular treatment at 6 a.m. and 6 p.m. and the intrathecal injection at about midday we have found low but adequate blood concentrations during the night period. This level is maintained by a slow transference of the drug from the C.S.F. to the blood-stream. It is of interest to record that from 20% to 50% of the streptomycin given intrathecally is excreted in the urine during the following twenty-four hours.

SOME SIGNIFICANT TYPES OF CLINICAL RESPONSE TO TREATMENT

A third of our cases showed no response to streptomycin. In three cases, although rapid deterioration occurred shortly after starting treatment, life was prolonged for a number of months and the C.S.F. elements approached normal values. At autopsy, however, there was still evidence of active meningitis in these cases. The C.S.F. findings alone are not a reliable prognostic index.

Five of our cases have shown an immediate and uninterrupted improvement on treatment. Fig. 3 shows the C.S.F. values in one of our recovered cases both on and off streptomycin.

Fig. 3.—Patient J. C., aged 9 years. Cerebro-spinal fluid values in a recovered case, during and after streptomycin treatment. Arrows indicate cessation of intrathecal treatment.

Even on treatment the levels show a promising trend. Three months after admission there were no abnormal physical signs and the child was ambulant. Her good progress continues. Only when the clinical betterment is paralleled by a steady improvement in the C.S.F. elements can there be reason for optimism. In such cases one course of treatment, as outlined above, may suffice. When treatment has ended the patient must be closely watched for relapse and we feel that lumbar punctures should be done weekly until the fluid is normal, and subsequently at greater intervals.

This favourable type of response to treatment is unfortunately the exception; the one great hindrance to recovery, especially in cases showing a good initial response, is the development of a block at the level of the free margin of the tentorium. As a result of this occlusive process the normal flow of C.S.F. to the vertex is interrupted and hydrocephalus of a communicating type may result. Furthermore, streptomycin introduced from below is prevented from reaching the interpeduncular region in high concentrations, and it is here, as we know, that the maximal amount of exudate occurs in tuberculous meningitis. This stronghold of infection is probably the source of reinfection of the meninges in cases that relapse after an initial good response. Smith, Vollum and Cairns (1948) have recently demonstrated the presence of this block at the tentorial level by air studies in their patients, and we have confirmed their findings in a similar manner in several of our cases. Attempts have been made to attack this stronghold by the instillation of streptomycin through plastic tubes placed in the cisterna interpeduncularis. If this manoeuvre is to be successful, and technically it is quite feasible, it must be done if possible before the exudate in this region has become organized and impenetrable, in other words, during the early weeks of the illness.

Spina Bifida Occulta and Nulliparous Prolapse. [Abstract]

By ARTHUR A. GEMMELL, M.C., T.D., F.R.C.O.G.

[This paper was prepared in conjunction with Dr. P. H. Whitaker of the Department of Radiology and Mr. R. L. Plackett of the Department of Applied Mathematics (Statistics) of the University of Liverpool.]

GENITAL prolapse is a condition commonly associated with the trauma caused by childbirth. It is, however, seen also in women who have not borne children. This group is variously called congenital or virginal or nulliparous prolapse. We prefer the term nulliparous as the condition occurs in childless women whether they are married or not. It is not present from birth and is therefore not properly described as congenital.

A number of cases of true congenital prolapse in newborn infants have been described and in nearly all these there was an associated lumbo-sacral spina bifida which proved fatal.

This knowledge led others before us to consider whether lesser defects of the posterior arches of the vertebræ, which might possibly involve the fibres of the fourth and fifth sacral nerves, could be associated with a weak pelvic floor.

An examination of the literature of the subject shows a conflict of opinion. This might be due to (1) An absence of clear indication of the parity of the patients. (2) Lack of definition of what the author means by spina bifida occulta. (3) Controls which, in our opinion, are not well chosen.

We, therefore, investigated the subject afresh and collected the following material:

(a) With the help of many colleagues all over the British Isles, to whom we express our thanks, we obtained X-rays of the sacrum and lower lumbar spine from 52 patients suffering from nulliparous prolapse, none of whom had, at the same time, an abdominal tumour.

(b) X-rays from a control group of 101 healthy nulliparous women (51 factory workers and 50 women medical students and nurses) all of whom declared themselves free from the following: (1) Motor weakness in the lower limbs or some segment of them. (2) Paræsthesia, or pain in corresponding zones, with loss of sensibility. (3) Defective sphincter control—e.g. nocturnal enuresis in adult life. (4) Abolition of tendon reflexes—knee or ankle.

In order to facilitate comparison and to provide groups of large enough size we made four groups, namely, non-closure of S5; 4 and 5; 3, 4, 5 or any other three segments and 2, 3, 4, 5 and any other four or all five segments. The results are:

	Non-closure of segments		Normals		Nulliparous prolapse
S5..	..	26	25.7%	10	19.2%
S4, 5	..	43	42.6%	19	36.5%
S3, 4, 5, &c.	..	25	24.7%	11	21.1%
S2, 3, 4, 5, &c.	..	6	5.9%	7	13.5%

At first glance these figures might suggest that there is a higher proportion of defects at the caudal end of the sacrum in the normal women and at the cephalad end in the prolapse patients but the series of differences between the groups has been tested by the χ^2 test which gives a value of 2.87. Consequently $P=0.4$, P being the probability that these or greater differences are due to chance. As P here is considerably greater than 0.05 there is so high a degree of chance that the differences have no significance.

The individual groups which appear to give the greatest differences are those with

Recovered Cases

I.—M. D. M. (Advanced). C.S.F. (April 1948) normal. Home and back at school. Slight (L) external rectus weakness. Normal mentality. Period of observation off treatment, 9 months.

II.—R. S. (Intermediate). (?) C.S.F. Receiving orthopaedic treatment for healing tuberculous osteitis of the left ischium at a convalescent home. Normal mentality. Period of observation off treatment, 9 months.

III.—B. A. (Early). C.S.F. (April 1948) biochemically normal: 20 lymphocytes. Mental and physical status normal. Period of observation off treatment, 6 months.

IV.—J. C. (Early). C.S.F. (April 1948) biochemically normal: 20 lymphocytes. Mental and physical status normal. Period of observation off treatment, 60 days.

V.—B. R. (Early). C.S.F. (April 1948) normal. Home and back at school. Mental and physical status normal.

POSTSCRIPT (October 1948).—All 5 recovered cases continue to make good progress. Cases II and IV now have a normal spinal fluid. The C.S.F. of Case III is normal except for 10 cells.

SUMMARY OF RESULTS

Five cases have recovered out of a total of 33 cases; 7 of the advanced cases were moribund on admission and died in the first week; 12 children were under 3 years of age and all have died; 3 cases are at this moment improving on treatment. A conservative estimate of the recovery rate is therefore 20% at the moment. The ultimate prognosis in the 5 cases classified as "recovered" will, of course, remain in doubt for some time. Psychometric tests performed on the 5 recovered children by Dr. Margaret Ferguson have shown them all to be normal.

I wish to express my gratitude to Dr. Dermot MacCarthy, and to Dr. Mary Barber and Dr. I. Doniach.

Dr. J. Rubie: In a series of 50 cases of tuberculous meningitis treated at Highgate Hospital with streptomycin there are 21 surviving. These include 2 who have survived for more than 300 days, 4 more than 250 days, 2 more than 200 days and 1 more than 150 days. 6 have normal cerebrospinal fluid and 10 are clinically fully recovered. Two cases show slight ataxia and one of these two is deaf.

However, of the 29 who died, 8 died within seven days of admission and a further 14 cases received streptomycin by the intramuscular route only—a method now regarded as inadequate since only 2 of the cases thus treated recovered.

Failure is almost invariably due to the exudate causing mechanical obstruction to the circulation of the cerebrospinal fluid which in turn causes hydrocephalus. It is the hydrocephalus which causes death and it seems to be rather a matter of chance how soon it develops in the course of the disease. The hydrocephalus determines the stage of the disease and not the length of the history. It develops sooner in infants, and of the 50 cases, only one under 3 years of age survives and 14 under 3 years of age have died.

Our efforts must be directed to the prevention and treatment of the block—by early diagnosis and prompt treatment, and possibly by earlier surgical intervention such as ventricular drainage.

POSTSCRIPT.—The above figures were given in April 1948. The figures in October 1948 show that 8 of the above series have survived for more than one year and 11 have a normal cerebrospinal fluid.—J. R.

Dr. J. W. Crofton: The result of a course of streptomycin treatment for a case of pulmonary tuberculosis will probably depend on several factors. If the patient is left with large unclosed cavities, which cannot be controlled with collapse therapy, he will probably relapse, and this has occurred in at least two of our patients treated under the M.R.C. Scheme at the Brompton Hospital. The second factor is the development of streptomycin-resistance in the patient's tubercle bacilli. This is obviously important but its exact significance is yet to be assessed. It is possible that the present crude methods of testing for streptomycin resistance may show the development of resistant organisms when these, in fact, represent only a small proportion of the total population of tubercle bacilli in the patient. Streptomycin may therefore continue to attack the remaining susceptible organisms.

The third factor is, of course, the resistance of the patient which must take on where the streptomycin leaves off. The tubercle bacilli from most of our cases have developed streptomycin-resistance, yet many of the patients have continued to improve and some have become sputum-negative. Either the streptomycin maintained its effect on a significant residuum of susceptible tubercle bacilli, or the patient's powers of resistance were adequate to cope with the remaining infection.

fibroids, or even a carcinoma. The chief advantage of the operation is that when the uterus has been removed a very efficient fascial shelf can be reconstructed from the total depth of the broad ligament down to and including the utero-sacral ligament. The chief recommendation of this shelf is that by sewing the round ligaments together, and anchoring them to the triangular ligament, they form under the bladder neck a kind of Millin's sling, made of round ligament. The effect that this has upon stress incontinence is most beneficial.

Once a surgeon is used to this method he will find it easier to perform than Fothergill's operation. The great criticism of vaginal hysterectomy in the past has been its liability to produce a subsequent hernia of Douglas's pouch. In my small series, in which every case has been personally examined by me, I have found one such hernia, and I operated on it at once, so that I should have a clean bill to present to this Meeting. I have now altered the technique of the operation and direct special attention to the suturing of the utero-sacral ligaments across Douglas's pouch. With improved technique and greater experience, hernia here should become uncommon.

A film was shown by the author to illustrate his own technique.

Anæsthesia, post-operative care and results were then discussed, and the author continued: I should like to conclude with a plea for a bold surgical handling of all women with prolapse, regardless of their age. This is a most distressing and disabling condition, limiting the social activities of the citizen. The day of pill and pessary gynaecology is passed, and I am happy to say that I have inserted no rings or Napier's pessaries, or any other contrivance in the last two years. There is no more grateful, and no more rejuvenated person than the successfully operated upon prolapse patient and there is no more pathetic spectacle than the woman who has worn a ring for twenty or thirty years, with stress incontinence, which a ring never cures, and pessary ulceration and vaginitis, not to mention the possibility of a cancer developing from the ring. We should not, therefore, deny the benefit of surgery to any of these cases.

The following speakers also contributed to the Discussion:

Mr. V. B. Green-Armytage; Mr. Wilfred Shaw; Mr. Arthur Gemmell; Mr. Leslie Williams; Professor C. H. G. Macafee; Mr. William Hawke; Mr. A. J. Wrigley; Mr. Everard Williams; Mr. C. M. Gwillim.

Advanced Ovarian Pregnancy.—ARNOLD WALKER, F.R.C.S.

Mrs. I. Y., aged 38, was admitted to the Luton Maternity Hospital on May 16, 1946, at about 34 weeks with a history of severe abdominal pain for two or three days. She had had one previous pregnancy which was normal. The foetal heart was heard and the pain improved. About four weeks later, the foetal heart stopped and after waiting some ten days in the expectation that labour would start, laparotomy was performed.

On opening the abdomen, a large mass of necrotic tissue was found adherent to the abdominal wall. On passing the hand between the tumour and the parietal peritoneum, membranes were ruptured and a macerated foetus weighing 6 pounds 4 ounces was removed. The tumour separated with ease and was lifted out of the abdomen. It looked like a twisted ovarian cyst with a thrombosed but untwisted pedicle. It arose from the right side and the right tube could be seen stretched over the tumour. Around one circumference, the amniotic membrane was attached and this was stripped off the abdominal wall and abdominal organs with the greatest of ease. The pedicle was not more than 5 centimetres across with the ovarian ligament and ovario-pelvic fold clearly defined. When this pedicle had been tied and the tumour removed, the peritoneum which had been in relation to it appeared to be undamaged. The uterus, left tube and ovary were adherent but except for this the

non-closure of four or five segments in (a) the students, and (b) the prolapse patients—2 in 50 students and 7 in 52 prolapse patients, but even here using Fisher's exact test (which can be used for very small numbers) $P=0.09$ and so there is no significance in the difference especially as we have selected the group where it is greatest.

Thus the conclusion from this investigation is that there is no relationship between the occurrence of spina bifida occulta and that of nulliparous prolapse, where spina bifida occulta is used to mean non-closure of the posterior arches of the sacral vertebrae.

There remains one possibility which has not been examined during this investigation. It might be that the elements of the fourth and fifth sacral nerves, which supply the pelvic floor, are involved in different degree even where the defects in the sacral vertebrae have the same or similar appearances. This hypothesis could be tested by examining the muscular and sensory reactions of the structures supplied by these segments, but it seems unlikely since 5 in 52 prolapse patients show complete closure of the dorsal wall of the sacrum and the only individual with complete absence of the dorsal wall had no prolapse.

3. DISCUSSION ON THE ROLE OF VAGINAL HYSTERECTOMY IN TREATMENT OF PROLAPSE. [Abstract]

Mr. A. C. Palmer: About 1920, the idea took shape that some forms of prolapse require removal of the uterus in the attempt to rebuild the pelvic diaphragm. During the last twenty-five years, this idea has ripened into conviction.

It is interesting that the surgical treatment of prolapse is not yet standardized and that it lies somewhere near the frontier of gynaecological surgery. It does this, in spite of the fact that prolapse must be very nearly contemporary with the first labour. It remains true that men of great experience are not yet agreed on the best methods of obtaining a stable result.

My answer to the question, "What is the position of hysterectomy in the surgical treatment of prolapse?" can be summarized in three words: (1) Never, (2) Sometimes, and (3) Always. *Never* applies when prolapse is confined to the walls of the vagina; *Sometimes*, when the cervix is in the first stage of procidentia, i.e. when it has fallen to round about the vulval level; *Always*, when the cervix is outside the vulva.

The variations in treatment depend upon what has happened to the utero-sacral ligament. If the cervix has reached the vulva by stretching and without damage to the utero-sacral ligament, hysterectomy is contra-indicated. If on the other hand, the cervix has brought the utero-sacral ligament down to the vulva with it, so that the index finger can easily be hooked round the ligament, then I think hysterectomy is indicated. When the cervix is well outside the vulva, it must bring the utero-sacral ligament down with it and, in my opinion, is always an indication for hysterectomy. Removal of the uterus means that the utero-sacral ligaments are in fact shortened and, when approximated in the mid-line, stabilize the vault of the vagina. In my hands, infolding the ligaments below and in front of the cervical stump does not stabilize the vault of the vagina and too many of my cases have come back in a year or two, with the vagina again everted. After hysterectomy, only 3 out of 300 cases have returned with an enterocele and 1 with a cystocele. These were due to errors in judgment during the operation.

Mr. John Howkins: Though I am fully conscious of the value and efficiency of Fothergill's operation, and I am not proposing that Mayo's operation should replace this well-tested old friend, which has held the field in the hands of so many different surgeons, employing many different techniques, I would submit that the keystone doctrine is open to a fallacy. The vault of the vagina and the cardinal ligaments are not rigid structures, and do not give strength in compression as an arch does.

In removing the uterus, at or near the menopause, one frequently eradicates an organ which may be causing symptoms of excessive bleeding, which may harbour

(3) It is not uncommon to find a considerable reduction in plasma chlorides in anuric patients, in which case sufficient sodium chloride should be administered by mouth, either in tablet or capsule form or dissolved in the daily fluid allowance to return this level to normal. This may, however, prove impossible as the salt may cause vomiting. If any urine is being passed, the sodium chloride lost should be balanced by sodium chloride administered, similarly with vomiting. Where a chloride level is normal and there is no chloride loss, no salt whatever should be administered.

It is the rule to find a reduction in carbon-dioxide combining power of the plasma, but if the fluid balance and diet are carefully controlled this will not require any special attention. In cases in which the management has not been ideal and a severe acidosis is present, this can probably only be righted effectively by dialysis.

If a patient remains anuric, or virtually so as considered by urea output, six days after the onset of the acute renal failure, dialysis is undertaken with the artificial

FIG. 1.—Urea removed: The three tall blocks represent grammes of urea removed by the "artificial kidney". Approximately 40 litres of blood were dialysed on each of the three occasions. The small block represents the total urea excreted by the kidneys in the twenty-eight days.

kidney in order to remove protein breakdown products and to right any electrolyte imbalance.

On the sixth day of anuria in this patient the blood urea had risen to 220 mg.%. Dialysis was performed and 38 grammes of urea removed and the blood urea reduced to 112 mg.%. On the twelfth day the blood urea had again risen, now to 290 mg.%, dialysis removed 88 grammes of urea and the blood level was reduced to

abdominal cavity was as clean as it is after the removal of a simple, pedunculated ovarian cyst. The tumour was roughly globular in shape and its diameter varied between 13 and 20 centimetres. Its surface was smooth and divided into two halves by the attachment of the amnion. From the foetal surface which bulged into the amniotic cavity, there arose a necrotic umbilical cord. On the smooth maternal surface could be seen the stretched-out fallopian tube which appeared to be intact.

The tumour was examined by Professor Willis and Dr. L. W. Proger at the Royal College of Surgeons but owing to its advanced state of necrosis it is not possible to identify even the limits of the placenta. From its anatomical relations the tumour clearly consists of the placenta and a right ovarian tumour.

It is believed that this is a primary ovarian pregnancy in an ovarian tumour sufficiently large to contain the pregnancy until the chorion had lost its invasive properties. At some stage, the bag of membranes must have herniated out of the tumour probably before the attack of pain which may have been due to hæmorrhage into the tumour.

Accidental Hæmorrhage with Bilateral Cortical Necrosis of the Kidneys, Treated by Artificial Kidney.—A. M. JOEKES, M.A., B.M., B.Ch., and G. M. BULL, M.R.C.P. (for GLADYS DODDS, F.R.C.S.).

The patient was a young married woman of 24; last menstrual period in 4th week of August 1947; expected date of delivery June 20, 1948. She was seen in January and February of this year in the Ante-Natal Clinic at the Mothers' Hospital, Clapton; B.P. 110/80 and no albumin in the urine was found.

9.3.48: Trace of albumin in the urine. B.P. 114/70, and Hb 60%. Treated with iron and liver injections as out-patient. 16.3.48: Urine: no albumin. B.P. 110/70.

31.3.48: Admitted 9 a.m. to Mothers' Hospital, Clapton, under the care of Dr. Gladys Dodds having vomited three times in the night and at 4 a.m. onset of acute abdominal pain with a small loss of blood *per vaginam*. The previous day she had felt perfectly well.

On examination.—Pale, face puffy, slight œdema of the ankles, B.P. 160/120. Uterus wood hard, tender, and the size of 36 weeks as opposed to actual 29 weeks. $\frac{1}{2}$ oz. of urine was obtained by catheter; this boiled solid with albumin. Diagnosis: Toxæmia of pregnancy with concealed accidental hæmorrhage.

The same afternoon normal delivery occurred of a stillborn fœtus; the placenta was expelled with a large retro-placental clot. After delivery B.P. 150/100. No urine was obtained on catheterization.

1.4.48 and 2.4.48: B.P. 150/100. No urine obtained on catheterization.

With a diagnosis of bilateral cortical necrosis she was at once transferred to the Hammersmith Hospital for treatment by blood dialysis with the "artificial kidney" [1] if anuria persisted.

The subsequent course of events can be seen from the chart. The total urinary output in the twenty-nine days that the patient survived from the start of anuria amounted to less than 2 litres. The urea concentration in the urine was less than 300 mg.% and the total amount of urea excreted by the kidneys in the twenty-eight days was only 5 grammes.

The treatment of anuria or oliguria can be divided into three main headings: (1) Fluid balance. (2) Diet. (3) The maintenance of or correction of an abnormal to a normal electrolyte pattern.

(1) *Fluid balance.*—The total fluid intake by any route intravenous, rectal or oral is maintained at 1,200 to 1,500 c.c. per day in excess of fluid loss in urine and vomit.

(2) *Diet.*—An intake of 2,000 calories per day is aimed at, with a minimal protein content. This diet is extremely difficult to administer successfully owing to the unpalatable food that the restricted choice permits; those that are available are fat in the form of margarine, carbohydrate as cane sugar, glucose or lactose and fruit. Borst [2] has described in some detail the diet as he uses it.

Experimental Investigation Into Factors Concerning the Growth of Cysts of the Jaws

By P. A. TOLLER, L.D.S.

INTRACYSTIC PRESSURE

THERE is much evidence to suggest that certain cysts increase in size by reason of the fluid tension within them. This was recognized early by the French and German surgeons after the discovery that opening a cyst into the mouth checked further growth and subsequently led to a decrease in size of the tumour. Cysts occurring between the roots of teeth cause these roots to be displaced apart as if by pressure (cases quoted by Potts, 1927). Another observation concerns the migration of teeth associated with dentigerous cysts. Included teeth are frequently found lying at relatively great distances from their sites of development. These occurrences are strongly suggestive of a pressure effect, since if the growth of the cyst had simply been due to the proliferation of tumour cells then it would be expected that the tooth would remain static in relation to the bone and the tumour would grow around and pass it.

An interesting point to notice is that teeth included in dentigerous cysts appear to be moved by forces acting on the crown and its epithelial attachment. Collected cases and reports of cases show that cementum is not exposed in a cyst cavity even when cysts are in long-standing contact with tooth roots. Slow absorption of roots sometimes occurs. These facts tend to argue that simple pressure largely effects the expansion of a cyst.

Warwick James (1926) was the first worker to investigate whether a true positive pressure existed within cysts. He made a number of interesting observations on the various factors possibly concerned with the aetiology of cysts and maintained that pressure was a very important factor affecting the growth of a mature cyst. He performed a number of experiments to determine intracystic pressure and he found that all his results showed higher pressure values than the known value for capillary pressure. He suggested that cysts showing higher pressure may display a more flattened appearance of the cells of their epithelial linings.

James also showed that intracystic pressure fluctuated slightly in accordance with the cardiac pulse, and he considered that this was accounted for by the normal pulsations in the capillary bed surrounding a cyst wall. He stated, however, that the methods he had at his disposal at that time prevented an accurate measurement of fluid pressure being made.

Experimental

It was considered that an investigation into cyst growth might well begin by an attempt to obtain accurate experimental data on the hydrostatic pressure within cyst cavities *in vivo*.

The first procedure was to study the various types of apparatus for pressure recording and to design an apparatus most suited to the problem under consideration. The pressure ranges likely to be encountered were known to be between 10 cm. and 100 cm. of water (James). A water manometer was selected as a suitable type of apparatus since it would enable a sufficiently extended scale of measurement to be used, which in practice provides an error of about 0.1%.

The disadvantage of this apparatus is that a manometer tube of at least one meter in length is needed, which is manageable in a laboratory but not in the ward or operating theatre. Mercury manometer or simple aneroid types were not considered sufficiently accurate although both have occasionally been used for the sake of convenience.

The size of the exploring cannula had to be selected carefully for several reasons: (a) The semi-fluid contents of some cysts tend to choke a narrow cannula; (b) a wide cannula has a lacerating effect on the tissue as it is inserted and a minute escape of fluid might result. A wide cannula would also have a disturbing effect on the volume of a small cyst, especially if it had to be passed through bone; (c) a narrow bore tube results in increasing the inertia of a hydrostatic system, by reason of the "drag effect" varying as a function of the diameter of the bore.

130 mg. % of urea. On the seventeenth day the blood urea had again risen to 210 mg. %, dialysis removed 42 grammes of urea and the blood level was reduced to 110 mg. urea %.

After the third dialysis the patient remained relatively well for several days and a period of over three weeks had elapsed since the original renal catastrophe. It was decided that while the diagnosis of cortical necrosis was almost certainly correct, were there sufficient kidney tissue surviving to keep the patient alive a considerable diuresis would by this time have been expected. In view of the very small amounts of urine and extremely poor urea concentration, it was not felt justifiable to try to maintain this patient's life yet further by means of the artificial kidney, the more so as one could only give a virtually hopeless prognosis to the young husband.

The patient died on the twenty-eighth day and a post-mortem confirmed the diagnosis of bilateral cortical necrosis. Typically the naked-eye appearance of a longitudinal section of the kidney showed sparing of a thin rind of subcapsular tissue and a rather wider juxtamedullary zone. The histological examination showed tubules but no glomeruli in the subcapsular zone, a fairly large number of surviving glomeruli in the juxtamedullary zone but the majority of the accompanying tubules, however, were dilated and had debased epithelium¹.

That it had been possible to maintain a patient's life for twenty-eight days in the absence of any significant renal function would seem to justify the claim that the artificial kidney is an effective treatment for acute uræmia, and should enable us to tide over a patient during the crucial time that the kidneys might be recovering from an acute catastrophe.

Experimental Investigation Into Factors Concerning the Growth of Cysts of the Jaws

By P. A. TOLLER, L.D.S.

INTRACYSTIC PRESSURE

THERE is much evidence to suggest that certain cysts increase in size by reason of the fluid tension within them. This was recognized early by the French and German surgeons after the discovery that opening a cyst into the mouth checked further growth and subsequently led to a decrease in size of the tumour. Cysts occurring between the roots of teeth cause these roots to be displaced apart as if by pressure (cases quoted by Potts, 1927). Another observation concerns the migration of teeth associated with dentigerous cysts. Included teeth are frequently found lying at relatively great distances from their sites of development. These occurrences are strongly suggestive of a pressure effect, since if the growth of the cyst had simply been due to the proliferation of tumour cells then it would be expected that the tooth would remain static in relation to the bone and the tumour would grow around and pass it.

An interesting point to notice is that teeth included in dentigerous cysts appear to be moved by forces acting on the crown and its epithelial attachment. Collected cases and reports of cases show that cementum is not exposed in a cyst cavity even when cysts are in long-standing contact with tooth roots. Slow absorption of roots sometimes occurs. These facts tend to argue that simple pressure largely effects the expansion of a cyst.

Warwick James (1926) was the first worker to investigate whether a true positive pressure existed within cysts. He made a number of interesting observations on the various factors possibly concerned with the aetiology of cysts and maintained that pressure was a very important factor affecting the growth of a mature cyst. He performed a number of experiments to determine intracystic pressure and he found that all his results showed higher pressure values than the known value for capillary pressure. He suggested that cysts showing higher pressure may display a more flattened appearance of the cells of their epithelial linings.

James also showed that intracystic pressure fluctuated slightly in accordance with the cardiac pulse, and he considered that this was accounted for by the normal pulsations in the capillary bed surrounding a cyst wall. He stated, however, that the methods he had at his disposal at that time prevented an accurate measurement of fluid pressure being made.

Experimental

It was considered that an investigation into cyst growth might well begin by an attempt to obtain accurate experimental data on the hydrostatic pressure within cyst cavities *in vivo*.

The first procedure was to study the various types of apparatus for pressure recording and to design an apparatus most suited to the problem under consideration. The pressure ranges likely to be encountered were known to be between 10 cm. and 100 cm. of water (James). A water manometer was selected as a suitable type of apparatus since it would enable a sufficiently extended scale of measurement to be used, which in practice provides an error of about 0.1%.

The disadvantage of this apparatus is that a manometer tube of at least one meter in length is needed, which is manageable in a laboratory but not in the ward or operating theatre. Mercury manometer or simple aneroid types were not considered sufficiently accurate although both have occasionally been used for the sake of convenience.

The size of the exploring cannula had to be selected carefully for several reasons: (a) The semi-fluid contents of some cysts tend to choke a narrow cannula; (b) a wide cannula has a lacerating effect on the tissue as it is inserted and a minute escape of fluid might result. A wide cannula would also have a disturbing effect on the volume of a small cyst, especially if it had to be passed through bone; (c) a narrow bore tube results in increasing the inertia of a hydrostatic system, by reason of the "drag effect" varying as a function of the diameter of the bore.

In a study of intracranial pressure O'Connell (1943) demonstrated an experiment to show that variations in pressure were imperfectly transmitted through a system which incorporated a ventricular cannula of 2 mm. internal diameter when the rate of variation was about that of the cardiac rhythm. When a lumbar-puncture needle of small bore was used (0.8 mm. bore) the inaccuracy was very pronounced, though slow variations (four variations per minute) can be recorded accurately through a system of such narrow bore. This consideration is only of importance when measuring variations of intracystic pressure with the cardiac pulse.

Manometer.—A simple direct manometer was not considered sufficiently accurate to measure intracystic pressure, owing to the fact that fluid must flow out from the cyst cavity in order to cause the manometer to register. This egress of fluid slightly reduced the volume of the fluid in the cavity and consequently the pressure within the cavity diminishes, so the final reading is not strictly true. This error is most important when examining small cysts completely surrounded by bone.

FIG. 1.—Manometer for measuring intracystic pressure.

A method was evolved in which the final reading was of that pressure required to prevent egress of fluid from the cyst. This method of applying counter-pressure effectively overcomes the tendency to inaccurate recording which might be due to blockage of the cannula by the semi-solid nature of the cyst fluid.

Description of apparatus.—A Greenfield's pattern spinal cannula is connected by 12 in. of narrow pressure tubing to the reservoir of the first manometer. The vertical limb of this manometer is made so that it is of very narrow bore in its lower part. This capillary portion is provided with a fixed mark. The level of this mark is made to correspond exactly to the vertical height of the tip of a horizontal rod which is fixed rigidly to the manometer. A spirit level is fixed to this rod. (Error would be introduced if there was a difference in vertical height between the manometer and the cyst cavity, owing to a siphon effect (fig. 1).)

The upper end of the vertical limb is connected by rubber tubing to an enclosed space above the reservoir of a second manometer. This space is also connected to a sphygmomanometer bulb, an air reservoir of at least 500 c.c. being included in the system in order that even pressure variations can be exerted by the rubber bulb.

Operation.—A sterile technique is adopted when using the apparatus, the cannula and pressure tubing being boiled and filled with sterile water.

The apparatus is held next to the patient at the level of the cyst, reference being made to the spirit level provided on the horizontal arm.

The cannula is first introduced into the cyst cavity with its tap in the closed position, and held to cause as little tension on the surrounding tissues as possible. The tap is then turned to connect the cyst cavity with the first manometer. Intracystic pressure will cause water to rise in the limb of the manometer. Air pressure is then applied to the surface of the water in this limb until the water is returned to, and maintained at, its original level. The air pressure needed to prevent egress of fluid from the cyst cavity is then noted by recording the water levels in the second manometer.

This reading represents the hydrostatic pressure within the cyst. Correction can be made for the volume of the portion of cannula which is inserted within the cyst cavity.

SUMMARY OF INTRACYSTIC PRESSURES FOUND IN A SERIES

Dental cysts

Highest recorded pressure	95.0 cm. water
Lowest recorded pressure	56.6 cm. water
Average pressure in 51 cases (to nearest whole number)	70 cm. water

Dentigerous cysts

Highest recorded pressure	94.7 cm. water
Lowest recorded pressure	22.5 cm. water
Average pressure in 9 cases (to nearest whole number)	65 cm. water

Adamantinoma

3 cases (1)	10.0 cm. water
(2)	12.0 cm. water
(3)	8.5 cm. water

Developmental cyst—premaxilla

One case—Recorded pressure	—87.5 cm. water
----------------------------	-----------------

This series of cases is too small to draw any significant conclusions, but the following points were noted:

- (1) The intracystic pressures fall within similar limits, whether the cyst, either dental or dentigerous, was large or small, or whether the patient was young or old.
- (2) Similar pressures were recorded in dental and dentigerous cysts.
- (3) The pressures in the three adamantinomata were much lower than those found in other types of cyst.

Variation of Cyst Pressure with Cardiac Pulse

It was noticed in several cases that the water level in the first manometer varied slightly with the cardiac pulse. Using a cannula and capillary tube of much larger diameter than usual in order to reduce the fluid inertia of the system, an attempt was made to assess the intracystic pressure differences due to the cardiac pulse.

Fluctuations in the first manometer limb were observed and readings were taken of the counter-pressure required to return the fluid level: (1) To the original level at maximum displacement of the fluid column; (2) to the level at minimum displacement.

In the three cases tested, the average pressure difference between the displacement levels was 4.5 cm. water. This figure will be inaccurate, erring on the low side of the true figure, owing to the inherently high fluid inertia of the system when recording such relatively rapid changes of pressure.

DISCUSSION

The foregoing experiments serve to confirm that positive fluid pressure exists within cystic cavities. The pressures recorded are all above capillary blood-pressure which Hill gives as about 3.5 cm. of water. (Starling states that capillary pressure can often be as high as 10 cm. water.)

It is obvious that if this full intracystic pressure was exerted upon the surrounding capillary bed, the walls of the capillaries would collapse resulting in cessation of the local circulation of blood. There may in fact be a slight compression of the surrounding capillaries, producing a slight ischaemia. This may be a factor in the pressure atrophy of the surrounding bone.

In some cysts it is possible to find degenerating cells close to a capillary. Such cases are not easy to explain on the grounds that the degeneration is caused by the cells being too far removed from a blood supply unless that blood supply itself is inadequate. Local ischaemia due to abnormal pressure of the cyst may hasten the degeneration of the cells of a cyst lining.

It is likely, however, that the main bulk of the cystic pressure is borne by its own epithelial and fibrous walls, in a similar manner to the way in which blood-vessels carry a positive pressure.

In a study of intracranial pressure O'Connell (1943) demonstrated an experiment to show that variations in pressure were imperfectly transmitted through a system which incorporated a ventricular cannula of 2 mm. internal diameter when the rate of variation was about that of the cardiac rhythm. When a lumbar-puncture needle of small bore was used (0.8 mm. bore) the inaccuracy was very pronounced, though slow variations (four variations per minute) can be recorded accurately through a system of such narrow bore. This consideration is only of importance when measuring variations of intracystic pressure with the cardiac pulse.

Manometer.—A simple direct manometer was not considered sufficiently accurate to measure intracystic pressure, owing to the fact that fluid must flow out from the cyst cavity in order to cause the manometer to register. This egress of fluid slightly reduced the volume of the fluid in the cavity and consequently the pressure within the cavity diminishes, so the final reading is not strictly true. This error is most important when examining small cysts completely surrounded by bone.

FIG. 1.—Manometer for measuring intracystic pressure.

A method was evolved in which the final reading was of that pressure required to prevent egress of fluid from the cyst. This method of applying counter-pressure effectively overcomes the tendency to inaccurate recording which might be due to blockage of the cannula by the semi-solid nature of the cyst fluid.

Description of apparatus.—A Greenfield's pattern spinal cannula is connected by 12 in. of narrow pressure tubing to the reservoir of the first manometer. The vertical limb of this manometer is made so that it is of very narrow bore in its lower part. This capillary portion is provided with a fixed mark. The level of this mark is made to correspond exactly to the vertical height of the tip of a horizontal rod which is fixed rigidly to the manometer. A spirit level is fixed to this rod. (Error would be introduced if there was a difference in vertical height between the manometer and the cyst cavity, owing to a siphon effect (fig. 1).)

The upper end of the vertical limb is connected by rubber tubing to an enclosed space above the reservoir of a second manometer. This space is also connected to a sphygmomanometer bulb, an air reservoir of at least 500 c.c. being included in the system in order that even pressure variations can be exerted by the rubber bulb.

Operation.—A sterile technique is adopted when using the apparatus, the cannula and pressure tubing being boiled and filled with sterile water.

The apparatus is held next to the patient at the level of the cyst, reference being made to the spirit level provided on the horizontal arm.

The cannula is first introduced into the cyst cavity with its tap in the closed position, and held to cause as little tension on the surrounding tissues as possible. The tap is then turned to connect the cyst cavity with the first manometer. Intracystic pressure will cause water to rise in the limb of the manometer. Air pressure is then applied to the surface of the water in this limb until the water is returned to, and maintained at, its original level. The air pressure needed to prevent egress of fluid from the cyst cavity is then noted by recording the water levels in the second manometer.

This reading represents the hydrostatic pressure within the cyst. Correction can be made for the volume of the portion of cannula which is inserted within the cyst cavity.

SUMMARY OF INTRACYSTIC PRESSURES FOUND IN A SERIES

Dental cysts

Highest recorded pressure	95.0 cm. water
Lowest recorded pressure	56.6 cm. water
Average pressure in 51 cases (to nearest whole number)	70 cm. water

Dentigerous cysts

Highest recorded pressure	94.7 cm. water
Lowest recorded pressure	22.5 cm. water
Average pressure in 9 cases (to nearest whole number)	65 cm. water

Adamantinoma

3 cases (1) 10.0 cm. water
(2) 12.0 cm. water
(3) 8.5 cm. water

Developmental cyst—premaxilla

One case—Recorded pressure—87.5 cm. water

This series of cases is too small to draw any significant conclusions, but the following points were noted:

- (1) The intracystic pressures fall within similar limits, whether the cyst, either dental or dentigerous, was large or small, or whether the patient was young or old.
- (2) Similar pressures were recorded in dental and dentigerous cysts.
- (3) The pressures in the three adamantinomata were much lower than those found in other types of cyst.

Variation of Cyst Pressure with Cardiac Pulse

It was noticed in several cases that the water level in the first manometer varied slightly with the cardiac pulse. Using a cannula and capillary tube of much larger diameter than usual in order to reduce the fluid inertia of the system, an attempt was made to assess the intracystic pressure differences due to the cardiac pulse.

Fluctuations in the first manometer limb were observed and readings were taken of the counter-pressure required to return the fluid level: (1) To the original level at maximum displacement of the fluid column; (2) to the level at minimum displacement.

In the three cases tested, the average pressure difference between the displacement levels was 4.5 cm. water. This figure will be inaccurate, erring on the low side of the true figure, owing to the inherently high fluid inertia of the system when recording such relatively rapid changes of pressure.

DISCUSSION

The foregoing experiments serve to confirm that positive fluid pressure exists within cystic cavities. The pressures recorded are all above capillary blood-pressure which Hill gives as about 3.5 cm. of water. (Starling states that capillary pressure can often be as high as 10 cm. water.)

It is obvious that if this full intracystic pressure was exerted upon the surrounding capillary bed, the walls of the capillaries would collapse resulting in cessation of the local circulation of blood. There may in fact be a slight compression of the surrounding capillaries, producing a slight ischæmia. This may be a factor in the pressure atrophy of the surrounding bone.

In some cysts it is possible to find degenerating cells close to a capillary. Such cases are not easy to explain on the grounds that the degeneration is caused by the cells being too far removed from a blood supply unless that blood supply itself is inadequate. Local ischæmia due to abnormal pressure of the cyst may hasten the degeneration of the cells of a cyst lining.

It is likely, however, that the main bulk of the cystic pressure is borne by its own epithelial and fibrous walls, in a similar manner to the way in which blood-vessels carry a positive pressure.

In a study of intracranial pressure O'Connell (1943) demonstrated an experiment to show that variations in pressure were imperfectly transmitted through a system which incorporated a ventricular cannula of 2 mm. internal diameter when the rate of variation was about that of the cardiac rhythm. When a lumbar-puncture needle of small bore was used (0.8 mm. bore) the inaccuracy was very pronounced, though slow variations (four variations per minute) can be recorded accurately through a system of such narrow bore. This consideration is only of importance when measuring variations of intracystic pressure with the cardiac pulse.

Manometer.—A simple direct manometer was not considered sufficiently accurate to measure intracystic pressure, owing to the fact that fluid must flow out from the cyst cavity in order to cause the manometer to register. This egress of fluid slightly reduced the volume of the fluid in the cavity and consequently the pressure within the cavity diminishes, so the final reading is not strictly true. This error is most important when examining small cysts completely surrounded by bone.

FIG. 1.—Manometer for measuring intracystic pressure.

A method was evolved in which the final reading was of that pressure required to prevent egress of fluid from the cyst. This method of applying counter-pressure effectively overcomes the tendency to inaccurate recording which might be due to blockage of the cannula by the semi-solid nature of the cyst fluid.

Description of apparatus.—A Greenfield's pattern spinal cannula is connected by 12 in. of narrow pressure tubing to the reservoir of the first manometer. The vertical limb of this manometer is made so that it is of very narrow bore in its lower part. This capillary portion is provided with a fixed mark. The level of this mark is made to correspond exactly to the vertical height of the tip of a horizontal rod which is fixed rigidly to the manometer. A spirit level is fixed to this rod. (Error would be introduced if there was a difference in vertical height between the manometer and the cyst cavity, owing to a siphon effect (fig. 1).)

The upper end of the vertical limb is connected by rubber tubing to an enclosed space above the reservoir of a second manometer. This space is also connected to a sphygmomanometer bulb, an air reservoir of at least 500 c.c. being included in the system in order that even pressure variations can be exerted by the rubber bulb.

Operation.—A sterile technique is adopted when using the apparatus, the cannula and pressure tubing being boiled and filled with sterile water.

The apparatus is held next to the patient at the level of the cyst, reference being made to the spirit level provided on the horizontal arm.

Description of osmometer.—Two brass cylinders are provided with flanges which are ground together to have a perfectly flush fit. The cylinders are held on a hinged clamp so that they may be swung apart or brought tightly together. The chamber in each cylinder is slightly sloping upward away from the face of the flange and is accurately machined to be of equal volume with the other chamber. At the base of each cylinder is a narrow inlet tube leading to a small tap provided with an attachment for a record syringe (figs. 2 and 3).

A vertical glass capillary tube leads out from the uppermost point in each chamber and a horizontal mark is provided at the same level in each tube. The design is such that liquids introduced through the inlets at the base of each chamber fill the chamber and rise into the capillary tubes without the inclusion of air bubbles. The inlet tubes are also directed so that the incoming fluid tends to flush over the face of the flanges, so bringing it into immediate intimate contact with any membrane that is placed over the face of the flange.

FIG. 3.—Osmometer with cylinders apart ready for reception of semipermeable membrane.

FIG. 2.—Diagram of osmometer used in the experiments.

A fine nickel gauze screen is let into the mouth of each chamber. This ensures that any membrane clamped between the cylinders will be supported firmly and atraumatically and it will prevent bulging or bursting of the membrane if an excessive pressure is applied to one side of it.

An extra manometer reservoir, provided at the side of the apparatus, is connected to the top of one of the vertical capillary tubes by rubber tubing. By raising or lowering this reservoir (usually filled with oil of known specific gravity) a counter-pressure can be applied to the surface of the fluid in the capillary tube. The reservoir can be moved up or down a vertical rod, this rod being supplied with an extension piece to enable the reservoir to be held at a greater height if necessary.

Operation of apparatus.—A membrane of unknown permeable qualities may be clamped between the two cylinders, and fluids of known character introduced simultaneously into the chambers on either side of it by injection with Record syringes. The two liquids are levelled to the marks on the capillary tubes and the taps closed.

The system then consists of two equal volumes of fluids separated by the membrane under examination.

Those studying pathology in relation to the orthodontic traction state that the pressures used in orthodontic appliances must not cause a tooth to apply a pressure on its surrounding structures more than capillary pressure, otherwise necrosis of bone may result instead of physiological absorption. Necrosis of bone is not observed in relation to cyst growth. It would seem that the actual expansive pressure that the cyst exerts on the surrounding tissues is likely to be very small, i.e. below 3.5 cm. water.

Intracystic pressures which have been recorded can be considered as high in comparison with capillary blood-pressure; they are comparable to pressures found in arterioles. The only arteries of any large size that are found in relation to cysts of the jaws are the inferior dental vessels and sometimes a fairly large vessel is encountered on the deep posterior aspect of maxillary cysts.

No opportunity has yet presented itself for the study of pressure in enclosed hamatomata. No "bone cysts" have been investigated, although this type of fluid collection will be studied if the opportunity arises, since it may lead to a better knowledge of the pressures that may be expected in passive fluid collections in the tissues. Such study would provide a clearer idea of the part played by simple hydrostatic effects (i.e. the pressures due to blood-pressure, muscle-tone, posture) or cyst pressure.

The positive pressure remains much the same whether the cyst is small or large, in fact this pressure is maintained even when the cyst wall is just beneath the surface of the oral or nasal mucous membrane. An investigation was therefore carried out to determine whether there were other than purely hydrostatic factors maintaining the positive pressure.

THE OSMOTIC FACTOR

It has seemed most likely that the factor causing the pressure within a cyst to be raised above the pressure of the surrounding tissues would be a difference in osmotic tension. This was suggested by James (1926) and has been mentioned from time to time since he published his experiments in connexion with cysts. Thoma mentions that it is possible that osmosis maintains intracystic pressure, and in 1939 Tratman wrote a paper suggesting that diffusion of fluids influenced cyst growth. In fact, he appears to have performed the only experimental work in the dental field to verify this theory. His experiments consisted of aspirating the contents of four cysts and observing that at the end of twenty-four hours the cyst cavities had again become distended with fluid. This interesting observation, which he recorded with care, suggests that the refilling of the cysts occurred by osmosis. However, any fluid remaining in the cavity after the original aspiration would need to have a fairly high osmotic tension, above that of the surrounding tissues, otherwise the incoming fluid from the tissues would bring about an osmotic balance before the cavity had completely refilled. It may therefore be a simple transudation of fluid from the surrounding tissues.

In other fields it is well to note that Schalyt (1930) suggested that the development of ovarian cysts was dependent on secretory activity and disturbance in osmotic equilibrium of the ovarian tissues. Gardner (1932) showed that the contents of old subdural cysts were of higher osmotic tensions than the surrounding cerebrospinal fluid and he suggested that the increase in size of these cysts was due to osmosis.

Osmotic pressure of a solution depends upon the number of submicroscopic particles in solution or colloid suspension. Animal tissues are pervious to water and dissolved crystalloids but are impervious to colloids except under certain circumstances. It will be seen that if a large molecule should break down into two simpler molecules, the number of particles dispersed in solution will be increased and the osmotic tension will rise, independent of the chemical nature of the molecule. If substances such as cytoplasm, nucleoprotein and other complexes associated with vital cells should be broken down to simpler molecules, as would be expected in a degenerative process in the tissues, then the osmotic tension of the resulting product would rise. If the products were surrounded by a membrane permeable to the solvent and impermeable to the solute then the pressure within that membrane would rise. This phenomenon may account, at least in part, for the presence and maintenance of positive intracystic pressure.

With this in view, an investigation was proposed: (a) To examine the epithelial linings of cysts and to determine whether they act as semipermeable membranes; (b) to examine some chemical and physical properties of cyst fluid.

Experimental

An apparatus has been devised to examine the permeability of freshly dissected cyst membrane.

The apparatus was also designed to study the osmotic tension of cyst fluid, blood and tissue fluids, and to compare the osmotic tensions of fluids directly through actual cyst membranes and through artificially prepared membranes.

cyst. This will exert a pressure dependent upon the hydrostatic pressure within the surrounding vessels and its effect may be likened to that of a sphygmomanometer cuff. Then there is the effect of "tissue pressure" mentioned by Starling, which is the result of the tone of the living tissues and amounts to only a few millimetres of water. There is also the effect of the osmotic differences between cyst fluid and blood and the intervening tissue fluid which is in common relationship to both.

It has been shown that the osmotic pressure of cyst fluid varies over relatively small limits, which variations would be insufficient to account for the wide variations of pressure actually found within cysts. It has also been demonstrated that variations in fluid pressure due to the cardiac pulse (approximately 5 cm. water) are greater than the difference in osmotic pressure between blood and cyst fluid, so that it would seem that the main factor influencing positive intracystic pressure is the hydrostatic factor due to the surrounding vascular network.

If, for instance, a small semipermeable sac is partly filled with a hypertonic solution and it is immersed a few inches beneath the surface of some water, then, so long as the sac is not completely filled by its contained fluid, the hydrostatic pressure within the sac will be the same as that of the surrounding water. Only when the sac becomes filled with fluid and the walls become taut does the pressure within the sac rise above that of the surrounding water. Then the pressure within it is the sum of the difference in osmotic pressure between the fluid and water, and the pressure due to the depth it is immersed in that water.

Hydrostatic pressure in the larger capillaries and arterioles varies between 10 cm. and 100 cm. of water (Starling).

If hydrostatic equilibrium is attained between the cyst and the surrounding vascular and tissue pressure, there is always the tendency to slightly greater pressure within the cyst due to the osmotic imbalance and it is likely that this slight but ever-present osmotic pressure is responsible for the increase in size of the cyst.

If the osmotic imbalance is always present in the cyst fluid, despite the fact that the cyst grows larger and that there is always a tendency to bring about isotonicity, then it follows that there must be a continual supply of substances maintaining the hypertonicity.

It has been previously mentioned that degeneration of tissues is likely to produce a liberation of substances of lower molecular weight than those which make up vital tissue. Analysis of the proteins involved in vital tissue is itself a vast study, and one about which knowledge is yet in its infancy. Suffice it to say that molecular weights as high as 300,000 have been calculated for certain tissue proteins. An analysis of cyst fluid shows that it is made up largely of simple proteins with molecular weights of about 30,000. Thus it is likely that the breakdown of complex tissue proteins into a larger number of molecules of simple proteins is responsible for the raised colloid osmotic pressure found in cyst fluid.

I wish to express my special thanks to Mr. Rainsford Mowlem, Mr. B. W. Fickling and Dr. A. B. MacGregor at the Plastic and Jaw Unit, Hill End Hospital, for their patience and assistance.

The behaviour of the membrane can be assessed by observation of the fluid levels in the capillary tubes. A rise of level in one tube would be accompanied by a depression in the other if an osmotic transference takes place through the membrane.

The difference of osmotic tension between the two fluids, if the membrane is known semipermeable membrane, can be measured by applying a counter-pressure so that the levels in the two capillary tubes are kept the same so that equal volumes and the original concentrations of solutions are maintained. An oil manometer is used, oil not being miscible with the fluids under investigation, and, being of a small specific gravity, oil gives a good range of measurement for small differences in osmotic pressure.

First experiment.—Experiments were performed using freshly dissected cyst wall from 12 cases of dental cysts and 6 cases of dentigerous cysts. The wall was placed between the manometer cylinders and Ringer's solution introduced on one side. Ringer's solution to which had been added 5% egg albumin was introduced on the other side.

In all cases fluid passed through the membrane to the side containing the dissolved albumin. Transference of fluid continued until the capillary tube overflowed on one side and the fluid level disappeared in the other tube.

Second experiment.—A group of tests was made using direct comparisons of whole blood and cyst fluid taken simultaneously from the same patient. A known semipermeable membrane of cellophane was used.

In 11 cases of uninfected dental and dentigerous cysts: 4 cases showed no registrable osmotic difference, 7 cases showed cyst fluid to be of slightly higher colloid osmotic pressure than whole blood.

In these last 7 cases an average osmotic pressure difference of 3.7 cm. of oil (sp. gr. 0.8) was recorded, which represents an average pressure difference of 2.96 cm. of water.

Third experiment.—In 5 cases, the freshly dissected cyst membrane was placed in the osmometer and the aspirated cyst fluid from the same patient introduced on the epithelial side of it while the patient's blood was introduced on the other side.

In one case only (from a small dental cyst) was there a rise on the side of the cyst fluid (0.8 cm). The other 4 cases showed no change in level.

Summary of Experiments

- A. I. A manometer has been described for accurate measurement of hydrostatic pressure within closed fluid-filled cavities within the body.
- II. Intracystic fluid pressures have been measured in a series of cases of uninfected cysts before surgical interference.
- III. Pressures ranging between 8.5 cm. of water and 95.0 cm. of water have been recorded.
- IV. Lower pressures were noted in adamantinoma.
- V. Blood-pressure has a direct effect on intracystic pressure.
- B. I. An osmometer suitable for examination of the permeability of cyst wall and for comparing osmotic pressures of cyst fluid and blood has been described.
- II. It has been shown that freshly dissected cyst wall behaves as a membrane impermeable to a colloid (albumin) and permeable to crystalloids and water.
- III. Osmotic tensions of cyst fluid and blood from the same patient have been measured and compared directly. In some cases the osmotic tension of cyst fluid was found to be greater than that of the blood. In other cases no measurable difference in tension was noted. In no case has the cyst fluid shown a lower osmotic tension than that of blood.

DISCUSSION

The results of the foregoing experiments support the theory that positive hydrostatic pressure within cysts is a factor influencing their growth. The fact that the exteriorization of a cyst cavity effectively checks further growth is strong clinical evidence in favour of the theory, although this does not rule out the possibility of the effect of accumulated products of degeneration of the tissues stimulating epithelial cells to proliferate.

The experiments indicate that the cause and maintenance of positive cyst pressure in dental and dentigerous cysts are likely to be related to the osmotic tension of the cyst fluid.

The positive pressure within a cyst is liable to be the result of several forces. First, there is the effect of pressure of the surrounding vascular network within the walls of the

Kostecka's Osteotomy for the Correction of the Prognathous Mandible¹

By C. BOWDLER HENRY, L.D.S.Eng., M.R.C.S., L.R.C.P.

I SHOWED this patient (M. K.) before the Odontological Section in April 1946, nine weeks after operation, as an example of Kostecka's closed method of bilateral osteotomy of the rami for the correction of mandibular prognathism. I had followed Kostecka's technique precisely as to the surgery, but I had varied the form of fixation. Kostecka favours fixing the floating mandible by ligating the upper and lower teeth together with orthodontic wires applied after cutting through the rami. The operation is thus extended by a somewhat fiddling procedure which would also have manifold disadvantages in cases where several teeth were missing. It seemed to me, when considering this operation, that the duration of operation could be markedly reduced and a more positive result, according to pre-operative planning, would be obtained if cast metal splints with a simple rapid interlocking device were to be cemented on to the upper and lower teeth previous to operation. I modified Kostecka's technique accordingly.

This patient, therefore, when shown originally before the Section, was still splinted and the sites of puncture for the needle and saw were clearly visible. Immobility was maintained for six weeks after which progressive function was allowed and within the next fortnight he was masticating ordinary food. The splints were left in situ so as to discipline the mandible for a further period of ten weeks. After they were removed the final occlusion was established by slight grinding of the cusps. Mastication became normal and there was no limitation of opening.

In view of the novelty of the operation and certain adverse criticism when the case was shown, I offered to keep the Section informed as to progress. Accordingly, the patient was demonstrated again twelve months later (Clinical Meeting, Odontological Section, April 1947) as a clinically completed case, when the functional and æsthetic results were seen to be entirely satisfactory. This demonstration of the final skiagrams on April 26, 1948, concludes the case.

The Million-Volt X-Ray Plant — Its Development and Application

By G. S. INNES, B.Sc., A.M.I.E.E., A.Inst.P.

THIS note, which gives a short history of the million-volt X-ray equipment at St. Bartholomew's Hospital, and some of the physical advantages we believe million-volt X-rays have over those generated at 200-250 kilovolts, is only intended to indicate the general background conditions under which the clinical results reported in the two following papers were obtained.

History of the plant.—It was in the year 1934 that the Cancer Committee of St. Bartholomew's Hospital, with the generous financial backing of Mrs. Meyer Sassoon, contracted with Messrs. Metropolitan Vickers Electrical Company for the supply and installation of a continuously evacuated X-ray tube, together with the necessary High Voltage D.C. Generators, to operate at a guaranteed voltage of 600,000 volts, with the proviso that an attempt would be made to operate continuously at one million volts. At that time, the High Voltage and Vacuum Sections of Metropolitan Vickers Research Department, under the direction of Dr. Allibone and Mr. Bancroft [1, 2], had designed, built, installed and had operated for some eighteen months, two 200,000 volt continuously evacuated X-ray tubes at Sheffield Royal Infirmary. These were the first demountable tubes to be used for radiotherapy in this country, and the accomplishment was in no small part due to the encouragement and enthusiasm shown by Dr. Ellis, then Director of the Therapy Department at Sheffield.

Tube.—From 200 kV to 1,000 kV was a considerable step, involving many unknown factors. In the short time available for experimentation, an attempt was made to

find how far the behaviour of supervoltage tubes could be predicted from theoretical calculations [3]. From these researches grew the design of the equipment as it was installed in St. Bartholomew's Hospital in the second half of 1936 [3, 4 and 5] (fig. 1). The exploded view of the equipment shows that the tube spans the treatment room, projecting on the left into the room which houses the 500 kV Positive D.C. Generator and on the right into the Negative Generator room.

FIG. 1.—Perspective view of 1,000 kV X-ray tube installation.

The vacuum envelope of the tube proper comprises a 14 in. diameter steel cylinder

An Appliance for Exerting Pressure Upon a Skin Graft of the Lip or Cheek

By J. F. LOCKWOOD, M.R.C.S., L.R.C.P., L.D.S.Eng.

THE application of a pressure dressing to a skin graft of the lip or cheek is made difficult by the mobility of the part, and, in cases where teeth have been lost, by the absence of anything against which pressure may be exerted.

The use of a suitable acrylic appliance in such cases facilitates immobilization of the part and the maintenance of firm and consistent pressure upon the graft.

FIG. 1.

FIG. 2.

Such an appliance consists of two pieces: an intra-oral part made to fit the area normally covered by any necessary denture—upper or lower, as may be convenient—and having a smooth labial or buccal face fitting the inner aspect of the lip or cheek; and an external part in the form of a cupped plate made to overlie the area to be grafted. The two pieces are articulated by means of square rod and tubing, the former being threaded to take a lock nut (fig. 1).

At operation the graft is inserted, the intra-oral part of the appliance fitted, the graft covered with a flavine and paraffin pack, and the external part of the appliance screwed home (fig. 2).

The appliance illustrated was worn with moderate comfort and without adjustment for twenty-two days. On its removal the graft proved to be in excellent condition.

the section of the treatment room floor under the tube. These two movements, rotation of the applicator cylinder and movement of the floor, provide positioning movements which in practice are found to be as simple and satisfactory as those of the normal 200 kV unit.

Generators and control.—The two high-voltage D.C. generators, employing the Cockroft voltage multiplier circuit, are fitted with four 250 kV continuously evacuated rectifiers each. The generators on test generated a total voltage of 1.5 million volts and produced a thirty-foot-long spark in air. The kilovoltage, applied to the tube from these generators, is in the hospital indicated on the control desk by means of direct reading resistance voltmeters. The result is simple and accurate control conditions—tube kilovoltage and X-ray monitor output and/or dose given.

Protection.—The treatment room and generator rooms are surrounded by barytes brick walls, which provide such a degree of protection outside these rooms that X-ray films can with safety be kept in the department for many years. In the treatment room with the shutter closed, the protection is such that with the tube operating at one million volts and 5 kilowatts, the leakage intensity anywhere in the treatment room is not greater than one-half of tolerance.

Operation.—The tube, as installed in 1936, was composed of the following electrodes: (a) The steel vacuum envelope which was earthed; (b) a six-element filament assembly which was supported by a steel cathode support tube bolted to the end of the tube negative porcelain and connected to the H.V. output terminal of the negative generator; and (c) a gold disc target supported by a steel target support tube, bolted to the tube positive porcelain and connected to the positive generator output terminal.

One hour after the final erection and evacuation of the untried tube at the hospital, a voltage of 700 kV with a load current of 3 ma. was attained with perfect stability. On attempting to raise the voltage applied to the negative end of the tube above 350 kV, the electrical stresses on the steel cathode support tube became so great that the support tube acted as an electron emitter and many milliamperes of electrons flowed from it to the tube envelope. The calculated electrical gradients at this voltage were much below those at which this phenomenon was expected. This was one of the unknown factors, the possibility of which had been envisaged. The low voltage onset of field currents was caused by incalculable high gradients due to microscopic roughness of the electrodes, vitiating simple theory. Thereon, it was decided that the equipment would be used for treatments at 700 kV, while modifications to the tube were carried out during the week-ends. This was rather a harassing process since the equipment had to be in operation first thing on Monday mornings at 700 kV without fail.

After many modifications the tube, as it is now (fig. 2A), was put into operation, in 1939, on patients at one million volts 4 to 5 ma. It will be seen that the tube has become a multiple acceleration tube, in which the electrons are accelerated from the cathode (k) through three nozzles in four stages of 250 kV to the target (f), i.e. from 500 kV negative to 500 kV positive. The radial tube gradients are catered for by the intermediate thin steel tube electrodes (l, n) connected to the mid-potential points on each generator.

Reliability and maintenance.—The vacuum pumping plants on the tube and rectifiers have operated day and night continuously since the plant was installed, some 95,000 hours, equivalent on the electric motors to about three million car miles. The oil in the diffusion and rotary vacuum pumps has not been changed since 1937 and, except for some distillation of oil from the first diffusion pump, necessitating, after seven years, extraction of excess oil from the O₂s, failures of the pumping plants have been rare and primarily caused by brushes sticking in the rotary pump driving motors.

The longest single period of breakdown, since the plant has been operating at a million volts, has been one afternoon. Occasionally there has been a stoppage of one and a half hours while a rectifier filament is replaced. These rectifier filaments have been replaced normally about every 1,250 hours, while the rectifier stacks have been dismantled, cleaned, and the electrodes burnished

with bolted-on insulator on either end; the whole being evacuated by two 250 litre per second pumping plants. Round the portion of the tube envelope, spanning the treatment room, is a hollow steel cylinder filled with some eight tons of lead shot. This cylinder has one portal in it, and the cylinder being rotatable, it acts both as the protection and the X-ray shutter. In the "safe" or shutter shut position the portal points upwards into the lead block suspended above the centre of the tube (fig. 2A).

Surrounding the "lead" cylinder is the outer or "applicator" cylinder which carries the beam sweep lead protection, the control ionization chamber, the filters

FIG. 2A.—Million-volt X-ray tube. (Reproduced from *Brit. med. Bull.*, 1946, 4, 52.)

FIG. 2B.—Light-centring device. (Reproduced from "Supervoltage X-ray Therapy", by R. Phillips, London.)

and the beam limiting devices. The control ionization chamber is cable connected to an indicating instrument on the control desk, which gives both monitor dosage rate and monitor dose given. The "applicator" cylinder is rotatable, such that the angle of the X-ray beam emerging from the applicators can be varied from pointing vertically downwards, forward and upwards to 24° above horizontal (i.e. 114° rotation in all). Since the tube is some 30 feet long, overall, and weighs about 10 tons, adjustment of the patient to the tube is more easily accomplished by raising or lowering

The output from the tube operating at a million volts and 4.5 ma. is equivalent to that which would be obtained from 7 kilograms of radium under the same conditions and the beam wavelength is approaching that of gamma rays.

PHYSICAL ADVANTAGES

Depth dose.—The main physical advantage in operating with million-volt X-rays, when compared with the usual 250,000 volts X-rays, is the gain in depth dose; that is the dose at a depth relative to the dose at the surface. For comparison, consider the usual therapeutic conditions and our own, for a beam of 10×10 cm. and at 10 cm. depth.

The usual conditions are 250 kV, 1.5 mm. Cu H.V.L., 50 cm. F.S.D.

Our conditions are 1,000 kV, 9.3 mm. Cu H.V.L., 100 cm. F.S.D.

If we give an air dose of 100 r under each condition (fig. 3), the total dose at 10 cm.

10x10cm 50cm FSD FIELD 250kV 1.5mm Cu HVL

10x10cm 100cm FSD FIELD 1000kV 9.3mm Cu HVL

FIG. 3.—Composition of dose at depth, at 250 and 1,000 kV.

deep at 250 kV is 45.5 r and at a million 53 r, a gain with a million, but not a great one. However, the shorter the wavelength of the X-rays used, that is the higher the kilovoltage employed, the more forward becomes the scatter from the absorption processes. Therefore at 250 kV, there is considerably more scatter back to the surface than there is at a million. The result is that the surface doses are 133 r and 107 r respectively. This gives percentage depth doses, that is the doses at the depth as a percentage of the surface doses as 34.3 and 50% respectively, representing a gain of about 50% in the dose at the depth by employing million-volt X-rays.

Now consider how this happens apart from the effect of the large difference in surface backscatter. The dose at a depth can be regarded as being made up of three components (fig. 3); first, the direct or through dose, comprising the primary rays which penetrate right through the patient to the depth and are absorbed there; secondly, forward scattered rays, scattered from the part of the patient above the level of measurement; and thirdly, backscattered rays, scattered back from the part of the patient below the level of measurement.

At 250 kV the direct component at 10 cm. depth is only 15.5 r while at a million it is 32 r. This great difference is due to the higher penetration of the million volt rays. Not only this, but the direct component is nearly $\frac{2}{3}$ of the total dose at the depth at a million volts, whereas at 250 kV it is only approximately $\frac{1}{3}$. Therefore if the direct component

every 2,500 hours. Since the final modification to the tube in 1939, the tube has operated approximately 15,000 hours at a million volts and until the middle of 1947 it had not been dismantled. Then it was dismantled, primarily to alter one of the electrodes, so that a new type of target could be accommodated, and secondly for inspection, since a slight instability had appeared, which occasioned some inconvenience during the initial application of voltage every Monday morning. The only deterioration found was flaking of the surface of the nose of one of the intermediate electrodes, due to an occlusion of sand in the steel of the electrode. Tube filaments, of which there are six, now generally last for 1,000 hours each. The gold-faced target, on an average, has been replaced every 3,000–4,000 hours, not because it has been leaking, but because by that time the gold surface has become extremely rough.

At the commencement of the war, the department was closed for three months, but during the rest of the war, although the department lost its ceilings, windows and doors three times, and part of its roof another time, the plant functioned, providing that electrical and water supplies were available; sensitive relays and mechanisms damaged by concussion and vibration being temporarily locked in, by match sticks, until patients' treatments were completed for the day, whereon repairs were carried out. During the nine years of operation at a million volts, the expenditure on maintenance material, and replacements used on the plant has been under £200.

Clinical intention.—The intention of the clinical investigation was to find whether there was an improvement in the relative lethal effectiveness of X-rays on malignant cells when compared with normal cells as the wavelength of the radiations was reduced, other factors being kept the same. It soon became obvious, during the initial period of operation at 700 kV, that this simple test was impossible of accomplishment, since there were so many complicating ancillary factors, which automatically appeared with change in wavelength; for example, change in depth dose altering the dose distribution in the normal tissue surrounding the malignant cells, and changing to some unknown extent the indirect action on the tumour. Therefore it was decided to use the tube under its best conditions, with all the benefits it gave from the physical aspect, and from the clinical results to try to assess the overall change in lesion response and whether it could be attributed directly to change in wavelength.

X-ray beam limitation.—From our early experience with applicators at 700 kV, 60 cm. F.S.D., it was apparent that at a million volts and one metre F.S.D., applicators would be too heavy to handle. An adjustable diaphragm was constructed (fig. 2B), fitted with a light beam device which indicates the X-ray field size, shape and position. This diaphragm makes available any field size from 4×5 cm. to 40×40 cm., in centimetre steps, some 450 different field sizes and provides no limitation as far as field planning is concerned. The one disadvantage of this diaphragm is that, owing to its size, it is located at 45 cm. F.S.D., and with the existing focal spot size of 2.5 cm. diameter, a considerable "inumbra" and penumbra is cast on the fields at 100 cm., the normal operating F.S.D. It is hoped that when manufacturing facilities are available it will be possible, by reducing the focal spot and by adding secondary diaphragms, to remove these disadvantages.

Treatment Conditions—

1937–39: 700 kV, 5 ma., 60 cm. F.S.D., filter 3.2 mm. Fe, 1.5 mm. Al, 2 mm. Pb, 2.4 mm. Sn, 0.5 mm. Cu, 1 mm. Al, H.V.L. 7.6 mm. Cu; Output 50 r/min. with B.S. for 10×10 cm. field.

1939–48: 1,000 kV, 4.5 ma., 100 cm. F.S.D., filter 4.2 mm. Fe, 2 mm. Al, 2 mm. Pb, 2 mm. Al, H.V.L. 9.3 mm. Cu; Output 40 r/min. with B.S. for 10×10 cm. field.

During this later period a few cases were treated at 1,000 kV 70 cm. F.S.D., filter 4.2 mm. Fe, 4 mm. Al, H.V.L. 7.6 mm. Cu with a dosage rate of 200 r/min. This was done to see whether there was any advantage in operating at high dosage rate levels [6, 7], but the complication of varying other physical factors to obtain the necessary high dosage rate made the results difficult to assess. It is hoped with the modified target to operate at 12 kW, when the necessary high intensity will be available at 9.3 mm. Cu H.V.L.

The output from the tube operating at a million volts and 4.5 ma. is equivalent to that which would be obtained from 7 kilograms of radium under the same conditions and the beam wavelength is approaching that of gamma rays.

PHYSICAL ADVANTAGES

Depth dose.—The main physical advantage in operating with million-volt X-rays, when compared with the usual 250,000 volts X-rays, is the gain in depth dose; that is the dose at a depth relative to the dose at the surface. For comparison, consider the usual therapeutic conditions and our own, for a beam of 10×10 cm. and at 10 cm. depth.

The usual conditions are 250 kV, 1.5 mm. Cu H.V.L., 50 cm. F.S.D.

Our conditions are 1,000 kV, 9.3 mm. Cu H.V.L., 100 cm. F.S.D.

If we give an *air* dose of 100 r under each condition (fig. 3), the total dose at 10 cm.

FIG. 3.—Composition of dose at depth, at 250 and 1,000 kV.

deep at 250 kV is 45.5 r and at a million 53 r, a gain with a million, but not a great one. However, the shorter the wavelength of the X-rays used, that is the higher the kilovoltage employed, the more forward becomes the scatter from the absorption processes. Therefore at 250 kV, there is considerably more scatter back to the surface than there is at a million. The result is that the surface doses are 133 r and 107 r respectively. This gives percentage depth doses, that is the doses at the depth as a percentage of the surface doses as 34.3 and 50% respectively, representing a gain of about 50% in the dose at the depth by employing million-volt X-rays.

Now consider how this happens apart from the effect of the large difference in surface backscatter. The dose at a depth can be regarded as being made up of three components (fig. 3); first, the direct or through dose, comprising the primary rays which penetrate right through the patient to the depth and are absorbed there; secondly, forward scattered rays, scattered from the part of the patient above the level of measurement; and thirdly, backscattered rays, scattered back from the part of the patient below the level of measurement.

At 250 kV the direct component at 10 cm. depth is only 15.5 r while at a million it is 32 r. This great difference is due to the higher penetration of the million volt rays. Not only this, but the direct component is nearly $\frac{2}{3}$ of the total dose at the depth at a million volts, whereas at 250 kV it is only approximately $\frac{1}{3}$. Therefore if the direct component

obtained by the employment of supervoltage X-rays, there are two other factors that should be mentioned.

Variation of transmission through body components.—Recently, we have made measurements of the transmission and scattering from fresh post-mortem specimens of various components of the human body. Considering here primarily the effect on X-ray beams of H.V.L. 1.5 mm. Cu and 9.3 mm. Cu (250 and 1,000 kV) we obtain the results shown in the second and third columns of fig. 6. The figures in the table

represent the ratio of the transmission through the specimens, compared with the transmission through the same thickness and shape of presswood which we see has the same transmission as water, muscle and brain tissue down to at least 0.15 mm. Cu H.V.L. Some of the results are rather surprising. The vertebra for instance at 250 kV only causes an excess loss of 5% while at a million it is 2%. Presumably this loss is low because there is really little dense bone in the vertebra. On the other hand ribs, skull and in particular femur, cast appreciable shadows across our 250 kV beams, while at a million volts the shadows are practically negligible.

It has long been realized that our isodose plans, as has been emphasized by Spiers [8, 9], make no allowance for these extra absorptions. Just how our results can be applied to this planning is not simple. From preliminary experiments it would appear that an approximate idea of the depth doses in the "shadows" can be obtained by

appreciably up to F equal to 100 cm., so as the surface of the nose of one of the intermediate percentage depth dose at a million volts will be electrode. Tube filaments, of which there the effect will be small. Investigating the scatter of a flat-faced target, on an average, has been at 10 cm. depth, they total 30 r and at a million volts

$\frac{1}{3}$ of their respective total doses at the depth. Therefore, three months, but during the in the amount of scatter will produce a greater effect on the floors three times, and part than it will at 1,000 kV. The scatter component at any one of the food water supplies were the volume of material irradiated, which for a fixed F.S.D. and time, whereon repairs are made, varies with the field size. Therefore alteration in the field size will increase the scatter and hence the depth dose much more than it will

volts. This means that at a million volts there will be very little loss in dose and whether with very small fields compared with the depth dose for medium and malignant while at 250 kV, as we all know, there is a very marked falling off in depth dose was re-

the small fields. Fig. 4 shows the very appreciable gain in the dose delivered to any depth at a million volts when compared with that delivered at 250 kV for the same surface dose

FIG. 4.

cases. It will be seen that the gain is maximum for the smallest fields at the greatest depths, e.g. for a 4×5 cm. field, the gain in the dose at 10 cm. depth is as high as 72%.

Opposed fields.—A common misconception is that with the increased depth doses obtained at a million volts, there will be a reduction in the effectiveness of treatment by opposed fields. That this is not the case is illustrated in fig. 5, in which the curves give the maximum separation between two opposed fields by tissue, up to which the dose at the centre of the tissue is at least equal to the skin dose. For a 5×5 cm. field at 250 kV this is 5.5 cm., while at a million volts it is 9.5 cm., a considerable gain in the permissible separation, making possible the treatment of a number of sites by the simple and accurate method of opposed fields. Further, in the treatment of cases like the œsophagus where the main dose is obtained by two opposed fields and the supplementing glancing fields pass through vital organs, the increased effectiveness

Presumably this loss is low because there is really little dense bone in the vertebra. On the other hand ribs, skull and in particular femur, cast appreciable shadows across our 250 kV beams, while at a million volts the shadows are practically negligible.

It has long been realized that our isodose plans, as has been emphasized by Spiers [8, 9], make no allowance for these extra absorptions. Just how our results can be applied to this planning is not simple. From preliminary experiments it would appear that an approximate idea of the depth doses in the "shadows" can be obtained by

multiplying our standard depth doses for water by the factors given in fig. 6 or 7.

The figures for lung were obtained with the lung aerated to a pressure representing the mean negative pressure it would be subjected to in the living body. Its absorption under these conditions makes it equivalent to half its own thickness of muscle tissue over the whole range of wavelengths investigated.

From these results it can be said that generally with million-volt X-rays our actual dose distributions in the patient are very nearly the same as those calculated

FIG. 7.—Relationship between the transmission through human body components and water, for different qualities of X-rays.

from our phantom isodoses irrespective of whether the beams have to pass through bones. On the other hand at 250 kV, if possible the beams should be routed away from bones, particularly of the compact type, in order to avoid an appreciable loss in depth dose, of unknown value, and also possible detrimental clinical effects on the irradiated bone by its relatively high absorption. Finally, it should be noted from comparison of columns one and two of fig. 6 that there is an appreciable reduction in the relative transmission of bone when the 250 kV tube is used with light filtration such as that produced by a H.V.L. of 1 mm. Cu, indicating that the maximum economical filtration should always be used.

IONIZATION LEVELS

Following the measurement of the transmission by different body components at various X-ray wavelengths, it was thought that there might be different ionization intensities in the superficial layers of the patient and near heavy absorbing media such as bone. These might be of clinical significance.

Ionization in the superficial surface layer.—A chamber of tissue equivalent walls, with a front wall $25\ \mu$ thick, was built into a presswood phantom (fig. 8). With the addition of tissue-equivalent material to the thin wall of the chamber, the ionization current in the chamber per r will indicate the ionization occurring in tissues just beyond the thickness of tissue above the chamber.

The two conditions investigated so far have been, as nearly as possible, those under which the skin reactions have been compared, namely:

250 kV, 1.85 mm. Cu H.V.L., 53 cm. F.S.D. with an 8×8 cm. field defined by a 50 cm. F.S.D. wooden-ended applicator, and 1,000 kV, 9.3 mm. Cu H.V.L., 100 cm. F.S.D. with an 8×8 cm. field defined by a diaphragm at approximately 45 cm. F.S.D.

In fig. 8 the ionization curves are plotted, in each case, as percentages of the peak ionization observed as the front wall of the chamber was thickened. At a million volts and the minimum front wall of 0.025 mm. thickness, the ionization was only 67% of the peak value which occurs with 1.0 mm. depth. However, the increase of ionization is rapid so that with 0.2 mm. depth the ionization is 90% of the peak value.

At 250 kV, however, the ionization is nearly at its peak with the minimum wall of 0.025 mm., reaching full saturation at 0.2 mm. depth. Not only this, but if the applicator end had been in contact with the chamber top surface, as it would have been

FIG. 8.—Ionization with depth in "tissue" as a percentage of peak ionization.

FIG. 9.—Effect of bone above chamber.

clinically, peak ionization would already have been attained, the applicator end acting as the saturator.

Therefore in the two clinical conditions compared, there is an appreciable difference in the level of ionization in the superficial layers and hence in the energy absorbed in these layers (under the physical conditions used, the relative energy absorption in tissue, per ion pair produced in air, only differs by some 3%). The clinical significance of this information will be indicated in Dr. Jones' paper.

Ionization near bone.—Since bone contains elements of medium atomic number, there is some photo-electric absorption with 250 kV X-rays, but very little with 1,000 kV rays. It was therefore expected that there would be a considerable difference under the two conditions in the ionization levels per r in the superficial tissues surrounding bony structures. To examine this, the thin wall chamber in its phantom was covered by 13 mm. of tissue-equivalent material and 1 mm. of bone. By traversing the bone through the tissue and observing the alteration in the ionization produced in the air of the chamber, we have an indication of the ionization produced in the tissue at a distance from the bone just greater than the thickness of tissue-equivalent material, intervening between the bone and the air of the ionization chamber.

At a million volts only 2% extra ionization could be detected and the effect of the bone on the surrounding tissue is therefore negligible. At 250 kV, however, the results as shown in fig. 9 indicate that the bone has a considerable effect on the level to which the superficial layers of tissue surrounding it are ionized. With between 13 mm. and 0.2 mm. of tissue between the bone and the chamber the ionization is constant, but as

the bone approaches closer to the chamber, the ionization current rises rapidly until with 0.025 mm. of intervening tissue the level is 72% above that with 0.2 mm. of intervening tissue. This means that tissue cells at this distance of 0.025 mm. from the bone receive 72% more ionization than that equivalent to the roentgen dose level estimated at that point. Extrapolating the curve it would appear that those tissue cells in contact with the bone probably receive as much as 130% excess ionization, while on the other hand the effect of the bone has disappeared in the tissues beyond 0.2 mm. from the bone.

It follows that at a million volts we need not worry about the increase in ionization in tissue around bone, as this is negligible, but at 250 kV we must remember that the ionization in tissue round bone may be as much as 2.3 times that indicated by the estimation of the dose there.

TREATMENT PLANNING

The treatment of every patient by the million-volt equipment has been regarded as a separate and individual problem requiring its own plan. The isodose plans (figs. 10 to 13) are those on the transverse sections of the patients through the centre of the treated volume. They illustrate a few representative methods of treatment of various sites, indicating particular points of interest and advantages gained by employing supervoltage X-rays.

Deep-seated lesions in large patients.—Applying the physical advantages which we have already discussed, it can be stated in general that at a million volts, due to the high depth doses for even small fields and the increased tolerance of the skin, a large dose of radiation can be delivered to a lesion no matter how deep-seated in the largest of patients. A typical case is:

Fig. 10, a carcinoma of the œsophagus.—In a patient of anteroposterior dimension of 23 cm., using the same six fields, an anterior, posterior and four glancing fields, the section shows, on the left, the isodose if treatment were carried out at 250 kV, 1.5 mm. Cu H.V.L., 50 cm. F.S.D.; and on the right, as it is done at 1,000 kV, 9.3 mm. Cu H.V.L., 100 cm. F.S.D. To deliver a dose of 6,000 r to the lesion at 250 kV, a dose of 4,000 r per field is required, resulting in a maximum skin dose of 5,000 r. It is doubtful if this could be accomplished. On the other hand, at a million volts only 2,760 r per field is required, giving a maximum skin dose of 3,530 r, 1,000 r below the dose which will produce a second degree erythema at this wavelength.

It will be noticed that at a million volts not only is it easier to attain a high lesion dose level, but also that the dose level falls off more rapidly in the normal tissue outside the lesion, a valuable factor in maintaining the patient's vitality during the treatment and convalescence.

TREATMENT OF LARGE SECTIONS

Carcinoma of the breast.—Fig. 11 shows the treatment plan for a very advanced carcinoma of the breast involving the posterior axillary skin fold, necessitating treatment of nearly one-third of the skin periphery. At a million volts, two opposed glancing beams were used, 29 cm. apart, resulting in a central deficiency of about 20% when compared with the maximum skin dose. This deficiency is readily corrected by the application of a "straight-on" central field which required only one-quarter of the dose given to the main glancing fields. As the dose to this field is low there is little extra irradiation of the lung.

At 250 kV employing opposed glancing fields [10], the dose at the centre of the lesion would only be about 50% of the maximum skin dose. A supplementary "straight-on" central field would not produce anything like uniformity throughout the section, since with the high dose required, and the rapid fall off in the field depth

There would be a very steep gradient in dose from the skin at the centre, to the edge of the field.

Comparison of the two diagrams shows the ease with which uniform irradiation can be achieved to large sections at million volts.

FIG. 13.—Ca. Bladder. Treated by 10^6 V, 9.3 mm. Cu H.V.L., 100 cm. F.S.D.

REDUCTION OF DAMAGE TO VITAL ORGANS

In this group of cases the high depth doses available at a million volts are used to permit either a reduction of the dose to fields passing through vital organs or employment of a plan in which the beams do not take the most simple and economic route to the lesion, but are directed to avoid irradiating a vital organ.

Carcinoma of the fauces, unilateral.—In the case in fig. 12 the general line of approach at 250 kV would be by two lateral fields, damaging all the salivary glands and

the bone approaches closer to the chamber, the ionization current rises rapidly until with 0.025 mm. of intervening tissue the level is 72% above that with 0.2 mm. of intervening tissue. This means that tissue cells at this distance of 0.025 mm. from the bone receive 72% more ionization than that equivalent to the roentgen dose level estimated at that point. Extrapolating the curve it would appear that those tissue cells in contact with the bone probably receive as much as 130% excess ionization, while on the other hand the effect of the bone has disappeared in the tissues beyond 0.2 mm. from the bone.

It follows that at a million volts we need not worry about the increase in ionization in tissue around bone, as this is negligible, but at 250 kV we must remember that the ionization in tissue round bone may be as much as 2.3 times that indicated by the estimation of the dose there.

TREATMENT PLANNING

The treatment of every patient by the million-volt equipment has been regarded as a separate and individual problem requiring its own plan. The isodose plans (figs. 10 to 13) are those on the transverse sections of the patients through the centre of the treated volume. They illustrate a few representative methods of treatment of various sites, indicating particular points of interest and advantages gained by employing supervoltage X-rays.

Deep-seated lesions in large patients.—Applying the physical advantages which we have already discussed, it can be stated in general that at a million volts, due to the high depth doses for even small fields and the increased tolerance of the skin, a large dose of radiation can be delivered to a lesion no matter how deep-seated in the largest of patients. A typical case is:

Fig. 10, a carcinoma of the œsophagus.—In a patient of anteroposterior dimension of 23 cm., using the same six fields, an anterior, posterior and four glancing fields, the section shows, on the left, the isodose if treatment were carried out at 250 kV, 1.5 mm. Cu H.V.L., 50 cm. F.S.D.; and on the right, as it is done at 1,000 kV, 9.3 mm. Cu H.V.L., 100 cm. F.S.D. To deliver a dose of 6,000 r to the lesion at 250 kV, a dose of 4,000 r per field is required, resulting in a maximum skin dose of 5,000 r. It is doubtful if this could be accomplished. On the other hand, at a million volts only 2,760 r per field is required, giving a maximum skin dose of 3,530 r, 1,000 r below the dose which will produce a second degree erythema at this wavelength.

It will be noticed that at a million volts not only is it easier to attain a high lesion dose level, but also that the dose level falls off more rapidly in the normal tissue outside the lesion, a valuable factor in maintaining the patient's vitality during the treatment and convalescence.

TREATMENT OF LARGE SECTIONS

Carcinoma of the breast.—Fig. 11 shows the treatment plan for a very advanced carcinoma of the breast involving the posterior axillary skin fold, necessitating treatment of nearly one-third of the skin periphery. At a million volts, two opposed glancing beams were used, 29 cm. apart, resulting in a central deficiency of about 20% when compared with the maximum skin dose. This deficiency is readily corrected by the application of a "straight-on" central field which required only one-quarter of the dose given to the main glancing fields. As the dose to this field is low there is little extra irradiation of the lung.

At 250 kV employing opposed glancing fields [10], the dose at the centre of the lesion would only be about 50% of the maximum skin dose. A supplementary "straight-on" central field would not produce anything like uniformity throughout the section, since with the high dose required, and the rapid fall off in the field depth

dose, there would be a very steep gradient in dose from the skin at the centre, to the chest wall at the centre.

Comparison of the two methods shows the ease with which uniform irradiation can be delivered to large sections at a million volts.

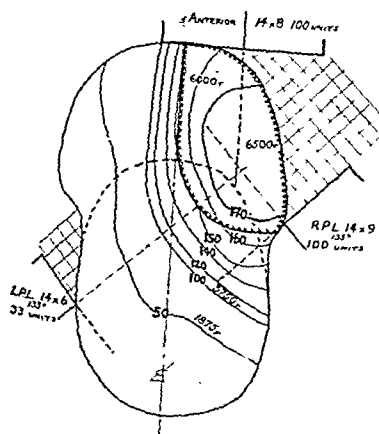

FIG. 12.—Ca. Faucial Pillar, R.
100% = 3,750 r.

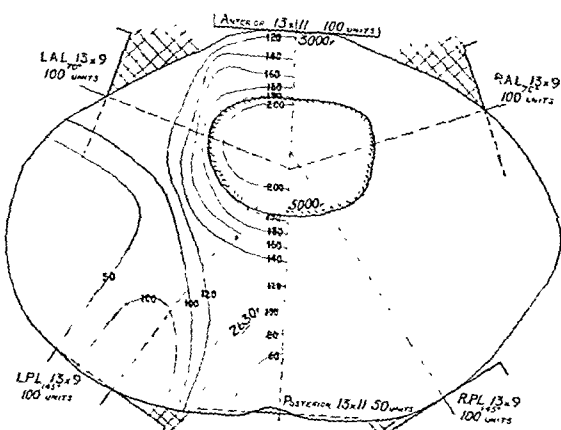

FIG. 13.—Ca. Bladder. Treated by 10^6 V, 9.3 mm. Cu H.V.L., 100 cm. F.S.D.

REDUCTION OF DAMAGE TO VITAL ORGANS

In this group of cases the high depth doses available at a million volts are used to permit either a reduction of the dose to fields passing through vital organs or employment of a plan in which the beams do not take the most simple and economic route to the lesion, but are directed to avoid irradiating a vital organ.

Carcinoma of the fauces, unilateral.—In the case in fig. 12 the general line of approach at 250 kV would be by two lateral fields, damaging all the salivary glands and leaving

the patient with a permanently dry mouth. At a million volts the treatment can be effectively carried out by an anterior field and a posterior glancing field on the diseased side, with a small supplementary posterior glancing field from the other side to increase the dose in the postero-medial part of the lesion. This supplementary field only requires a dose of one-third that applied to the main fields, and is so aimed as to miss the salivary glands on the unaffected side. The result is that the salivary glands receive less than one-third of the lesion dose, a dose which does not cause functional damage.

Carcinoma of the œsophagus.—In the case of carcinoma of the œsophagus (fig. 10) we have already indicated the great increase in tumour dose per field r with the employment of supervoltage X-rays. This gain can be usefully employed in permitting a reduction of the dose applied to the glancing fields commensurate with the delivery of the necessary tumour dose. This reduction to the dose level of the glancing fields reduces the lung irradiation and damage.

Carcinoma of the cervix.—In order to avoid bladder and rectal upset in the treatment of this condition, the major portion of the dose to the lesion is delivered through four glancing fields, with an anterior and posterior field each receiving only one-half of the dose applied to each glancing field. The result is an isodose of the shape required with a fairly rapid fall off anteriorly and posteriorly, so reducing the radiation effects on the bladder and rectum to a level much below that which would occur if full dosage had been applied to the anterior and posterior fields.

Carcinoma of the bladder (fig. 13).—In this case the patient was enormous, with an anteroposterior measurement of 26 cm. and a width of 37 cm. Nevertheless it is possible with an anterior and four glancing fields, supplemented by a posterior field raised to only one-half the dose of the others, to deliver a maximum dose of 7,500 r to the bladder lesion, if required. The application of only one-half the dose to the posterior field effectively lowers the dosage level to which the rectum is raised, so diminishing the likelihood of proctitis.

LESIONS OF SMALL CROSS-SECTION

Carcinoma of the rectum.—(For the isodose distribution see fig. 94, p. 128, *Supervoltage X-ray Therapy*, by R. Phillips, London.) In this case the lesion was of small cross-section, 5 cm. diameter. The plan shows on the left the isodose at 250 kV, and on the right at 1,000 kV when ten 8 cm. wide fields are employed in both cases. The most prominent feature is the rapid fall off in dose outside the lesion at a million volts, compared with the relatively large block of tissue which is raised to the lesion dosage level at 250 kV. Secondly, the maximum skin dose is the same in both cases for the same field doses (200%) but the million-volt lesion dose is some 50% higher than that at 250 kV. It is not often that the lesion sections are so small or are enclosed by a longitudinal ellipsoid of such central cross-section, which this isodose implies, and it is now more common to use field plans with larger and fewer fields.

General.—It should be pointed out that in this survey of treatment isodose sections, no allowance has been made in the isodoses for the absorption of bone or the reduction of depth dose due to lack of scatter from lung. Both of these will have a detrimental effect on the 250 kV isodoses but little effect at 1,000 kV. This would even further emphasize the advantages of the million-volt radiations.

Summary of the Physical Treatment Advantages of 1,000 kV X-rays

Due to the increased depth doses, other physical factors and reduction in the skin reaction, the following advantages are obtained:

(1) Fewer fields can be used to deliver the lesion dose required and hence we obtain a simplification of the treatment plan with a resulting gain in accuracy.

(2) Alternatively we can reduce the dose level to some or all of the multiple fields.

(3) It is possible either to reduce the dose on fields passing through easily upset organs or alternatively in some cases to avoid irradiating them altogether, attaining the necessary tumour dose by a less efficient routing of the beams to the lesion.

(4) In nearly all cases, 6,000 r can be delivered to the lesion in five weeks, no matter how deeply seated it is or how large the patient.

(5) By careful planning the dosage level can be made to fall off rapidly outside the volume to be irradiated, reducing the ill-effects on the patient.

(6) It will be noticed that no attempt is made to avoid beams passing through bony structures, since bone absorption at a million volts is very little greater than tissue, with the result that the isodose plans are a very near approach to the actual dose distribution in the patient, irrespective of whether bone is present or not. Also round the bone there is only a negligibly small trace of ionization in excess of that indicated by the r dosage level of the isodose. On the other hand at 250 kV the shadow effect of the bone is high, and the ion density around bones may be as much as twice the level inferred by the r dose level indicated by the isodose. This may be of clinical significance.

In this note it has only been possible to deal with some of the physical aspects of treatment at a million volts, and many of the isodose plans have had to be omitted; other physical aspects will be mentioned in Dr. Jones' paper.

Before closing, I should like to express my indebtedness to my ex-colleagues at Messrs. Metropolitan Vickers, whose enthusiasm made such an equipment possible; in particular to Mr. T. C. Crichton who was responsible for the erection of the equipment, and who has made the instruments necessary for the experimental work reported herein; to our Pathology Department, especially Dr. Cureton, who supplied the pathological specimens; to the eight Medical Officers with whom I have had the pleasure of working on the million volt equipment, I can only say "thank you" for the understanding way they have helped with the physical treatment problems, making treatments in effect a combined operation of medical and physical knowledge.

Clinical Reactions and Injuries in Supervoltage Therapy

BY ARTHUR JONES, M.D., M.R.C.P.

THE following is a brief account of the clinical effects of supervoltage radiation as we have observed them, and of the injuries which have resulted during the treatment of malignant disease with the million-volt apparatus.

The extension of the roentgen unit of X-ray dosage has enabled clinicians to compare the biological reactions produced at different photon energies, and it is a matter of general experience that to produce a given skin reaction requires a larger dose of gamma radiation than of X-rays. It is commonly agreed that if 600 r of X-rays at

200 kV is required to produce a standard erythema, then about 1,000 r of gamma radiation is needed to give this same response (both doses being stated "with back-scatter"). A voluminous literature, much of it empirical, has accumulated about this variation of skin response with radiation quality, and the advent of million-volt X-rays, intermediate in mean energy between the "deep therapy" range and gamma rays from radium, gave promise of elucidating the problem. Early experiments by Phillips (1944) confirmed the theoretical supposition that the *threshold* erythema dose was some 50% higher at one million volts than at 200 kV, but further experiment was difficult, since it was unjustifiable to treat superficial lesions with this penetrating radiation, and treatment of malignant disease was by fractionation of the dosage. Here was encountered, as in its wider context, "the opportunity fleeting; experiment dangerous, and judgment difficult". However, one definite observation has been that the skin dosage for a second degree erythema, by fractionation over three to five weeks, is between 4,000 and 5,000 r. The erythema develops more slowly than at 200 kV, reaches its maximum later, and takes longer to subside.

The mechanism of this differential threshold with wavelength has been attributed by some to the different absorption processes, whereas others regard it as a true function of photon energy. The experimental determination of maximal ionization depth by Innes provides some new light on the problem (*see* fig. 8 in Mr. Innes' paper). Since the depth of the basal layer and subpapillary vascular plexus in the skin is some 0.2-0.4 mm., it will be seen that the maximal ionization at one million volts occurs measurably below this level, whereas with the 250 kV beam saturation has already occurred in the wooden end of the applicator on the skin surface. This will account for a difference of over 7½% in local energy absorption. The absence at one million volts of the photo-electric absorption process by the sulphur in the superficial skin strata accounts, according to Gray (1940), for some 13% difference in ionization. These two effects taken together may account for 20-25% of the difference in energy absorption, and it cannot yet be ruled out that the remaining difference in skin reaction is not an inherent function of the quality of the beam.

MUCOSAL REACTIONS

In the "deep therapy" range of X-rays the factor limiting radical treatment is often the severity of the skin reaction, but the penetrating properties of a million-volt beam may produce a deep mucositis in the region of the tumour and thereby effectively limit the amount of radiation permissible. This is best seen in two sites: (a) in the mouth, pharynx and larynx, and (b) in the pelvis.

During irradiation of the oropharynx by a fractionated dose method, reddening of the mucous membrane develops between the tenth and fifteenth day. A few days later a white fibrinous membrane appears, and if heavy dosage is used the membrane may become quite thick; it is adherent, and bleeds like a diphtheritic membrane if its premature removal is attempted. During the mucositis the patient has sore throat, cough, dysphagia and dryness of the mouth. The mucosal reaction always precedes the skin reaction; it subsides about three weeks after the end of treatment, but the dryness of the mouth may last for months. The skin reaction, developing later than the mucositis, also takes longer to resolve. In a few cases of post-cricoid and pharyngeal irradiation, gastrostomy has been required during treatment, and one or two of the laryngeal and thyroid cases have required emergency tracheotomy.

In the pelvis, the mucosal reactions may affect the rectum, the bladder and the vagina, and in treating one of these organs the methods described by Mr. Innes are used to minimize the dose received by neighbouring structures. Irradiation of a rectal tumour commonly produces a proctitis starting at the end of the first week of treatment, manifesting itself by tenesmus and watery diarrhoea; it is rarely severe enough to interrupt treatment, but it adds to the patient's discomfort. Proctitis of

less severity may occur during irradiation of the ovaries, uterus, parametrium, prostate and bladder.

Cystitis occurs in most cases of pelvic irradiation at about the eighth day, but the dysuria and frequency of micturition merely inconvenience the patient, and are partly relieved by alkaline mixtures containing hyoscyamus. Transient vaginitis may be mentioned as occurring similarly, but it produces no disability.

These mucosal reactions have proved to be the major burden which patients with malignant disease have had to bear during their course of supervoltage therapy. Soreness of the mouth and dysphagia may render an out-patient's life a misery, and it is necessary to have the patients in hospital for symptomatic treatment during the active phase of the mucositis.

There is one other aspect of mucosal reaction which I would like to mention. In a number of cases, especially in the pharynx and œsophagus, the mucositis has been unduly severe, and has limited the dose administered to perhaps 3,000 r in three weeks instead of the planned 4,000 or 5,000 r in five weeks. In a few of these cases, the ultimate result has been unexpectedly good—it is as though some factor common to both tumour and its mucosal bed has enhanced both the radiosensitivity and the radiocurability of the lesion. Experience had previously shown that the curative dose in these cases would have been quite inadequate in the absence of this "flare" reaction. This aspect of tumour response appears worthy of further biological study.

GENERAL REACTIONS

It was claimed by American workers in the early days of supervoltage therapy that the general reactions in the patients were less severe than at the "deep therapy" range. The physical investigation of total energy absorption has shown that the integral dose, expressed as gm. r per r on surface, rises with increase in the half-value layer of the beam, so that at H.V.L. 9 mm. Cu it is some 11% greater than at H.V.L. 2 mm. Cu. This integral dose has been given as *per r on surface*. For a given deep tumour dose, however, the integral dose at one million volts is considerably less than at 250 kV. The implications of this are shown in fig. 1. The benefit derived may be seen in Table I of the comparison of the integral doses in treating a case of

TABLE I.—COMPARISON OF INTEGRAL DOSES IN RADIOTHERAPY OF RECTAL CARCINOMA

Date	1,000 kV	200 kV
Lesion-dose (5 weeks)	6,000 r	6,000 r
Dose per field ..	1,620 r	2,400 r
Dose per day ..	650 r	960 r
Maximum skin dose	3,400 r	5,030 r
Integral dose ..	40 m.-g.r	65 m.-g.r

FIG. 1.—Relationship between integral dose at 1 M.E.V. 9.3 mm. Cu H.V.L. and 250 kV 2.0 mm. Cu H.V.L. when delivering the same tumour dose. Field 10 × 10 cm. 100 cm. F.S.D. Patient 20 cm. thick.

carcinoma of the rectum. (The figure of 40 Mega-gm. r is nearing the limit of tolerance.) While radiation sickness does occur in patients undergoing supervoltage therapy, it is probably less frequent than at 250 kV. Considering the extent of the lesions treated and the total tumour doses given, it can be concluded that the general reactions are less severe in the supervoltage range.

Blood changes have followed closely those occurring at the deep therapy range. In one respect, however, there has been a definite advantage in using the million-volt tube. This has been in the treatment of localized mediastinal masses in certain cases of reticulosis in which "deep X-ray" therapy had resulted in a dangerous leucopenia and radiation therapy had been abandoned. The use of small fields with the million-volt apparatus enabled us to deliver an adequate lesion dose before severe blood changes supervened.

INJURIES FROM SUPERVOLTAGE RADIATION

When the Year Book of Radiology for 1937 recorded the opening of the Mozelle Sassoon Department at St. Bartholomew's Hospital, the Editor observed: "Presumably the operators of the new plant will familiarize themselves with the not always happy effects of such high-voltage radiation by conferring with their American colleagues before starting therapy on a large scale". This statement is a reminder of the unfortunate injuries and necroses which occurred in America in those early days, before the dosage distributions and other potentialities of supervoltage apparatus were fully appreciated.

We can record that relatively few severe injuries have occurred at Bart's and this is a tribute to the careful planning of each individual case by Mr. Phillips and Mr. Innes, and also to their care in setting up each patient for treatment, when several small fields are in apposition and each exit dose has to be considered.

(a) *Injuries to skin and subcutaneous tissue.*—The early skin reactions already described have often left a mild chronic radiodermatitis as sequel. Telangiectasia is not uncommon and, as at 200 kV, appears more frequently after daily doses of 500 r on the skin than if each skin dose is limited to 300 r per day. Mild skin atrophy is less common than at 200 kV but intracutaneous fibrosis and œdema, giving a leathery skin, are more common. Similarly, subcutaneous fibrosis, especially in fatty tissue (e.g. buttocks), is more common with supervoltage. This would accord with the observations on the depth at which maximal ion density occurs—the endarteritis is occurring mainly in the deep vascular plexus and not in the subpapillary plexus.

Of all the 800 cases treated, in only 12 has true late radiation necrosis of skin and subcutaneous tissue occurred. One of these was a small pre-auricular necrosis following the irradiation of a recurrent parotid tumour which had actually shown chronic radiodermatitis from previous 200 kV irradiation when first treated. The other cases all followed pelvic irradiation—6 cases of rectal carcinoma and 5 of anal canal carcinoma. The 6 necroses out of 192 cases of rectal carcinoma is a small figure, and in 4 of these the precipitating factor was obvious—two had had re-treatment at 1,000 kV after previously having had a full course of treatment; one had a subsequent radium implantation; one other had gone to another hospital and, without divulging his previous history, had been re-treated at 200 kV. Two of these rectal patients with necroses are alive and comparatively well (figs. 2 and 3).

The incidence of necrosis in anal canal carcinoma is unfortunately quite different—out of 23 patients treated, 5 developed necroses. Treatment of the anal growth was by anterior, posterior and oblique fields, supplemented by a perineal field, the maximum skin dose being 4,200 to 4,600 r on the posterior perineum; one case had interstitial radium at another hospital later; and one case had had a maximal skin dose of 5,250 r to the perineum. It is of interest that, although in rectal cases the perineal skin has received a similar maximal dose to that given to the anal cases, necrosis has been rare in comparison with the anal series. The tumour response in anal carcinoma has been excellent, and it would appear that the high incidence of necrosis here is due to failure of the normal repair processes in a heavily irradiated, moist and perhaps schæmic field, which has already been the site of ulceration.

(b) *Injuries to connective tissue.*—The deep mucosal reactions already described are occasionally followed by late fibrosis in the organs concerned. This has been most common in the rectum, where clinically recognizable fibrosis was present in 30 of the 192 cases treated; but in very few was it of such severity as to necessitate colostomy

for stricture. One uterine case was followed by persistent rectal ulceration and fibrotic stricture requiring colostomy.

One case of rectal carcinoma is of considerable interest because of the sequel of pelvic fibrosis. A man of 42 had a partial removal of a Stage 2 adenocarcinoma of the lower third of the rectum, followed by X-ray therapy at 1,000 kV-4,500 r to the tumour in four weeks. Six months later he developed a posterior perineal radionecrosis which healed in eight months. Soon afterwards he had enlarged inguinal glands, which were treated to 4,500 r in each groin. The patient became symptom free and returned to work, but eight months later was admitted with anuria to another hospital

FIG. 2.—Necrosis at upper end of natal cleft following supervoltage irradiation of stage 3 rectal carcinoma in 1943 (tumour dose of 5,000 r in twenty-seven days; maximal skin dose 5,600 r in posterior perineum). Colostomy, 1942. Patient is well, with no evidence of active growth, in 1948.

FIG. 3.—Necrosis in natal cleft following supervoltage irradiation in 1945 of a recurrent rectal carcinoma (originally treated by perineal excision and colostomy in 1944). Tumour dose of 3,350 r in twenty-two days, followed ten weeks later by 2,000 r in eighteen days; maximal skin dose 5,600 r on posterior perineum. The patient leads a busy life and has no evidence of active neoplasm in 1948.

and died in uræmia. Autopsy showed no evidence whatsoever of rectal growth, but he had pelvic fibrosis, bilateral hydro-ureters, hydronephroses and pyelonephritis.

Brachial neuritis followed irradiation of the supraclavicular and axillary region in one case of mammary carcinoma.

(c) *Muscle fibrosis*.—This has occurred mainly in the neck, where platysmal and sternomastoid fibrosis has followed irradiation in 3 out of the 15 cases of thyroid carcinoma. The only disability resulting has been slight restriction of neck extension.

(d) *Respiratory tract*.—Persistent laryngeal œdema with fibrosis has been noted in 6 cases—one being in thyroid, one in post-cricoid, and 4 in laryngeal irradiation; in one of these latter, the œdema masked a perichondritis and necrosis of the cartilage. 5 of these cases ultimately required tracheotomy, and one needed gastrostomy also.

Apical pulmonary fibrosis has been noted in one case of thyroid irradiation, and in one case of œsophageal carcinoma the patient died of massive fibrosis of both upper lobes one year after the X-ray therapy. Lung fibrosis has, of course, been relatively common in the cases of bronchial carcinoma; but with the exception of one case has been overshadowed clinically by the primary neoplastic condition.

(e) *Œsophagus*.—Irradiation of the œsophagus has resulted in rather dramatic sequelæ in two cases:

OCT.—RADIOL. 2.

(1) A man of 59 was given supervoltage radiation to a squamous-cell carcinoma of the œsophagus (with mediastinal lymph-node involvement) at the level of the tracheal bifurcation. A tumour dose of 5,500 r was given in thirty-seven days, by a 6-field technique. Clinical improvement was excellent, but five weeks after irradiation the patient was admitted with mediastinitis and died two days later. Autopsy revealed a perforation into the right main bronchus (5×3 cm.). No growth was found in the necrotic mediastinal lymph-node mass, but microscopically there were a few carcinoma cells in the œsophageal wall.

(2) A man of 57 was given a tumour dose of 5,500 r in thirty-five days by 6 fields for an undifferentiated squamous-cell carcinoma of the middle third of the œsophagus. The clinical response was good, but two months later he died of a sudden hæmorrhage. At post-mortem there were no signs of growth, but œsophagus and aorta communicated through a large hole. There was no other evidence of necrosis above or below the perforation.

These two cases emphasize the view, put forward originally by Phillips, that here we are dealing, not so much with true necrosis, but with a failure of reparative processes by the normal tissues, after ablation of the growth. Possibly with some different method of fractionation, to minimize injury to the tumour bed, these unfortunate results might be avoided.

(f) *Bladder*.—There have been two cases of persistent hæmaturia from telangiectasia of the bladder wall—one, in a case of carcinoma of the bladder, which had a desquamative cystitis, was treated by total cystectomy (no growth was found in the operation specimen); the other, a case of carcinoma of the body of the uterus, has recurrent mild hæmaturia, but is otherwise well.

(g) *Bone*.—Two cases of bone necrosis—one of the mandible in carcinoma of the tongue, and one of the clavicle in carcinoma of the breast—have occurred, but showed no unusual features. Three of the cases of perineal necroses already described had involvement of coccyx and sacrum.

(h) *Eye*.—Conjunctivitis during treatment of carcinoma of the maxillary antrum has been unavoidable in treating certain cases, because of the anatomical extent of the growth. Of 18 antral cases treated, in 2 the conjunctivitis persisted, one other patient developed iritis, and 2 have X-ray cataracts.

(i) *Liver*.—Finally, a most unusual case of hepatic disorder has occurred during irradiation of a bronchial carcinoma. The patient, a Leading Aircraftsman, aged 24, had an oat-celled carcinoma of the right lower lobe bronchus diagnosed in the Middle East in June 1943 and treated by 2,200 r deep X-rays in Palestine (no further details available). He was treated at Bart's in October 1943 for persistent neoplasm by the million-volt apparatus. A tumour dose of 4,500 r was given in twenty-five days, followed by 2,400 r in five days to the right supraclavicular nodes, and then 775 r to the epigastric nodes in five days (with an 11×8 cm. epigastric field). His condition remained unchanged until mid-November 1943 when he became pyrexial and developed the rash of chickenpox. Radiation treatment was suspended. Thus the patient had been incubating varicella for half the total period of irradiation. The patient's condition deteriorated, and he died of pneumonia three days later. No clinical evidence of hepatic insufficiency had been observed. Autopsy showed, in addition to the bronchial tumour, a gross abnormality of the liver. The anterior surface of the right lobe was covered with petechiæ, and the upper part was intensely congested on section. The line of demarcation was at about the lower level of the anterior thoracic field of irradiation. Within the hyperæmic area there was intense active congestion of the liver sinusoids, chiefly *centrilobular*, with atrophy of liver cells; outside the congested area there were numerous areas of scattered *focal* necrosis.

This picture is unlike that previously described (e.g. Case and Warthin, 1924) in hepatic necrosis due to irradiation—the incidence of damage is stated to be usually peribiliary. The technique in this case differed in no way from that used in 3 other cases of bronchial carcinoma who suffered no ill-effects, and one can only conclude that some other factor, possibly the varicella, was involved in this case.

Such are the effects and injuries from supervoltage irradiation as we have seen them at St. Bartholomew's. The injuries, because of their relative rarity, have been described in some detail, and if any defence is demanded for the methods which have unfortunately produced them, one can only reiterate the Hippocratic aphorism of "extreme methods of cure for extreme diseases".

Million-Volt X-ray Therapy

By I. G. WILLIAMS, F.R.C.S., D.M.R.E.

THIS report analyses the results of the treatment of malignant disease by means of X-rays generated at one million volts. As a primary research, five main sites were chosen: (1) Carcinoma of the breast, inoperable but without distant metastases. (2) Carcinoma of the cervix in all stages of the disease. (3) Cancer of the upper air and food passages. (4) Inoperable carcinoma of the rectum. (5) Carcinoma of the œsophagus—thus continuing a research into the results of X-ray therapy in malignant disease commenced in 1924 and elaborated in 1931. The research was, however, handicapped by the war; Mr. Ralph Phillips was the only therapist left in the hospital, and his time had to be divided between the million-volt and deep-therapy departments. Allocation of patients became dictated by the capacity of each department, and for humanitarian reasons patients not falling into the five groups were accepted for million-volt therapy. It has been the policy at St. Bartholomew's Hospital to treat early malignant disease by surgical rather than radiotherapeutic methods, if experience is favourable as judged by end-results. Thus patients referred for million-volt therapy were incurable by any other means, either because of the nature of the tumour, its anatomical extent or the general condition of the patient. Less than 5% of the total number fall into the early operable group. I think the tables are valuable as an indication of what we can and cannot do for our patients, in the conditions or stages in which they come to us for treatment. Our experience emphasizes clearly that early disease can be cured, that late disease cannot be cured, but that we can offer considerable palliation.

726 cases are available for study, no case has been eliminated and the figures are absolute values for those referred. We have been unable to trace a few of our patients, and these are counted as dead. As radiotherapists I believe we tend to over-emphasize our survival statistics. True, we have to present our successes as survival rates in order to compare with other forms of treatment or combined treatments, so as to give the patients the best possible chance of survival. But let us not lose sight of the degrees of palliation we can offer, the relief of physical and mental pain and distress, which cannot be recorded in graphs or statistics. When one remembers that less than 10% of malignant disease in all sites can be cured permanently, then the scope of radiotherapy as a palliative agent can be appreciated.

With these facts in mind, the following tables and remarks on the results of million-volt X-ray therapy in certain sites are presented.

Carcinoma of the Breast

Patients referred for million-volt therapy had advanced tumours, bulky primary growth and œdema of the skin, with extensive lymphatic metastases, often so large as

to be unsuitable and difficult for 200 kV therapy. A dose of 4,500 r can be delivered evenly to the chest wall, axilla and supraclavicular region in four to five weeks. This results in a brisk second-degree reaction which heals with fibrosis and later telangiectasia. There were no cases of pulmonary fibrosis resulting from treatment, but one patient developed a necrosis of the clavicle, and one patient has a fibrosis of the pectoral muscles, with a brachial neuritis, similar to the ones we used to get following radium implantation. Clinically, the primary tumour as well as large glandular metastases may disappear completely and histological examination of breasts removed after irradiation has shown either no recognisable carcinoma or degenerate carcinoma in fibrosed tissue. I can confirm Phillips' observation that disappearance of the primary tumour and regional lymphatic metastases is more certainly and more easily obtained with supervoltage than with deep X-ray therapy.

Total treated: 56.

Stages	No.	Dead	Alive		
(1) Operable	1	0	1	} 9/37 = 25%	} 9/50 = 18%
(2) Advanced or encephaloid	11	6	5		
(3) Inoperable	25	22	3		
(4) (Distant mets.)	13	13	0		
Recurrent	6	5	1		
					100% 46% 12% 0%

Stage 1: One patient. Refused operation. A/W 3 years. Dose: 4,500 r in 21 days.

Stage 2: Total: 11 patients. Two lactation carcinomas. Remainder: Breast or tumour too large to deliver an adequate dose with 200 kV therapy.

(a) Simple removal or biopsy and X-ray therapy.

7 cases. Alive 4 (8, 8, 6, 6 years).

Dead 3 (6½, 3, 1 year).

(1) Age 23. Encephaloid carcinoma in lactating breast—A/W 8 years. This patient developed a necrosis of the clavicle and the whole bone eventually sequestered.

(2) Age 26. Encephaloid carcinoma in a lactating breast. Alive 6 years.

(b) Radical mastectomy and post-operative X-ray therapy. 1 case died metastases at 14 months.

(c) X-rays alone. 3 cases. 1 A/W 3 years. 2 died at 1½ and 2½ years.

Stage 3: Advanced primary disease with inoperable regional glands.

Total 25: A/W 3 (5, 4, 4 years). Dead 22 (average survival 1·9 years).

One patient in this group who had radical mastectomy three months after therapy (and in whom the disease became operable without evidence of metastases) died of extensive generalized metastases within four months of operation.

If these three groups are combined:

Stages 1, 2, and 3: Alive 9 (7 over 5 years. All over 3 years.)

Dead 28.

Stage 4: Distant metastases.

Total 13 patients: All are dead.

1st year 9.

2nd year 3.

One survived for 6 years.

Recurrent disease.—Total 6 patients.

1 A/W 3 years.

Dead 5.

Carcinoma of the Tongue (including vallecula).

Total number 14. Alive 0. Dead 14.

Survival Dead

5—1st year 9 (1 untraced).

2—2nd year 3 (1 o.c. with healed primary and no glands).

1—3rd year 1

0—4th year 1 (died o.c. without recurrence of primary or glands).

(O.C. = other causes)

These were patients with advanced primary disease, together with glandular metastases, unilateral and fixed, or bilateral. In 6 patients the primary growth

regressed, without recurrence before the patient died from metastases. In 2 patients death was due to exhaustion and pulmonary metastases. In 8 patients, although some initial response was obtained in large glandular metastases, they rapidly recurred and extended. Mucosal reactions are severe with supervoltage, due to the large depth dose which can be delivered for a safe skin reaction. In spite of this, no difference was noted between those treated by million-volt therapy and deep X-ray therapy. Technically, however, it is easier to deliver the dose by million-volt therapy as an even distribution can be achieved by means of two opposing and parallel fields.

Carcinoma of the Antrum (1939-1945).

Total number of cases 20. Primary 13. Recurrent (following other forms of treatment) 7. All the cases with recurrent disease died within twelve months of treatment.

Survival (13 cases)

Alive 4.	8 years—1	Dead 9.	1st year 3 (1 senile decay. N.S.D.)
	5 years—1		2nd year 2
	3 years—2		3rd year 2
			4th year 1 50 months
			5th year 1 69 months
} Of disease			

(N.S.D. = No sign of disease—for which original treatment given)

All patients had advanced primary disease.

The average dose has been 4,500 r in twenty-one days through two oblique and opposed fields. The eye was included in an irradiated field in most patients and three out of four survivors have eye damage in the form of a radiation cataract. One of these has also a troublesome conjunctivitis and iritis, but apart from dimness of vision the other two are free of symptoms. Primary reactions are severe, but ultimate healing is good. The antrum has been explored in all, following therapy. Afterwards, all seem to have experienced some pain whilst dead bone was separating, but once this happened, pain was relieved, and with the fitting of an obturator they have been quite comfortable. The results are an improvement on ordinary deep X-ray therapy alone.

Extrinsic Carcinoma of the Larynx

This group includes growths of the pyriform fossa, aryepiglottic fold, epiglottis and pharyngeal wall. In two the primary was so large that the origin could not be determined.

Total cases 34. Males 29. Females 5. Two discarded, moribund on admission.

Stage 1: Local growth. 7 patients. 1 untraced.

Alive 1.	5 years.	Dead 5.	1st year 2
			2nd year 0
			3rd year 3

Stage 2: Mobile unilateral glands 7.

Alive 2.	1 at 5 years.	1 at 4 years.	Dead 5.	1st year 3
				2nd year 1
				3rd year 1
				} average 11 months.

Stage 3: Advanced primary with or without fixed glands.

Total 20 (Two moribund on admission).

All dead. Average survival 11 months.

Longest survival 3 years.

Absolute survival 3/32.

All the patients who died, died of their disease. In a few, large fixed masses became impalpable but they soon recurred, within the treated area. Of the three survivors, one had a carcinoma of the pyriform fossa with direct infiltration of the neck at the level of the primary. He is well with a strong voice, with slight persistent oedema following a tumour dose of only 3,000 r in fourteen days. In a second, the primary tumour was so large the origin could not be determined until it regressed. It was then thought to arise from the epiglottis. He also had hard mobile glands in the neck.

Intrinsic Carcinoma of the Larynx

Total 24.

Stage 1: A limited growth on a mobile cord. 1 case. Died 3rd year (senility also).

Stage 2: Whole cord involved or a fixed cord. 10 cases.

Alive 5.	3 at 5 years.	Dead 5.	1 o.c. and old age 18 months.
	2 at 4 years.		3 in 1st year.
			1 in 3rd year.

Stage 3: Both cords involved, or glandular metastases. 9 cases.

Alive 5.	1 at 5 years.	Dead 4.	3 in 1st year.
	2 at 4½ years.		1 o.c. in 2nd year.
	1 at 3½ years.		
	1 at 3 years.		

Recurrent: 4 cases. 3 dead.

2 in 1st year. 1 in 2nd year. 1 alive 5 years.

Summary: Total 20 cases.

Alive 10. 4 at 5 years. 4 at 4 years. 2 at 3 years.

Dead 10. Of disease 5. Of other causes, without evidence of laryngeal disease 2. Of damage due to treatment 3.

The recurrent cases were following fenestration and radium or surgical removal. Some palliation was achieved, but these died of disease; in one case growth was spreading and fungating in the irradiated area. One case survives five years:

Male, 56. 1941. Laryngo-fissure removal of left and anterior part right cord. 6/12 later hemilaryngectomy for recurrence. 2/12 later, post-operative deep X-ray therapy, 3,500 r in seventeen days. One year later, 1943, subglottic recurrence treated on million volt, 4,000 r in nineteen days. Remains well and free of recurrence to date (five years).

Most were treated through two opposing fields, either anteroposterior or lateral, the inequalities of the neck being filled up with bolus. "Dose" varied from 3,000 r in fourteen days to 6,000 r in thirty days. One patient with a well-differentiated squamous-cell carcinoma involving the whole of one fixed cord, and a hard lymph node in the neck, is alive and well five years after treatment, 3,000 r having been delivered to the tumour in ten days. Another patient, treated up to 4,500 r in twenty-seven days, developed a recurrence in the third year, on the cord. He had a laryngectomy, section of the cord being positive for carcinoma. Two cases in Stage 2 died from undoubted other causes (both were old and feeble) without any laryngeal symptoms. Another developed a local recurrence on the cord, four years after a dose of 5,600 r in twenty-eight days, delivered to the cord. He had so much fibrosis œdema and skin changes that further treatment was not possible, either surgery or radiotherapy.

Three other patients died from perichondritis and œdema within a few weeks of tracheotomy.

On the assets side, however, in 5 of the patients an absolutely fixed cord became mobile, and these survive.

Carcinoma of the Œsophagus(1) *Post-cricoid carcinoma*—

Total 15. Females 13. Males 2. With Plummer-Vinson syndrome 3 females. Alive 1. Dead 14.

The patient who survived had an early squamous-cell carcinoma in the post-cricoid region. 5,000 r was delivered in forty-six days, and apart from telangiectasia of skin and laryngeal mucosa she remains well, swallowing normally four years later.

Analysis of patients who died

At months	Alive	Dead	At months	Alive	Dead
6	11	3	24	5	0
12	7	4	30	3	2
18	5	2	36	2	1
			48	0	2

In all these dysphagia was relieved for varying periods of time, but later returned. Tumour dose varied from 4,500 r in sixteen days to 6,000 r in thirty-five days with an average of 5,000 r in twenty-eight days. 5 patients developed a local recurrence in the post-cricoid region, after doses of 4,500 to 5,000 r. All developed lymph-node metastases and 3 died from disseminated neoplasm. 4 patients had to have tracheotomy because of laryngeal obstruction due to œdema, and 2 of these, gastrostomy as well. The doses of radiation delivered are probably the maximum the tissues in this region can tolerate in this period of time.

(2) Carcinoma of the œsophagus proper—

Total treated 42. Males 33. Females 9. Youngest 37 years. Oldest 80 years. Average age 61 years. Alive 0. Dead 42.

At months	Alive	Dead
6	18	24
12	7	11
18	3	4
24	1	2
30	0	1

The average tumour dose has been 5,000 r in thirty days, delivered through six strip fields. Those patients treated up to 6,000 r in thirty-six to forty days did no better than those where only 4,000 r was given in twenty-eight days. In most patients dysphagia was relieved until the death of the patient. Apart from metastases, other causes of death were perforation of the œsophagus into the mediastinum, great vessels or lung. Some died suddenly of heart failure, and at post-mortem growth was found invading the heart muscle. 5 patients died suddenly following a sudden severe hæmorrhage, and in one of these at post-mortem there was no sign of growth, but the aorta and œsophagus communicated through a large smooth opening. There was no mediastinitis and no sign of X-ray necrosis above and below the aortic perforation. This particular case received a dose of 5,500 r in thirty-five days, and Phillips suggested that in these the appearances point to a failure on the part of the normal tissues to repair the gap left by the destruction of the carcinoma, so that the question of cure in carcinoma of the œsophagus appears to be less one of radiation dosage, than of tissue healing under adverse conditions. However, in at least 5 patients local recurrence of growth developed at the primary site, in 2 within six months, in 2 within twelve months and in 1 twenty-four months after treatment.

In 2 patients who died and on whom a post-mortem was performed, the pathologist was unable to find evidence of carcinoma. One death was from a perforation into the aorta and one from pneumonia.

Six patients died with extensive metastases in chest, liver, abdomen and spine.

Carcinoma of the Bronchus

Total cases 148. Palliative therapy for pain 46. Cases analysed 102. Males 94. Females 8. Average age 50 years. Youngest 20 years. Oldest 69 years.

Alive 2 (5 years, 4 years). Dead 100.

Total 15. Females 13. Males 2. With Plummer-Vinson syndrome 3 females. Alive 1. Dead 14.

The patient who survived had an early squamous-cell carcinoma in the post-cricoid region. 5,000 r was delivered in forty-six days, and apart from telangiectasia of skin and laryngeal mucosa she remains well, swallowing normally four years later.

Analysis of patients who died

At months	Alive	Dead	At months	Alive	Dead
6	11	3	24	5	0
12	7	4	30	3	2
18	5	2	36	2	1
			48	0	2

(1) *Recurrent disease*.—These patients had advanced disease, invading abdominal wall, rectum, &c. 4 died, the average survival being six and a half months. One is alive four and a half years after treatment:

Man, aged 70. 1936, partial cystectomy. 1941, recurrence—large sessile papilloma—fulgurated. Six months later, further recurrence. H.V. X-rays, 5,000 r in fifty-two days to the bladder. Two years later, 1943, further recurrence treated by H.V. X-rays to 5,000 r in forty-two days. He remains well to date (four and a half years).

(2) *Malignant ulceration with infiltrating carcinoma*.—All these 8 patients are dead, average survival being eight months. 2 patients died of other causes and at post-mortem no microscopic evidence of growth could be found. 2 further patients died from metastases with controlled primary disease. In 4 patients the primary growth was not affected.

(3) *Malignant papilloma*.—This forms the largest group, 7 out of 22 patients having survived for periods from two to five years. All had extensive bladder involvement—15 patients had had repeated fulgurations either cystoscopically or through open cystotomy for varying periods of time up to twelve years previously, the average being four years. 7 were new patients treated primarily by radiotherapy. 7 out of the 22 are alive and well, and 5 of these are nearing their fifth anniversary since treatment. They are symptom free.

Of those that died, 5 developed extensive papillomatous recurrences in the bladder following doses of 4,000 r and 5,000 r, one three months and one twenty months after treatment. In 2 of these there was no appreciable effect on the primary growths—but all had marked relief of hæmaturia.

In only one case is there evidence of severe damage to the bladder due to the treatment. One patient developed a desquamative cystitis following 4,500 r in six days which persisted and necessitated a total cystectomy. He died twenty months later from metastases.

Carcinoma of the Anal Canal

	Cases	Survived	Dead	Cases
Stage 1	3 (1 alive)	1	2 years	1st year .. 10
Stage 2	8 (3 alive)	4	3 years	2nd year .. 2
Stage 3	12 (4 alive)	2	5 years	3rd year .. 1
	—	1	6 years	4th year .. 1
Totals	23	8 alive	5 years	6th year .. 1 (o.c.)

Of the survivors, 3 had fixed inoperable lymph-node metastases in the groins, one had a large necrosis, another a small, dry, symptomless necrosis, whilst 2 have anal strictures, in both precluding the closure of a colostomy. One developed a local recurrence in the primary site and he had to have a perineo-abdominal excision.

Dead.—15 are dead, 10 dying in the first year after therapy. 12 were old and feeble, in poor general condition. In 7 the primary growth regressed completely and they died from metastases. One died five and a half years after treatment from a cerebral hæmorrhage, without local or metastatic disease.

Five patients had a serious radiation necrosis, probably responsible for the death of one. In only one of these did healing occur before death. One of these had further deep X-ray therapy at another hospital, whilst a second had radium applied. Both of these developed huge necroses.

Carcinoma of the Rectum

Total: 192 patients.

Stage 1	..	4	..	1 alive
Stage 2	..	18	..	1 alive
Stage 3	..	106	..	10 alive
Stage 4	..	12	..	0 alive

192

20

Dead: 172.

The average tumour dose given has been 4,000 r in twenty-eight days, the maximum received being 5,000 r in fifty days.

Many cases were advanced when first seen and the general condition poor; they were ill patients, thin and wasted. Out of the 146, 59 had metastases when first seen, many had massive opacities and no attempt was made at selection. The length of history was short, the average being under six months, suggesting that carcinoma of the bronchus is a highly malignant cancer leading to cachexia sooner than most tumours. Although the oat-cell carcinoma appears the most sensitive type as judged by the radiological evidence of response, no marked prognostic difference was found between this growth and the squamous-cell variety. The average duration of symptoms in each was six months, and the average survival after treatment nine to nine and a half months. In carcinoma of the bronchus as it comes to us, 50% of treated patients are dead in six months, 75% in twelve months, and about 90 to 95% in two years. As Phillips noted, the problem is not entirely one of dosage, for cases treated to high dosage have done no better than those given a lower dose. Relief of symptoms is real, in most hæmoptysis will cease, and cough and dyspnœa are relieved, as a blocked bronchus reopens. In some, recurrence of growth occurred at the primary site, following heavy irradiation, and death was due to the effects of the primary tumour. Those patients who died within six months of treatment derived a little benefit, such as relief of hæmoptysis, or of spasms of dyspnœa. In very few was there no effect at all, but return of symptoms was rapid. In those that survived up to twelve to twenty-four months the initial response was greater, and some died of cerebral or bony metastases without return of chest symptoms, but in the large majority pain and cough returned, although hæmoptysis was controlled. One patient returned to heavy manual work for eighteen months. Of the 13 that survived over two years, 3 remained weak and poorly, but 10 regained almost normal health for twelve to twenty-four months, and then died from metastases with return of pains in the chest and cough.

Carcinoma of the Bladder

Total number of cases 40. 5 died within three weeks of admission. Cases analysed 35. Untraced 1. Males 25. Females 10. Alive 8. Dead 27.

Million-Volt X-Ray Research at St. Bartholomew's Hospital

By N. S. FINZI, M.B., D.M.R.E.

THE objects of the research were to determine whether there were any advantage in the million-volt over the 200 kV machines already in use, either by increasing the proportion of successful results or by getting these results with less disturbance of the healthy tissues or the patients' general health. It was hoped to use the higher voltage under as nearly similar conditions to the 200 kV machines as was possible. This, however, was found to be impracticable as the weight of the applicators was so great that none but a very strong man could place them in the apparatus. The consequence was that the focal-skin distance had to be lengthened and a different method of localizing the rays by means of an adjustable diaphragm on the tube had to be employed. A lighting system was used to show the exact field on the patient. It was realized from the beginning that no staggering improvement in results was to be expected.

The research was planned on certain definite groups of cases, as already indicated by Dr. Williams. Unfortunately the war interfered very greatly with this programme. At the beginning, the department was shut completely for three months and, when it was reopened, it was found necessary owing to bombing to take cases outside the groups arranged, because on many occasions the 200 kV apparatus could not be used as it was on the fourth floor which had a glass roof. Alerts were frequent and bombs not unknown. Consequently there were many cases in which the machine had to be used for palliation only.

The results up to 1944 were published in Mr. Ralph Phillips' book: "Supervoltage X-ray Therapy", London.

Our treatment of breast carcinoma with the 200 kV apparatus does not equal the results of those treated at Manchester. I do not think this is due to any lack of skill in the application of these radiations, which were mostly in the very capable hands of Dr. Walter Levitt. They merely indicated a difference in the type of case with which the Department was supplied. For instance, stage 1 was almost unknown and stage 2 was relatively rare. The results in these breast cases treated in the million-volt department, therefore, must be compared with our 200 kV and not with those at Manchester. In the other groups our 200 kV figures are similar to Manchester's 250 kV. In many cases the figures are too small to be significant, but I think they are probably significant in the breast, the antrum, the intrinsic larynx, and possibly in the rectum cases. As regards these last, there is no question in the minds of those who have seen the cases that in many of them great palliation is obtained. For instance, a doctor came with an inoperable carcinoma of the rectum for which he had had a colostomy, but his pain was so intense that he felt something must be done. For a considerable time the pain was completely relieved, narcotics were stopped and he got back to his practice for over a year. He was known to have deposits in the liver before we started the treatment and this eventually caused a relatively peaceful and painless end. Palliation in many other cases was equally striking.

I can cite two cases in which the lower voltage had failed and the million-volt secured a successful result. One was a case of carcinoma of the body of the uterus in a very stout patient which I treated myself with 360 kV with rays having a H.V.L. in Cu of 3.9 mm. A local recurrence was treated a year and a half later with the same voltage, but there was a further recurrence in another eighteen months which was treated by the million-volt, and she has remained free from recurrence since that time for six and a half years, though she occasionally bleeds from telangiectases in the bladder. The other case is one of carcinoma of the vocal cords treated by laryngofissure in 1941. Recurrence six months later in the anterior commissure; treated

from the same source they are a fairly representative comparison of treatment in similar groups of patients.

Site	1,000 kV	200 kV (1925-38)	200 kV (1938-44)
Breast	25% (37)	9% (148)	—
Tongue	0% (14)	6% (109)	4% (45)
Antrum	30% (10)	12% (51)	—
Extrinsic larynx ..	10% (32)	5% (167)	7% (58)
Intrinsic larynx ..	50% (16)	22% (27)	15% (19)
Post-cricoid	7% (13)	0% (51)	—
Œsophagus	0% (42)	0% (143)	0% (71)
Bronchus	2% (102)	2% (145)	0% (58)
Bladder	32% (25)	—	—
Anal canal	29% (23)	—	—
Rectum	6% (98)	2% (43)	0% (6)

It can be seen that there is marked difference in results in breast, antrum, intrinsic larynx and rectum, a definite difference in extrinsic larynx, whilst in the bladder and anal canal, survivals have been obtained in sites previously not treated by X-ray therapy.

SUMMARY

In survivals no very marked difference or improvement can be shown, although I would like to emphasize that the cases treated seem to have been in very advanced stages of dissemination even for a radiotherapy department. Certain facts stand out:

(1) Those tumours that respond poorly to ordinary X-ray therapy show no very marked differences in response to million-volt therapy, with the possible exception of carcinoma of the rectum, carcinoma of the bladder, carcinoma of the antrum and carcinoma of the larynx.

(2) There is no evidence of any biological difference in response due to the shorter wavelength used.

(3) The question of dosage remains obscure. For instance, many tumours recurred in the treated area following heavy irradiation, others were arrested by 3,000 r in fourteen to twenty-one days.

(4) Any improvement in results is, I believe, due to the physical advantages of greater penetration, and greater accuracy due to ease of application, i.e. the treatment is more efficient.

(5) As Holmes and Leucutia have pointed out, "there is no quality dependence in that neoplasms that fail to respond to deep roentgen therapy can be destroyed by high voltage therapy".

It is a pleasure for me to acknowledge my debt and my gratitude:

For the foresight of Professor Hopwood, Dr. Finzi, Dr. Levitt, Dr. Donaldson and the late Dr. Canti and the Honorary Staff of St. Bartholomew's Hospital.

For the courage and hard work carried out under the trying circumstances of the war and his own ill-health of Mr. Ralph Phillips. These were mostly his patients, it is his labour, and I am but giving the results of his efforts.

For the toil, labour and perseverance of Mr. George S. Innes, who built, cared for and maintained the machine as well as being responsible for all the Physical work. My thanks are also due to Mrs. Yendall, Miss Brewer, and our Welfare Department.

" 'Tis weary watching wave by wave
And yet the tide heaves onward.
We climb, like coral, grave by grave
That pave a pathway sunward.
We're driven back, for our next fray
A newer strength to borrow,
And where the vanguard camps today
The rear shall rest tomorrow."

Section of Ophthalmology

President—HAROLD LEVY, F.R.C.S.

[February 13, 1948]

MEETING HELD AT THE BIRMINGHAM AND MIDLAND EYE HOSPITAL, BIRMINGHAM

Demonstration: Fundus Photography in Colour

Dr. H. Campbell Orr (Wolverhampton) gave a demonstration on this subject, illustrated by a large series of colour slides. With the history of the photography of the fundus, he said, they were all well acquainted, but of the practical difficulties many of those present probably knew nothing. Using the Zeiss-Nordensen reflex-free camera, he was formerly able to obtain colour photographs of the fundus with an exposure of about one-fifth of a second, but now, for some reason, the exposure had to be about half a second, which was something of a strain on the patient, with the result that too frequently there was a slight movement of the eye.

He showed first of all a view of the normal fundus, illustrating how sharp the focus could be and how clearly the detail could be seen. His next photograph was taken to show small white glistening dots in the macular area. He drew attention to the delineation of the column of blood in the upper vessel. The young man in whose macula these white spots were present went through the whole of the African campaign and had no difficulty at all. The next example was of the fundus in retinitis pigmentosa, illustrating the characteristic pigment changes. A striking case was one in which there had been avulsion of the optic nerve. The patient had a motor accident in which the optic nerve was pulled out of the back of his eye, "just like a cork out of a bottle", and the picture showed how the fibrous tissue had filled the gap. In another case, the fundus of which was shown, the patient had a history of a blow on the eye with a snowball some years before. A detachment had resulted which healed spontaneously. The photograph was taken about eight or nine years ago, and the latest information was that the patient had developed a cataract of this eye.

In showing a picture of a case of coloboma of the macula, Dr. Campbell Orr said that the case was specially interesting in that the grandmother, the mother, and the child all had the same condition. His next case showed the early stage of arteriosclerotic retinitis, with the sclerotic changes well in evidence. The next, with considerable retinal changes, was a man who had had Paget's disease twelve years earlier. One case, which had been thoroughly investigated, was one of what appeared to be albuminuric retinitis. He saw the patient first at hospital, and thought it an ordinary refraction case, and having made the examination, told her to come back the following week to be fitted with glasses. The patient, however, did not improve. Minute dots were noticed around the macula, which was photographed. The appearance became worse and was photographed at intervals of five weeks. But the interesting thing about the case was that no albumin was ever found in the urine, and there was nothing else to suggest a kidney lesion. On a later examination the whole condition appeared to have cleared up. The vision was now 6/12 without glasses and 6/9 with glasses, and only a few pigment changes remained.

The next case was of a boy with myopia who came to see him once a year to have his glasses corrected. On one of these occasions he found optic neuritis and queried cerebral tumour. The boy was sent to a specialist in Birmingham who investigated the case but could find nothing. He saw him again three months later and the appearance was practically the same as in the earlier photograph. This time he insisted that the boy should go to a neurologist, and he was proved to have cerebral tumour. He died the day after his operation.

Two pictures of the fundus in the same patient were next shown. This was a young woman who had been under treatment from Christmas 1939 until June 1940, when she was sent from Birmingham to Glasgow, and there an operation took place, a tumour the size of a small tangerine orange being removed from the base of the brain. She came back to Birmingham, and when he last saw her she was perfectly fit and well, with nothing to suggest any trouble except for a little white fluffy appearance on the disc which, if one did not know the history, one would not have put down as anything abnormal.

The next case was one of papilloedema. The patient had had a malignant growth removed from her breast. The fundus picture showed very marked pale swelling of the optic disc. She was returned to her own doctor and was followed up for six years afterwards, but no trace of secondary growth was discovered. Why she should have had this fundus appearance without showing definite evidence of secondary growth he did not know. The next was a case of disseminated sclerosis. He pointed out a shadow which interested him in the picture of the fundus. This was followed by a case of typical macular chorioretinitis. In diabetic patients a slight haze was seen in the fundus which made it extremely difficult to get a clear

200 kV, dose 3,450 r in fifteen days, second degree skin reaction. March 1943: Large subglottic recurrence, treated on million-volt, 4,000 r in nineteen days. Now, five years later, remains well. The dose, when the biological difference of the radiation and the time factor are taken into account, would be approximately the same.

The occurrence of necrosis was almost entirely in the early cases, when the treatment was being investigated, and when large fields were used. Later, multiple small fields, carefully checked by isodose charts in each case, were used and this has probably very much diminished these troubles.

When one gets used to the method of working, I should consider the million-volt more accurate, and, by using a suitable technique, one could get results with far less damage to normal tissues and also, as the volume dose proves to be smaller, with less disturbance of the patient's general health.

Apart altogether from improvement in results, one would feel that this apparatus is an advance, even if the statistics were no better than with the lower voltage. Those who have worked with it prefer it to the lower-voltage installations on account both of ease of manipulation and the greater accuracy that can be attained. Correct localization depends upon the radiotherapist's clinical knowledge and acumen and results will always to an extent be influenced by this.

Actually the improvement in certain cases is large enough to justify the hope that with further experience we shall get better results and, with a greater increase in voltage, one might get better results still. As it is, the results improve from year to year. One thing must be remembered: if one's successes with 200 kV amount in a particular type of case to 15% and with 1,000 kV to 20%, this increase, although only 5% on the total cases, is actually an increase of 33% of the previous successful results.

We consider, therefore, that a still higher voltage should be tried and some years ago a fund was started at St. Bartholomew's Hospital for this purpose and to this, Mrs. Sassoon has contributed liberally, and a patient of mine also contributed a considerable sum through myself. There is some difference of opinion as to whether we make a big jump up or whether we try the intermediate voltages. Personally, I am very strongly in favour of not too big a jump in case we should miss the optimum biological voltage. Also there is always the possibility of unexpected difficulties. We should aim at a machine which could work at first at from 3 to 5 million volts, but which could be subsequently put up to 20 million volts.

One question on which we had hoped to get information if we got improved results was whether there was any biological difference or whether it was only due to being able to get the radiation to the correct place in sufficient amount. It seems to me that the improvement in the results in the antrum and in the intrinsic larynx cases is strongly in favour of a biological difference, though in most of the other cases the improved results could be attributed to physical differences and in the skin to a chemical effect.

I suggest that the million-volt machine shows already a definite advance and indicates that malignant disease should be treated by higher voltages still.

I wish to record my most grateful thanks to all those who have worked and are working in this important research; particularly to Professor Hopwood, the late Dr. Canti, Dr. Donaldson, Dr. Levitt, Mr. Ralph Phillips, Dr. I. G. Williams, and to Mr. G. S. Innes.

Bilateral Facial Paralysis and Abducens Palsy (Two Cases).—A. A. DOUGLAS, F.R.C.S.Ed.

Jean W., aged 11, and John A., aged 6. The two children showed an almost identical degree of nuclear agenesis, which presumably led to the striking similarity—not only facial, but also of the tongue, palate, teeth and indeed of the body generally.

Jean was of the hypothalamic type and John was putting on weight. Both had complete bilateral facial paralysis and congenital abduction deficiency. Both had had difficulty in swallowing during their first two years and showed evidence of affection of the twelfth nerves.

By a strange coincidence, both had been brought to the Out-patient Department on the same afternoon.

The ocular movements showed many interesting features. Movements of dextro- or levo-version were absent and apart from head movements refixation could only be achieved by convergence, which was accompanied by contraction of the pupils, whether near or distant objects were fixed. Bell's phenomenon was well seen in both cases.

Presumably tracts in the region of the oculomotor nuclei were affected.

Bilateral Corneal Lesions Caused by Blast.—A. A. DOUGLAS, F.R.C.S.Ed.

This patient was an elderly man, who had been involved in a factory explosion. He sustained very little general injury, but a few hours later had photophobia and dimness of vision. When seen the following day, he presented a striking bilateral corneal lesion unfamiliar to the exhibitor.

There was oedema of the epithelium. From the centre of each cornea, doubly contoured grey lines radiated, which branched and enclosed between them polygonal areas milky white in appearance.

Slit-lamp examination showed that the doubly contoured lines were indentations of the posterior corneal surface and that the polygonal areas protruded into the anterior chamber, the whole cornea being very greatly thickened. This was Phase 1. A month later the condition had greatly changed.

Phase 2: The doubly contoured lines were now protruding more posteriorly; the polygonal areas were now only faintly opaque; the cornea was of normal thickness. The lines were now clearly seen to be folds in Descemet's membrane. When the beam fell on them at certain angles, they looked like streaks of viscous fluid on the posterior corneal surface. Vision (from less than 6/60 each eye) had now risen to 6/24 and 6/18. One month later the condition had reverted to Phase 1 and the vision had again deteriorated: it was at present again in Phase 2, but this time the vision had improved very little. It seemed likely that the appearances in Phase 1 were due to the entrance of fluid into the corneal substance, which became swollen and hydropic.

No alteration in the intra-ocular tension was observed.

Mr. P. Jameson Evans said that he had seen blast injuries arising from enemy action, though he had not followed these cases through. Similar conditions might arise after cataract extraction, where, even after a period of recovery of some six months, the cornea would be divided up into small polygonal areas. He had seen two such cataract cases, and apparently the condition became permanent.

Five cases by P. JAMESON EVANS, F.R.C.S.

Mr. Jameson Evans said that the first three of these cases were exhibited to show the effect of irradiation in regard to vasosclerosis.

I. Persistent Keratitis.

Male, aged 24.

This was a case of persistent keratitis of about two years' duration which had recovered and the patient had resumed an active life. When first seen, the condition looked strumous. It had been treated in various ways, including the use of tuberculin, but still persisted with active vascularity of the cornea in the interstitial layer. It was treated by stitching a 2 milli-curie radon seed underneath the conjunctiva close to the limbus and overlying the major vessels encroaching on the cornea; forty-eight hours later the seed was removed. Within twelve months the vision, which had been 6/60 or less, began to improve, and within eighteen months the vision was 6/12 and the opacity in the cornea had almost entirely absorbed.

II. Acne Rosacea Keratitis.

Male, aged 56.

The second case was similar to Case I—an acne rosacea keratitis which had resisted all sorts of treatment and was getting more and more frequently involved in attacks of vascularity. This was treated with two radon seeds on the nasal side under the conjunctiva, one in each eye, left in for forty-eight hours. It was noticeable that in this case there was very much less reaction to the radon, and the sclerosis of the vessels appeared to come on more quickly. That was about nine months ago, and there had been no recurrence of active vascularity of either eye since.

picture. Rarely did one get a picture of the diabetic fundus in which the detail was clearly seen, any more than in the view with the ophthalmoscope. But he pointed out how the changes in the vessel wall were gradually thinning down the stream of blood. In the case exhibited the blood-pressure was 220, and the albumin was rather marked in the urine, but the patient lived for at least three years after the picture was taken. The next example showed symmetrical macular degeneration in an old man with arteriosclerosis.

A great deal of information was obtainable from the appearance of the venous system of the fundus in such cases as diabetic retinitis. In some cases it was interesting to use the Gullstrand ophthalmoscope, with which the corpuscles could be seen rolling over and over in their passage down the vessel, the blood-stream having been slowed very considerably.

Dr. Campbell Orr showed the views of several other fundi, including one in the case of a stout plethoric individual, with a blood-pressure of 210, and another in an old lady of 70, with a blood-pressure of 240 and senile macular changes.

The fundus was shown of one interesting case in which a piece of steel had been embedded in the eye. The patient had felt a blow on the eye but had not paid much attention to it until he noticed, some time later, that he could not see quite as well as formerly. He came to hospital where the photograph of the fundus showed the piece of steel and how the fibrous tissue from the wound of entry above came down and covered the foreign body. Yet that piece of steel had not been in the eye for more than a few days. He always held that with a metallic foreign body which was magnetic the magnet should be applied first and the X-rays afterwards. Every hour that was lost made it more difficult to get the foreign body out. The X-ray photograph could be used afterwards if the magnet had failed. The rapidity with which this piece of steel was sheathed by the fibrous tissue was instructive.

The next patient whose fundus was shown was aged 72 and had detachment of the retina. Deutschmann's operation was done in 1922, and afterwards no view of the fundus could be obtained for many years. A picture of the eye of the same patient was taken recently because of the choroidal sclerosis. The retina was right back in position, but the eye was blind. The lecturer's final picture showed a case of choroideremia.

Three cases by Mrs. D. R. CAMPBELL, M.B.

I. Bitot Spot (photograph and report).

The interest of this case lies in the association of Bitot spot with a particularly low blood vitamin A. The patient had a Bitot spot of some size, and for about three months previously he had been on big doses of vitamin A. After these were stopped his blood vitamin A fell from 192 International Units per 100 ml. to 39 on one occasion, and 46 on another. In comparison a large number of estimations had been carried out at the hospital on normal individuals following various occupations, for about a year, and on present rationing the vitamin content of the blood was level—about 100.

The conjunctivæ in this patient were opaque and yellow, and the whole face was lustreless. On vitamin A his complexion improved, and the conjunctivæ regained a pink colour, but the Bitot spot did not disappear. It was possible to scrape off foamy epithelium, leaving a crater. It was subsequently excised, and the patient had had no recurrence.

Discussion.—A member asked what was the nationality of this patient and was informed that he was English. He said that he had seen Bitot spot in Arabs.

II. Bilateral Microphthalmos with Orbital Cyst.

This girl, who had been born blind, did not come to hospital until she was 18, when the cysts had become swollen, and one in the right eye, in the lower lid, was distended and was causing pain. The cysts were taken out, and with the idea of keeping the conjunctiva as far as possible, an external canthorhaphy was done, the lid margin was split, the cyst was dissected from below, and then everted right out. A good layer of conjunctiva remained, with a central hole, corresponding to the limbal margin of a normal eye. The patient was fitted with a pair of small artificial eyes which gave her a rather more normal appearance.

Primitive retinal tissue and the optic nerve were visible in the right cyst. The specimen from the left side showed a rudimentary eye with primitive cornea, pigmented uveal tissue, and a mass of tissue which corresponded to the lens. Posteriorly there was a patch of primitive neural tissue and another outside the rudimentary eye.

III. Sjögren's Disease: Case fitted with Contact Lenses.

All the symptoms and signs of Sjögren's disease were present in this case—parotid swelling and keratitis, &c. The patient also had rheumatic signs and still had intermittent pyrexia. She had had X-ray therapy to the parotids. The case had been diagnosed but no one could produce any better treatment for her. Cauterization of the punctæ brought about temporary improvement. Finally she had contact lenses, and was very much better so far as the eyes were concerned, but her general health was deteriorating. Vitamin therapy of all kinds had been tried, including riboflavine. The blood vitamin A was estimated and was perfectly normal.

Bilateral Facial Paralysis and Abducens Palsy (Two Cases).—A. A. DOUGLAS, F.R.C.S.Ed.

Jean W., aged 11, and John A., aged 6. The two children showed an almost identical degree of nuclear agenesis, which presumably led to the striking similarity—not only facial, but also of the tongue, palate, teeth and indeed of the body generally.

Jean was of the hypothalamic type and John was putting on weight. Both had complete bilateral facial paralysis and congenital abduction deficiency. Both had had difficulty in swallowing during their first two years and showed evidence of affection of the twelfth nerves.

By a strange coincidence, both had been brought to the Out-patient Department on the same afternoon.

The ocular movements showed many interesting features. Movements of dextro- or levo-version were absent and apart from head movements refixation could only be achieved by convergence, which was accompanied by contraction of the pupils, whether near or distant objects were fixed. Bell's phenomenon was well seen in both cases.

Presumably tracts in the region of the oculomotor nuclei were affected.

Bilateral Corneal Lesions Caused by Blast.—A. A. DOUGLAS, F.R.C.S.Ed.

This patient was an elderly man, who had been involved in a factory explosion. He sustained very little general injury, but a few hours later had photophobia and dimness of vision. When seen the following day, he presented a striking bilateral corneal lesion unfamiliar to the exhibitor.

There was œdema of the epithelium. From the centre of each cornea, doubly contoured grey lines radiated, which branched and enclosed between them polygonal areas milky white in appearance.

Slit-lamp examination showed that the doubly contoured lines were indentations of the posterior corneal surface and that the polygonal areas protruded into the anterior chamber, the whole cornea being very greatly thickened. This was Phase 1. A month later the condition had greatly changed.

Phase 2: The doubly contoured lines were now protruding more posteriorly; the polygonal areas were now only faintly opaque; the cornea was of normal thickness. The lines were now clearly seen to be folds in Descemet's membrane. When the beam fell on them at certain angles, they looked like streaks of viscous fluid on the posterior corneal surface. Vision (from less than 6/60 each eye) had now risen to 6/24 and 6/18. One month later the condition had reverted to Phase 1 and the vision had again deteriorated: it was at present again in Phase 2, but this time the vision had improved very little. It seemed likely that the appearances in Phase 1 were due to the entrance of fluid into the corneal substance, which became swollen and hydropic.

No alteration in the intra-ocular tension was observed.

Mr. P. Jameson Evans said that he had seen blast injuries arising from enemy action, though he had not followed these cases through. Similar conditions might arise after cataract extraction, where, even after a period of recovery of some six months, the cornea would be divided up into small polygonal areas. He had seen two such cataract cases, and apparently the condition became permanent.

Five cases by P. JAMESON EVANS, F.R.C.S.

Mr. Jameson Evans said that the first three of these cases were exhibited to show the effect of irradiation in regard to vasosclerosis.

I. Persistent Keratitis.

Male, aged 24.

This was a case of persistent keratitis of about two years' duration which had recovered and the patient had resumed an active life. When first seen, the condition looked strumous. It had been treated in various ways, including the use of tuberculin, but still persisted with active vascularity of the cornea in the interstitial layer. It was treated by stitching a 2 millimetre radon seed underneath the conjunctiva close to the limbus and overlying the major vessels encroaching on the cornea; forty-eight hours later the seed was removed. Within twelve months the vision, which had been 6/60 or less, began to improve, and within eighteen months the vision was 6/12 and the opacity in the cornea had almost entirely absorbed.

II. Acne Rosacea Keratitis.

Male, aged 56.

The second case was similar to Case I—an acne rosacea keratitis which had resisted all sorts of treatment and was getting more and more frequently involved in attacks of vascularity. This was treated with two radon seeds on the nasal side under the conjunctiva, one in each eye, left in for forty-eight hours. It was noticeable that in this case there was very much less reaction to the radon, and the sclerosis of the vessels appeared to come on more quickly. That was about nine months ago, and there had been no recurrence of active vascularity of either eye since.

III. Eales' Disease.

Female, aged 23.

Deep X-rays to the posterior half of the globe were thought to be indicated, and were given three months ago. For about twelve months the right eye had had very little vision; when first seen the vision in the right eye was 6/60. The patient had 4,000 r at the skin, equivalent to 2,000 r at the retina. This was given in doses of 500 r twice a week and occupied a month. In about two months the vitreous opacity had cleared up, but the patient had had a recurrence of hæmorrhage and the vision had gone back to 6/24.

Mr. Jameson Evans hoped to be able to show the case again in twelve months' time and to report that she had not had a recurrence of hæmorrhage.

IV. Marfan Syndrome.

Female, aged 18.

The patient had a typical subluxation of the lenses. She had long fingers and limbs, was very tall, and had a heart murmur.

V. Temple-Smith Operation.

Female, aged 9.

This case was shown to illustrate the result of the Temple-Smith or Himmelsheim operation, which had taken place about fifteen months previously. The child had an external rectus palsy of the left eye, and was treated by double tendon slip graft. In this case it was combined with a recession of the internal rectus. Her internal movement was not quite full.

Fibrosis of Posterior Vascular Sheath of Lens.—N. P. R. GALLOWAY, M.B.

Mr. Galloway said that this case showed a condition not often described and one, he thought, of great interest. The child was a twin and nine weeks premature. There was microphthalmia and nystagmus. The pupils did not react to light when he first saw them, and he could not make out whether the child could see or not. There was no history of similar trouble in the family. Terry had published very similar cases in *Archives of Ophthalmology*, Chicago, 1943, 29, 36.

In the discussion in the *Archives* there seemed to be a good deal of difference of opinion as to methods of treatment. In some of the cases the fibrous mass at the back of the lens had ruptured spontaneously after some months, allowing the fundus to be seen.

Mr. A. S. Philips said that in Mr. Galloway's case of persistence of the posterior vascular sheath of the lens he would needle the lens first, and when the lens substance had absorbed he would divide the tissue at the back with a Wheeler's knife.

Mr. P. McG. Moffatt said that he had had great difficulty in one such case in getting rid of the lens. He had already needled it three times, and when he looked at it afterwards the lens each time had not gone opaque.

Mr. Jameson Evans said, in reference to what Mr. Moffatt had just stated, that he had had some trouble with abnormal lenses. He had tried a number of the usual procedures, but it seemed that the abnormal lens was not absorbed in the normal way on needling. The true diabetic cataract in young people also did not absorb well, and he believed the same was true of cataract in infants whose mothers had rubella in early pregnancy.

Mr. P. McG. Moffatt said that in Professor Vogt's Atlas it was stated that where there were difficulties in getting rid of the lens, as happened frequently in the case of subluxated lenses, it was because the capsule was relaxed. He argued that relaxation of the capsule hindered the aqueous from entering the lens substance and thereby preventing absorption. If this were true the correct treatment for small uncomplicated perforating injuries of the lens would be the use of miotics and not mydriatics.

Mr. I. Lloyd Johnstone said that he had had some experience of cataract and microphthalmia with mental abnormality in young children. He thought there was a definite syndrome. He had tried to trace any relationship with illness during the mother's pregnancy, but had not succeeded. Some of these children had been under observation for seven years, and it was difficult to say how much they could see.

Meningioma en Plaque of Inner Sphenoidal Ridge (Two Cases).—BRODIE HUGHES, F.R.C.S.

CASE I. Mrs. A. K., aged 47. (Referred by Mr. G. N. Pattison.)

Localized left frontal headaches of five years' duration—failing vision left eye for three months. Vision and field of right eye normal, and no abnormality in the nervous system apart from left eye.

Left eye displaced forward, but no limitation of external ocular movement. No pulsation and no tumour palpable in the orbit. Vision reduced to doubtful light perception at the field periphery. Fundus: severe primary optic atrophy. X-rays show diffuse hyperostosis with bone sclerosis affecting the inner sphenoidal ridge and roof of orbit on the left side. Optic canal is narrowed and its whole circumference affected by the bony lesion.

Operation on 20.10.47: Small left frontal bone flap—no intradural tumour found but dura over affected bone was thickened and hyperæmic. Posterior half of orbital roof and

whole of sphenoidal ridge removed together with the superior and lateral walls of optic canal.

No recovery of vision but some diminution in proptosis.

CASE II. Mrs. E. G., aged 43. (Referred by Mr. C. Rudd.)

Localized right frontal headache for three years—failing vision and protrusion of the right eye for six months.

Abnormal physical signs confined to the right eye. This is displaced forwards but without limitation of external ocular movement. Vision reduced to bare light perception—fundus shows severe primary optic atrophy.

X-rays showed localized hyperostosis of the inner third of the sphenoidal ridge surrounding the optic canal.

Operation on 7.11.47: Small right frontal bone flap and removal of the whole of the sphenoidal ridge together with the superior and lateral walls of the optic canal.

No recovery of vision but some decrease in proptosis.

Monocular Congenital Cataract.—I. LLOYD JOHNSTONE, M.C., M.D.

Mr. Lloyd Johnstone said that the main points of the case were that it was monocular and had an interesting and unusual slit-lamp appearance: (a) slight anterior opacity; (b) perinuclear fine granular spotting; (c) posterior white fluffy ring with a hole in the centre.

Chainmaker's Cataract.—L. H. G. MOORE, M.B., Ch.B., D.O.M.S.

Dr. Moore said that in the Black Country chains were still made by hand and the workers developed this particular type of cataract. The case presented showed well the exfoliation of the anterior capsule. The ordinary link-maker worked always with the fire on his left, and his left cataract was always to a certain extent in advance of his right. It was because of the exfoliation of the lamella of the anterior capsule that he had brought this patient along.

In reply to the President, who asked whether it was possible to get these people to wear protective goggles, Dr. Moore said that they would not wear anything which they were compelled frequently to take off and wipe.

Mr. Lloyd Johnstone said that the condition took about twenty-five years to develop and that the workers could not see the reason for wearing protective goggles because of this long period.

Melanotic Sarcoma of Choroid in Second Eye, treated by Radon.—C. RUDD, M.B.

Mr. Rudd said this was an interesting case because the patient had had the left eye removed for definite sarcoma of the choroid in 1942, and two years later came up with a perfectly typical melanotic sarcoma in the other eye. He was reluctant to excise the second eye and so he had tried radon. The marked atrophy of the choroid in the region of the mass could be observed and the growth was smaller than formerly. The vision was 6/24.

Tumour of the Para-macular Region.—Major K. MEHTA, M.B. (introduced by P. JAMESON EVANS, F.R.C.S.).

Mr. Jameson Evans said that this was the case of a soldier with a raised mass below and extending out from the left macula. The mass showed pigmentary changes at the edges. The history was of three years' duration, and there had been no improvement of vision.

The general consensus of opinion among members was that the condition was exudative and allied to Coats's disease.

Angioma of Retina.—FLORENCE HENRY, M.B. (introduced by C. RUDD, M.B.).

Mr. Rudd, on behalf of Dr. Henry, said that this was the case of a child with a whitish patch in the retina. It has been observed now for about five years and there had been no change.

The following cases were also shown:

(1) Opaque Nerve Fibres. (2) Von Hippel's Disease.—Mr. H. W. ARCHER-HALL.

Foreign Body in Upper Temporal Quadrant.—Dr. H. CAMPBELL ORR.

Central Exudative Retinitis.—Mr. P. JAMESON EVANS.

Macular Swelling (for Diagnosis).—Mr. N. P. R. GALLOWAY.

Retinal Hole.—Mr. I. LLOYD JOHNSTONE.

Foreign Body on Iris, Simulating Neoplasm.—Mr. T. P. KERWICK.

(1) Exudative Retinitis. ? Coats's Disease. (2) Congenital Absence of Orbicularis Oculi.—Mr. C. MARTIN-DOYLE.

(1) Sjögren's Disease. (2) Central Retinopathy.—? Exudative, ? Neoplastic—for Diagnosis.—Mr. C. RUDD.

Arteriovenous Fistula at Base of Skull.—Mr. R. W. STEPHENSON.

Patch in Lower Part of Lens.—Mr. J. G. DRUMMOND CURRIE.

OCT.—OPHTHAL. 2.

III. Eales' Disease.

Female, aged 23.

Deep X-rays to the posterior half of the globe were thought to be indicated, and were given three months ago. For about twelve months the right eye had had very little vision; when first seen the vision in the right eye was 6/60. The patient had 4,000 r at the skin, equivalent to 2,000 r at the retina. This was given in doses of 500 r twice a week and occupied a month. In about two months the vitreous opacity had cleared up, but the patient had had a recurrence of hæmorrhage and the vision had gone back to 6/24.

Mr. Jameson Evans hoped to be able to show the case again in twelve months' time and to report that she had not had a recurrence of hæmorrhage.

IV. Marfan Syndrome.

Female, aged 18.

The patient had a typical subluxation of the lenses. She had long fingers and limbs, was very tall, and had a heart murmur.

V. Temple-Smith Operation.

Female, aged 9.

This case was shown to illustrate the result of the Temple-Smith or Hümelsheim operation, which had taken place about fifteen months previously. The child had an external rectus palsy of the left eye, and was treated by double tendon slip graft. In this case it was combined with a recession of the internal rectus. Her internal movement was not quite full.

Fibrosis of Posterior Vascular Sheath of Lens.—N. P. R. GALLOWAY, M.B.

Mr. Galloway said that this case showed a condition not often described and one, he thought, of great interest. The child was a twin and nine weeks premature. There was microphthalmia and nystagmus. The pupils did not react to light when he first saw them, and he could not make out whether the child could see or not. There was no history of similar trouble in the family. Terry had published very similar cases in *Archives of Ophthalmology*, Chicago, 1943, 29, 36.

In the discussion in the *Archives* there seemed to be a good deal of difference of opinion as to methods of treatment. In some of the cases the fibrous mass at the back of the lens had ruptured spontaneously after some months, allowing the fundus to be seen.

Mr. A. S. Philips said that in Mr. Galloway's case of persistence of the posterior vascular sheath of the lens he would needle the lens first, and when the lens substance had absorbed he would divide the tissue at the back with a Wheeler's knife.

Mr. P. McG. Moffatt said that he had had great difficulty in one such case in getting rid of the lens. He had already needled it three times, and when he looked at it afterwards the lens each time had not gone opaque.

Mr. Jameson Evans said, in reference to what Mr. Moffatt had just stated, that he had had some trouble with abnormal lenses. He had tried a number of the usual procedures, but it seemed that the abnormal lens was not absorbed in the normal way on needling. The true diabetic cataract in young people also did not absorb well, and he believed the same was true of cataract in infants whose mothers had rubella in early pregnancy.

Mr. P. McG. Moffatt said that in Professor Vogt's Atlas it was stated that where there were difficulties in getting rid of the lens, as happened frequently in the case of subluxated lenses, it was because the capsule was relaxed. He argued that relaxation of the capsule hindered the aqueous from entering the lens substance and thereby preventing absorption. If this were true the correct treatment for small uncomplicated perforating injuries of the lens would be the use of miotics and not mydratics.

Mr. I. Lloyd Johnstone said that he had had some experience of cataract and microphthalmia with mental abnormality in young children. He thought there was a definite syndrome. He had tried to trace any relationship with illness during the mother's pregnancy, but had not succeeded. Some of these children had been under observation for seven years, and it was difficult to say how much they could see.

Meningioma en Plaque of Inner Sphenoidal Ridge (Two Cases).—BRODIE HUGHES, F.R.C.S.

CASE I. Mrs. A. K., aged 47. (Referred by Mr. G. N. Pattison.)

Localized left frontal headaches of five years' duration—failing vision left eye for three months. Vision and field of right eye normal, and no abnormality in the nervous system apart from left eye.

Left eye displaced forward, but no limitation of external ocular movement. No pulsation and no tumour palpable in the orbit. Vision reduced to doubtful light perception at the field periphery. Fundus: severe primary optic atrophy. X-rays show diffuse hyperostosis with bone sclerosis affecting the inner sphenoidal ridge and roof of orbit on the left side. Optic canal is narrowed and its whole circumference affected by the bony lesion.

Operation on 20.10.47: Small left frontal bone flap—no intradural tumour found but dura over affected bone was thickened and hyperæmic. Posterior half of orbital roof and

discs were of good colour and the vessels of the retina of good size. The question arose whether it was a congenital condition or an inflammatory condition of some sort. There was no opacity in the vitreous and with such a degree of inflammatory lesion one might have

FIG. 1.

expected a little more evidence in other parts of the eye. In some cases the pigment was situated in front of the vessels. The Wassermann was negative. There was no evidence of any chest complaint or of anything wrong in the general condition. Other members of the family were examined without any abnormal condition being found.

Mr. Frank Law said that he had notes of a similar case. This was in a lady, aged 37, who was sent to him in 1943 because she was worried about her eyes. She said that her vision had always been bad. Her vision corrected was 6/12 in the right eye and a little over 6/18 in the left. He found similar changes in both fundi limited to the distribution of the vessels, in particular the veins. The pigment was coarse. The vessels were rather small and the discs yellowish in colour. The choroid was well seen in the areas concerned. He had never seen anything like it before. The patient had told him she was very fair as a child. She had married at the age of 22, and she had one child. The Wassermann was negative.

The appearance of the fields and the vision were unchanged in 1946 and in 1947. When she came to see him in 1946 she was pregnant and he wondered what the effect of the nervous and emotional strain associated with pregnancy would be upon her eye condition, but she miscarried at 3 months.

He showed a drawing of the appearance of the fundus. The colour of the disc was rather meagre, but the choroid, in particular in one area on the inferior part, was seen very clearly. It was not quite so well marked along the course of each vessel as in Mr. Morgan's case. The fields (which he showed) were extremely difficult to take.

Hypertensive Retinal Changes and Sympathectomy.—R. W. STEPHENSON, D.O.M.S.

J. S., male, 38.

April 28, 1947: Five years ago began to have severe headaches. His doctor found high blood-pressure. Condition improved with conservative measures. Recurrence of symptoms two years later, similarly relieved. A week ago R. vision misty, rapidly getting worse and affecting nasal side of field. V.R. 6/12 part.; V.L. 6/5. R. fundus: Some swelling of disc. Haemorrhages and exudates especially in lower temporal quadrant. Marked arteriosclerotic changes. Veins very tortuous and somewhat engorged, arteries narrowed. L. fundus: Similar to right but changes less marked. R. field contracted to within a few degrees of fixation point on nasal side, full on lower temporal side.

I advised that he was probably a suitable case for sympathectomy, as this would offer the only chance of ameliorating his condition and prolonging his life.

He was sent to Mr. A. L. d'Abreu of Birmingham.

C.N.S.: Pulse regular, 84. B.P. 220/150 remaining very constant during preliminary rest period. X-ray of chest showed increase in cardiac diameter.

[March 11, 1948]

? Conglomerate Tubercle. ? Sarcoidosis of the Iris.—A. J. CAMERON, F.R.C.S.

F. O'C., married woman, aged 25.

History.—This case was seen on routine "Out-Patient" examination on 3.11.47 when a history was given that her baby had poked a finger in the left eye. Previous history: "nervous breakdown" following upon childbirth in April to November 1946, and erythema nodosum in November 1947.

On examination.—There were massive "K.P." all over the cornea and a mass in the angle of the anterior chamber.

A diagnosis was made of ? Conglomerate Tubercle.

Investigations.—Kahn test negative. Mantoux test negative.

Blood-count.—Hb 96%; R.B.C. 5,000,000; C.I. 0.96; mean diameter 7.15μ ; W.B.C. 6,400 (polys. 59%, eosinos. 4%, basos. 1%, monos. 9%, lymphos. 27%). E.S.R. 14 mm. in 1 hour.

X-ray report: "Fairly extensive interstitial fibrosis and increased vascular markings of both lungs. Enlarged hilar shadows. The appearances are those of a Boeck's sarcoidosis."

Further X-rays revealed no other abnormality.

Dr. Clifford Hoyle of the Brompton Hospital reported: "The clinical course is that of sarcoid in its strikingly benign character with so little disturbance of her general health and so little in the way of focal symptoms, in spite of extensive lesions in both lungs and the bronchopulmonary glands. Moreover, the lesions are not changing rapidly radiologically, nor showing progressive cavitation. But, on the other hand, we not uncommonly see all these features early on in cases that later prove, by a positive sputum or biopsy findings, to have been tuberculous all along."

7.2.48: A new and separate nodule was found deep in the anterior chamber, about five o'clock, and the previous generalized mass seemed, perhaps, a little less.

25.2.48: The original mass had receded considerably and could just be seen deep in the angle with a large adhesion of the iris just about six o'clock on the margin of the pupil and a secondary nodule adjacent to it.

It is interesting that the condition remained stationary and quiescent for so long and then suddenly began to regress, but according to Parsons and to Duke-Elder that is, of course, the usual procedure which a conglomerate tubercle follows. It is also of some interest that the radiologist should have diagnosed sarcoid disease from the X-rays alone.

The patient's general appearance is good and she has been treated simply locally with atropine and her general health improved as far as possible.

Conglomerate tubercle of the iris and ciliary body was first described by Gradenigo as far back as 1860.

- DUKE-ELDER, WILLIAM S. (1942) *Textbook of Ophthalmology*, London.
PARSONS, J. H. (1908) *The Pathology of the Eye*. London.

Mr. R. Lindsay-Rea said that such a case as this was better appreciated by viewing it with a Zeiss binocular than by a slit-lamp. He himself had experience of a case, undoubtedly a sarcoid but which, in Switzerland, was diagnosed as osteitis cystica tuberculosa. The majority of authorities on this disease agreed that it was most probably tubercular.

Two Cases by B. W. RYCROFT, O.B.E., F.R.C.S.

I. Corneal Graft of Thirteen Years' Duration.

This patient had a 4 mm. circular corneal graft carried out in December 1934. Her vision is now 6/36 and she is able to get about by herself and do her own shopping and housework (see *Brit. med. J.*, 1935 (i), 919). She has been removed from the Blind Register.

Mr. Rycroft, in reply to a question by Mr. E. F. King, said that he had used a 4.1 mm. trephine and had trimmed the edge with scissors and forceps all the way round.

II. Malignant Hypertension with Severe Retinopathy, treated by Lumbothoracic Sympathectomy.

This patient was seen in July 1946 with severe papilloedema and superficial retinal haemorrhages of both eyes. In September 1946 Mr. R. C. Brock carried out lumbothoracic sympathectomy and there has been a steady improvement ever since then. Present condition: R.V. 6/9—L.V. 6/5.

? Congenital Pigmentation of the Retina.—O. GAYER MORGAN, M.Ch.

Mr. Gayer Morgan said that this boy, aged 11, had come up for routine examination at school. Vision was 6/6 in each eye but on examining the fundus a curious arrangement of pigment was found along the vessels, with a certain degree of atrophy. The appearance was relatively symmetrical, affecting both eyes (see fig. 1). There was no night blindness. The

discs were of good colour and the vessels of the retina of good size. The question arose whether it was a congenital condition or an inflammatory condition of some sort. There was no opacity in the vitreous and with such a degree of inflammatory lesion one might have

FIG. 1.

expected a little more evidence in other parts of the eye. In some cases the pigment was situated in front of the vessels. The Wassermann was negative. ? Congenital Pigmentation of the Retina.—O. GAYER MORGAN, M.Ch.

Mr. Gayer Morgan said that this boy, aged 11, had come up for routine examination at school. Vision was 6/6 in each eye but on examining the fundus a curious arrangement of pigment was found along the vessels, with a certain degree of atrophy. The appearance was relatively symmetrical, affecting both eyes (see fig. 1). There was no night blindness. The

perfectly normal raised blood-pressure. As a result of emotion, as we saw frequently in young recruits, such an individual may have a systolic pressure sent up to 160 or 180 with some increase in the diastolic. This is transient and then, as years go by, occur these changes in the kidney to which I have referred, the formation of the renal by-pass with a more persistent renin formation, and simultaneously the slowly increasing blood-pressure. Still at this stage there is the added effect of emotion, so that there is transitory spasm in the healthy parts of these kidneys, and therefore we have not only the permanent part of hypertension but also the transitory part as well.

It is not until perhaps the age of 40 or even higher that the arteriosclerotic degeneration occurs. This, of course, takes place in all sorts of diseases, but it seems to affect the kidney before anything else. It may also involve the coronary circulation, and it may and frequently does affect the retina as well. The heart remains normal and, unless there is arteriosclerosis of the coronary circulation or of the cerebral circulation, the individual will not have a vascular lesion.

I think it is perhaps true to say that hypertension itself is harmless. That sounds paradoxical. But we have all of us seen people in whom at the age of 20 a somewhat raised blood-pressure is found, and who for twenty years have remained perfectly well, without symptoms and without any change. I asked the Swedish surgeons who have been interested in coarctation of the aorta whether, in their cases, they had ever met retinitis as a result of what amounts to experimental hypertension in healthy young adults. They had never met it, so that it would seem that hypertension does not produce retinitis or other changes alone provided the blood-vessels remain healthy. In these cases one has a very good control experiment.

The cause of the hypertensive vascular complications is—to use the old phrase perhaps advisedly—a softening of the arteries. The change that occurs in every aorta at the age of 40-60 is atheroma. There are degenerative changes in the smaller vessels also but this is a separate change, it is a degeneration quite apart from that caused by hypertension. The change may be sometimes exaggerated and brought forward in the terms of the patient's age. For example, in a young individual with nephritis, whether it be due to a positive poisoning or to some negative deficiency, the arterial system shows this degeneration to a very extensive degree and very early, and I think it is extremely important to bring this point before ophthalmologists, because it means that in the search for a further explanation one must not be satisfied with hypertension alone as being the cause of retinitis in hypertension.

I have the notes of the case of such a young man, aged 21, who had what was called malignant hypertension. As a result of sympathectomy (this was the second operation) his systolic pressure fell from 220 to about 160 and his diastolic from 140 to about 120. He had a transitory increase in the blood urea which was afterwards considerably improved. The interesting thing is that sympathectomy in this sort of case clears up to an amazing extent the retinopathy, but it does not permanently cure the patient of the hypertension. I have at the present moment in my wards one of these patients who was very nearly blind and had extensive changes in his retinae which were cleared up so that he can now read small print whereas previously he could not read large headlines. But he has now again been admitted, this time with severe hypertension and heart failure. His blood-pressure is quite as high as before but his retinae have remained normal, so it would seem that the improvement of his renal circulation has helped in the regression of the degenerative process in the retinae. It has not permanently affected the hypertension, however, and one would not expect it to do so, because he must have permanently diseased kidneys from which renin is still coming.

When is sympathectomy justifiable? It may on the one hand be done twenty years before it is necessary. But on the other hand if it is done too late there is an established and permanent degeneration in the kidneys. Therefore one has to remember (1) that the changes in the kidney are usually in advance of those which occur in the retina, and (2) that it is upon the ophthalmic surgeon that we very greatly rely in helping us to decide what is the state of the visible peripheral arteries. It seems to me that certain definite criteria should be fixed to try to determine when the arteries in the kidney are perfectly normal, when there is spasm only, and when there is sclerosis; also, of course, the final change when there is papilloedema and hæmorrhage.

For research in the young adult records might be taken of specific vessels in the same patient from time to time and the effect of amyl nitrite or sodium amytal, which causes relaxation of the arterial pressure, might be elicited. Simultaneously a photographic examination might be made of the retina. It might be possible, on these lines, to produce and make available a series of tests that will tell us exactly what the retinal arteries are doing in the earlier stages.

Mr. E. G. Tuckwell: Sympathectomy and splanchnic neurectomy are often unsuccessful in lowering the blood-pressure to a normal figure, but it is apparent that the symptoms of the patient are relieved in a great many more cases; I believe this to be due to the fact that after operation the blood-pressure is steadier at a mean level, and that the fluctuating pressure

Renal functions: Blood urea 48 mg.%; urea concentration test—to 3.2%; urea clearance: 1st hour 131% of normal; 2nd hour 178% of normal. Urine: occasional hyaline and granular casts, otherwise normal.

Bilateral two-stage transthoraco-lumbar sympathectomy on 13.5.47 and 3.6.47.

Symptomatic improvement with freedom from headache. B.P. 185/140.

August 2, 1947: B.P. 185/100. V.R. 6/6 pt. V.L. 6/5. Fundi: No hæmorrhages or exudates or œdema. October 1947: B.P. 178/120; November and December: 180/120. January 180/125.

March 3, 1948: V.R. 6/6 with +0.5 D.sph. = 6/5 pt. V.L. 6/5 pt. with +0.5 D.sph. = 6/5.

R. fundus: No hæmorrhages or exudates. Arteries show very marked narrowing and sheathing. The veins are normal in calibre.

L. fundus: Similar to above but narrowing and sheathing not so marked as in R.

R. field still shows contraction on nasal side.

The most interesting point in the case is the considerable increase in the arteriosclerotic changes in the retinal vessels since the operation.

DISCUSSION ON THE EFFECT OF SYMPATHECTOMY ON HYPERTENSIVE RETINAL CHANGES

Dr. Geoffrey Bourne: It was thought for many years that raised blood-pressure was due to an actual sclerosis of the peripheral circulation. This, we know now, is not the case. The actual hypertension itself is, from the first to the last, spasmodic in its nature. It probably starts in the 'teens in many cases and it is then very little more than an excessive physiological reaction.

It is thought now by Trueta that the actual pressor substances formed by the kidney may at first be, as it were, a physiological reaction, and he tentatively suggests that in certain individuals psychological stimuli—the ordinary stimuli of the emotions, fear or excitement—do actually produce a blanching of the renal cortex. From this blanched cortex, of course, the blood is excluded. But by the blanching renin is produced. The purpose of the production of renin is to raise the peripheral circulatory pressure so that the cortex may not be further and unnecessarily deprived of its blood supply. It is very easy to see how this in such an individual can occur and recur, and after a number of years it has its effect. This effect as regards the renal circulation—and this is quite well proved by Trueta in his various methods of examining the kidney—is the formation of a collateral circulation which is in fact a link between the juxtamedullary glomeruli and the venous circulation of the kidney. Thus we have a vascular by-pass which shunts the blood-flow from the cortex first of all only during the period of cortical spasm, but as years go on, through a more or less perfectly formed renal by-pass. When this has happened to a large degree there will be a sufficient continuous formation of renin to send the blood-pressure up permanently.

Arteriosclerosis is another factor which produces the more obvious microscopic and macroscopic changes in the retina, with permanent renal ischæmia, completely healthy renal tissue, and between the two in the same kidney partially diseased renal tissue.

This is a summary of what we know about the causative pathology of hypertension, and I should now like to show a figure which is an attempt to describe what happens clinically in a case of hypertension (see Bourne, G., "Hypertension—ætiology and surgical treatment", *Brit. med. J.*, 1948 (i) 435). Here (fig. 1) we have in the 'teens a

FIG. 1.—S.I indicates sympathectomy done before the onset of permanent renal damage. S.II indicates sympathectomy after renal damage has occurred. (From *Brit. med. J.*, 1948 (i), 436.)

normal limits, is nevertheless substantially improved and—this I believe is very important—less variable from day to day and hour to hour.

I would conclude by saying that although sympathectomy and splanchnicectomy may not cure the patient with complicated hypertension, nor possibly prolong life, yet there is a very good chance of relieving the symptoms, especially those of headache and impaired vision.

In two cases there has been some optic atrophy after the retinitis has subsided; in both patients the retinopathy had been present for a long time.

The great contra-indication to operation is the elderly patient with generalized arteriosclerosis in whom the body has lost its adaptability to a lowered blood-pressure and who is likely to die of coronary or cerebral thrombosis if not operated upon, and certain to die of these complications with the added risk of renal failure after operation.

Mr. A. S. Philips showed some fundus pictures of patients before and after sympathectomy had been performed by Mr. Tuckwell. He said: These patients have not been specially chosen, being simply those patients who presented themselves at a moment when I had an opportunity to make a fundus drawing. It is fortunate that the fundus camera and colour film will soon make the laborious art of fundus-painting unnecessary. I am very grateful to Dr. Geoffrey Bourne and Mr. Tuckwell for the opportunity afforded for observing the fundus changes in these patients.

Hypertensive retinopathy is a comparatively new term which has come to replace arteriosclerotic and renal retinitis, for it seems evident that in both these conditions the retinal changes are brought about solely by arteriolar spasm and long-continued high blood-pressure, and that when this high pressure is caused to fall within normal limits many of the retinal lesions disappear. I have not found any one type of exudate confined to a particular kind of case and furthermore the cotton-wool patches, which used to be thought typical of renal retinitis, may occur in hypertension from any cause.

The Americans have classified hypertensive retinopathy into four stages. The method is by no means exact as the age of the patient makes a difference in the hypertensive changes produced.

Stage I is minimal arterial narrowing. What we should describe as mild arteriosclerosis.

Stage II shows a more marked degree of this plus arteriovenous compression.

Stage III includes retinal œdema, exudate and hæmorrhages.

Stage IV shows papillœdema.

This papillœdema, as understood by the physicians, does not mean the low degree of retinal œdema spreading on to the disc, which we, as ophthalmologists, commonly observe, but the more defined and isolated swelling of the disc due to raised intracranial pressure following hypertensive encephalopathy.

It seems that this same papillœdema, as I understand it, marks the dividing line between a benign and a malignant hypertension. A case with papillœdema and no other retinal change is called malignant hypertension while one with retinal œdema, hæmorrhages and exudates is called a benign hypertension. Perhaps I have interpreted this distinction too literally, but, it seems to be a purely arbitrary one, and I know it is made because I personally observed over two years the eyes of a friend of active habits and no symptoms except for interference with vision due to retinal exudate and hæmorrhage. He died at the end of that time and only at the last was his condition described as malignant hypertension. It seems to me that retinal œdema and exudate are a portent of things to come as surely as is papillœdema due to encephalopathy, and should denote a malignant and not benign condition.

The following case is included to illustrate the end-condition of the retina in hypertension when relief of the hypertension is not possible.

Mrs. G., aged 40, was admitted to St. Bartholomew's Hospital in April 1941 with a six months' history of migraine, breathlessness and œdema of the ankles. On admission to hospital she had a tachycardia of 112 and blood-pressure of 260/200. A drawing was made of her fundus appearance on admission (fig. 1). There was a moderate degree of retinal œdema, though the choroidal pattern could still be made out, with a partial star figure at the macula. Arteriovenous compression and scattered hæmorrhage and exudate: a Stage III hypertensive retinopathy.

The macular star figure is a fairly accurate record of the degree of retinal œdema. The retina appears to be held down at the fovea to the underlying pigment layer, and as it is elsewhere free, lines of tension form which radiate outwards from the fovea whenever the retinal tissues become stretched by œdema. These lines of tension are a sign of retinal œdema from whatever cause, and may also be seen in thrombosis of the central retinal vein and in papillœdema due to intracranial neoplasm, though in this condition the macular fan is always partial and is confined to the area between the disc and the macula. These are not original observations but were made twenty years ago by Foster Moore.

Ophthalmoscopically the lines of tension are marked out by lines of white exudate and I do not know whether it is that the exudate occurs only along those lines, or whether it is deposited everywhere

typical of essential, or renal, hypertension imposes more strain on the heart and small vessels as seen in the retina.

The operation consists of removal of the tenth dorsal to first lumbar ganglia inclusive and the terminal portions of the splanchnic nerves. To be a complete denervation of the renal and celiac plexuses the operation must be more extensive and possibly include most of the thoraco-lumbar sympathetic chain. Several exposures of the splanchnic nerves have been described. The most extensive operations involve partial or complete division of the diaphragm, with resection of the sympathetic nerves in the thorax and abdomen. I prefer the approach through the pleural cavity, partially dividing the diaphragm from above and removing the lateral ganglionated chain from the fourth or fifth dorsal to the first lumbar inclusive; at the same time the splanchnic nerves are removed in their entirety. The operation is technically not difficult and exposure of the nerves and ganglia is good; any damage to intercostal vessels, usually veins, is seen and hæmorrhage easily controlled; the operation on one side lasts not more than an hour and the patients stand it well and are fit for the second side in two or three weeks.

I believe that we ought to operate early on those patients who are going to develop complicated, so-called malignant hypertension, but the difficulty of early diagnosis of this group is very great. Surgeons usually see them when retinitis or papilloedema or both are already present, or there is already severe renal damage. In the treatment of this disease it is essential that the physician, the ophthalmologist and the surgeon work together. I have had the great pleasure of working on this subject with Dr. Geoffrey Bourne and Dr. Graham Hayward and an expert opinion on the fundus of the eye has always been obtained from Mr. Rupert Scott or Mr. Seymour Philips. We use the grading of cases according to the retinal changes as described by Keith and Wagener:

Grade I: Normal or arteriolar constriction only.

Grade II: Tortuosity of the vessels and nicking of the veins at the arteriovenous crossings.

Grade III: More marked arteriolar change and retinitis (exudate or hæmorrhage).

Grade IV: Papilloedema usually with exudate or hæmorrhage.

Spontaneous regression of the retinopathy with disappearance of the œdema, exudate and hæmorrhage does occur with sedation and rest in a few patients, but after sympathectomy there is usually an immediate and often dramatic improvement even in patients who have received long and adequate rest in bed. Most of the patients with the worst eyes noticed a definite subjective improvement in their vision before they had left the surgical ward, that is to say within two weeks of the second operation. This improvement is remarked by the patient before my unskilled eye can detect an improvement in the fundus.

Changes in the eye caused by thrombosis of the retinal vessels always improve spontaneously I believe; one such patient of mine now has an almost normal fundus although the second part of the operation was not attempted on account of coronary thrombosis and her pressure is more or less unchanged.

A good renal function is desirable for a good operative risk; but I have operated on three patients with poor excretion and raised blood urea, with remarkable improvement in their general health and regression of the disease from Grade IV to Grade I. In these patients the renal function is not improved; one of them is now moribund one year after operation, he still has normal fundi and has enjoyed some months of comparatively normal life at work after being practically blind.

Analysis of my personal cases of complicated hypertension would be of little value as they only amount to 12, 9 of Grade IV and 3 of Grade III; but Professor Paterson Ross has very kindly allowed me to include his cases giving a total of 16 Grade IV and 6 Grade III.

GRADE III

Regression to Grade II ..	3
Remained at Grade III ..	1
	(3 months)
Advanced to Grade IV ..	2
	(1 at 3 years, 1 at 8 months)

In addition two patients who had Grade II fundi at operation now have advanced to Grade IV, one three years and the other one year after operation.

In all those patients whose eyes have deteriorated the blood-pressure has not responded to treatment and the diastolic pressure is the same or higher than before operation.

In all those patients with improvement the blood-pressure, though seldom reduced to

The next picture (fig. 2) was painted in October 1947, i.e. six months' interval between pictures. This shows a disappearance of the hæmorrhage, exudate and œdema and some pallor of the disc. Collateral venous circulations have developed to overcome obstruction. His vision was 6/9.

He now writes that he is at work and his vision is good. Here again a very striking improvement is evident.

CASE III.—W. P., aged 23, male. First seen by me in St. Bartholomew's Hospital in December 1947, complaining of headaches and poor vision. Right vision was 6/18 and left was less than 6/60. Both fundi showed Stage III retinopathy with fairly complete star figures and moderate retinal œdema. He had a bilateral splanchnic neurectomy and I saw him again on January 21, 1948. There was still some retinal œdema but the blood-pressure had fallen to 170/110, and the exudate had become powdery, which is usually the last stage before disappearance. His vision had improved from right 6/18 to 6/6, and left 6/60 to 6/9 unaided.

I last saw him on March 1, 1948, when he was readmitted to Hospital under Dr. Bourne with some congestive heart failure from which he is now recovering. The fundi show hardly any exudate though there is still a little œdema. His blood-pressure is 160/100.

SUMMARY

Three patients, not specially selected, were described. All three complained of failing sight and in all there were such gross retinal changes that it seemed their vision must fail altogether before long unless some reduction in their blood-pressure could be achieved. The longest history of the three after operation is only a year, but all three have normal vision at this time, which seems to be a very remarkable thing considering the usual outcome of such cases.

Mr. E. F. King said it was surprising that patients with Stage IV hypertensive retinopathy rarely showed neurological disturbance. It might well be that the papilloœdema represented the terminal stage of generalized retinal œdema rather than the response to increased intracranial tension. In the few cases he had observed with gross papilloœdema there had been little improvement in the fundus condition following operation.

Mr. O. Gayer Morgan referred to a case which he saw over a year ago, with high blood-pressure, 240/160 and with Stage IV retinopathy. The patient, a student, had the first operation of sympathectomy on one side, and the next day he complained that one of his eyes was quite blind. He had been seeing about 6/18 with each eye. Now he had no perception of light in that eye at all. Mr. Morgan presumed that he had thrombosis of the central retinal artery, but there was no possibility of seeing the fundus changes in such a condition because it was masked by the extremely œdematous condition of the disc, macula and fundus generally.

The patient had his second operation three weeks later and he was now actually back at Cambridge engaged on his previous studies. On looking at his fundus he had complete optic atrophy on one side, with no perception of light. With the other eye he was able to see 6/6, but one was surprised that that was so in view of the irregularities at the macula and the extremely narrow arteries. Would it be a difficult thing to deal with the cervical sympathectomy at the same time? Would that in fact make his retinal arteries dilate and would it also help in preventing a thrombosis of the central retinal artery which had certainly occurred in this man.

Mr. R. W. Stephenson said that Mr. Philips had remarked upon the distinction between benign and malignant hypertension. Was there any real distinction between these two conditions? Was the second not merely an extreme degree of the first?

Mr. R. B. Terry said that the examination of the fundi was important not only for prognosis and diagnosis but also, one would like to think, because the condition of the fundi was a reflection of what was happening throughout the body. If these hæmorrhages took place in the fundi it was hardly conceivable that they should be only occurring there and not also in the kidneys and the heart. If that were true it would give a better indication of why things were going wrong elsewhere.

With regard to the ætiology of the hæmorrhages and the effect of sympathectomy on the retinal appearance, there might be another factor concerned, namely, capillary fragility. Capillary fragility had been shown to exist in quite a high proportion of cases—some 20% of hypertensives—and among those who showed this phenomenon there was an increased incidence of cerebral and retinal vascular catastrophes.

With regard to the effect of sympathectomy, it might be that if sudden and repeated rises in the level of the blood-pressure as mentioned by Mr. Tuckwell did not occur, the hæmorrhages also did not occur. It was possible that sympathectomy by some means also affected capillary fragility. That abnormal capillary fragility did exist in many hypertensives had been shown conclusively and it could be moderated by administering rutin. Sympathectomy

but only reflected from those points. In either case the rise and fall of retinal œdema can be gauged from the appearance and disappearance of the macular fan.

One month after admission there were additions to the star figure and on June 5—two months after admission—the next drawing was made (fig. 2).

There is a general increase in the œdema, as shown by the disappearance of the choroidal pattern and the increased blurring of the disc and we may now say that she has passed to Stage IV and has

FIG. 1.—Retinopathy in a woman of 40. (Mrs. G.) Systolic pressure 260. FIG. 2.—The same eye 3 days before death of the patient.

papilloedema. The star figure is more complete and the central pit is deeper. She died of terminal congestive heart failure and pneumonia three days after that picture was made.

These drawings are shown here in order to heighten the contrast between the fate of this patient and that of those whose blood-pressure can be reduced by surgical means, viz. Cases I, II and III.

CASE I.—A. D., aged 25, was admitted to St. Bartholomew's Hospital in January 1947. Blood-pressure 230/150. The patient complained of misty vision, headaches and that he saw white lights as green with the right eye. His retina showed a true Stage IV retinopathy, with papilloedema and an early star figure. During February and March 1947 he had two operations for transpleural sympathectomy. I next saw him on June 12, 1947, when his systolic pressure had fallen to 175, and his right vision had improved to 6/9. The papilloedema had disappeared and there was only a trace of retinal œdema at the macula with the last remaining fragments of a star figure. The interval between the paintings of his right eye was therefore six months. On January 29, 1948, his blood-pressure was 175/110, right vision 6/6 unaided and there was no hæmorrhage, exudate or œdema in either eye. The retinal arteries remain very thin especially round the disc, as one would expect for it is not upon their nerve supply that the operation is carried out, and the disc is pale.

This seems to me a striking improvement, maintained over one year and not to be accounted for by rest in bed or other coincidental treatment.

CASE II.—R. M., aged 50. Admitted to St. Bartholomew's Hospital April 11, 1947, complaining of "bursting headaches" and a film over the right eye. His blood-pressure was 232/126. His right vision was 6/36. In May and June 1947 he had bilateral splanchnic neurectomy and he left hospital on July 8, 1947. His blood-pressure on discharge was 150/100, but rose to 170/110 later. On admission he had shown a Stage III retinopathy, with a solid-looking œdema at the macula and no

FIG. 1.

FIG. 2.

star figure. There were many venous hæmorrhages due to compression of the vein at the arterio-venous crossings, and the constriction of the arteries at and near the disc was very marked (fig. 1).

Section of Medicine

President—MAURICE DAVIDSON, M.D.

[April 27, 1948]

DISCUSSION ON GENERALIZED DISEASES OF BONE IN THE ADULT

Dr. E. F. Scowen: *The effects of some hormones on osteogenesis.*—In order to make clear the subsequent discussion I will first review briefly the main steps in the formation of bone.

In endochondral bone formation, there is first proliferation of cartilage cells with an increase in intercellular substance and an arrangement of the cells in order. This is followed by calcification of the intercellular substance and the breaking through of blood-vessels into the areas containing the cartilage cells. Osteoid tissue is then laid down by the osteoblasts on to the surface of the calcified areas and into this osteoid is later deposited calcium and phosphorus complex.

Membranous bone is formed directly from a specialized tissue without preceding cartilaginous phase, and for the purpose of discussion this term as suggested by Fuller Albright will also be used to include periosteal bone.

I will use the term endosteal bone formation for bone laid down in the cortex and trabeculae of bones which occurs both during skeletal growth and throughout adult life, and I would like to point out that the final stages in all varieties of bone formation are essentially the same, namely the formation of bony matrix by the osteoblasts and the deposition of calcium and phosphorus in this matrix.

This definition of osteogenesis is, of course, over-simplified, but I have used it so as to be able to demonstrate the selective effect of some hormones on the different phases of osteogenesis. It will also be clear that the formation of bone, namely the formation of osteoid can be separated from calcification of this osteoid and this allows us to adopt a classification which may clarify the essential differences in three types of disease which are characterized by a deficiency of calcified bone. Thus, osteoporosis is used to designate any condition in which there is a decrease of bone due to a failure of osteoblastic activity and an insufficient quantity of osteoid formation. Such osteoid tissue as may be formed is normally calcified. Such a condition would not arise from a disturbance of calcium and phosphorus metabolism but from a true disturbance of bone growth. In such conditions, therefore, the serum calcium and phosphorus levels and the alkaline phosphatase are normal.

In the condition of osteomalacia, which arises as a result of a disturbance of calcium and phosphorus metabolism the bone is softer than normal owing to the failure of mineralization and this results in excessive osteoblastic activity. In contrast, therefore, to osteoporosis there is an excessive quantity of osteoid tissue elaborated and a deficient deposition of calcium and phosphorus in this matrix. The serum calcium and phosphorus vary with the severity of the condition but the phosphorus level is usually depressed and the alkaline phosphatase in the blood invariably increased.

In conditions of osteitis fibrosa generalisata, most commonly the result of hyperparathyroidism there is excessive resorption of bone which is accompanied by excessive osteoblastic activity. As a result of the over-action of the parathormone and the osteoblastic response to the bone resorption, there is a high serum calcium, a low serum phosphorus, and a high alkaline phosphatase.

The Effects of the Growth Hormone on Osteogenesis

I do not propose to discuss the evidence on which the identity of the growth hormone is established but to review briefly the clinical manifestations of alterations in the production of the growth hormone from the anterior lobe of the pituitary. It is difficult, of course, in many cases to distinguish the effects directly as the issue is often clouded by interference with the elaboration of other hormones at the same time. Nevertheless some clear-cut deductions emerge as a result of this study.

The failure of growth hormone production can occur as a result of pituitary destruction.

As an example here is a patient with a suprasellar cyst. Symptoms date from the age of 5; she is now 16 years old and is the size of a child of 7 or 8. The X-rays show a bone age of 9 and the epiphyses are all open but the bones otherwise would appear quite normal for the age of 9 and there is no suggestion of osteoporosis. The 17-ketosteroid excretion is in the normal range for a pre-adolescent child. There has been a failure of epiphyseal growth but endosteal replacement has not suffered.

There is another condition of dwarfism which is associated with anterior lobe failure. This is commonly called panhypopituitarism. In such cases all functions of the anterior

must be causing some change other than merely the reduction of blood-pressure, since in certain cases, in spite of the blood-pressure going up, there had been no return of the hæmorrhages.

The President asked what was the relationship between arteriosclerosis, hypertension and the kidney condition. In how far were these separate entities dependent on each other and what was the causal relationship between them.

Dr. Geoffrey Bourne said, in answer to the President, he would suggest that hypertension was a separate entity from arteriosclerosis, and that in those people whose arteries were liable to degenerate the hypertension would inevitably accentuate the arteriosclerotic changes. But hypertension might be present alone, certainly for twenty years, as in coarctation cases, and in other individuals who had hypertension for a long time without any clinical signs of actual arterial change. Therefore arteriosclerosis, he thought, could be definitely said not to cause hypertension. Hypertension certainly would accelerate changes.

With regard to the other points, he thought that the reason why one did get clinical information that an individual with a Stage IV change in the retina had apparently been perfectly well until quite recently was that such cases were far more commonly renal than hypertensive. These individuals had been apparently well until they came up to the ophthalmic department with loss of vision. There were a few cases of hypertension in elderly people who certainly manifested a Stage IV change in the retina. In some there had been quite a long history and the explanation of that was the difference in the aetiology of the two types.

As to whether there was any essential difference between benign and malignant hypertension, these were just useful labels, and not anything more. He would say that an individual had malignant hypertension when he had arterial retinal changes with papilloedema and that in most of such cases the progress of the disease had been accelerated, so that there was a story of continuous deterioration. Finally, most of such cases were rather young—not middle-aged.

Dr. Terry's statement about the possibility of fragility of the capillaries was an interesting one. He would stress again that there were two quite distinct things—there was hypertension and there was also a factor which caused the blood-vessels to become vulnerable to the effects of hypertension. That was something separate and distinct. It was frequently not present for many years, but after all everyone degenerated physically as he grew older, and the young individuals with nephritis unfortunately got a similar sort of change much earlier in life. Therefore the change in the blood-vessels was an extremely important and quite separate problem.

Mr. E. G. Tuckwell, also in reply, said that the term "malignant hypertension" was a bad one. It would be much better to use the term "complicated hypertension". He agreed with Dr. Bourne that it was all one disease, and it could be called complicated when there was retinopathy and other eye changes.

Mr. A. S. Philips, in reply, said that Mr. King had raised the question whether Stages III and IV were the same thing or degrees of the same thing. While he was not sure on that point he thought that in some cases Stage IV was different, as there was present in it not only hypertensive changes in the retina but a type of papilloedema which denoted a space-taking lesion in the skull. One of the pictures shown accompanying his paper did bring out this point.

Mr. Philips recalled that Mr. Paterson Ross and Professor Gask had carried out a cervical ganglionectomy at St. Bartholomew's Hospital. Mr. Foster Moore had been asked to see the patient afterwards and he had declared that he could not see any enophthalmos or difference in the calibre of the retinal vessels on the two sides.

effects of oestrogens on the skeleton of birds and mice. It appears probable that such experiments may help to elucidate the peculiarities of the skeletal distribution of bony abnormality since the same oestrogen may produce dissolution of one bone and yet proliferation in another bone.

The excessive skeletal growth in girls in association with granulosa-celled tumours of the ovary and the stimulation of growth sometimes seen in cases of ovarian agenesis under the influence of oestrogens suggest that the oestrogen itself may have a direct stimulating effect on epiphyseal growth. This, however, is not certain as it is impossible to prove at present that such effects are direct and are not mediated through secondary adrenal response. This latter effect has received some experimental support and further indirect support as we shall see in the discussion of the effects of the adrenal cortex on bone formation.

There is no doubt that oestradiol can affect the calcium balance and has been shown to reverse the negative balance in post-menopausal osteoporosis and in osteoporosis with Cushing's syndrome. Such change was produced without any appreciable effect on nitrogen metabolism.

Oestrogens can therefore undoubtedly influence the calcium balance and appear to influence endosteal bone growth. They may stimulate endochondral bone but like testosterone are not capable of producing excessive bone growth.

The Effects of the Adrenal Cortex on Osteogenesis

There is no doubt that the adrenal cortex profoundly influences bone growth but it is difficult to elucidate these effects from a gland as complex in its functions and which appears able to produce contrary actions.

I do not propose to discuss adrenal function and I will have to assume the acceptance of the conception of two main actions of the cortex through two groups of hormones, one of which has an androgen-like and the other a corticosterone-like action.

The adrenogenital syndrome is a demonstration of the androgenic action of the adrenal cortex. Children with this syndrome show rapid skeletal growth which is terminated early by the effect on the epiphyses and their early closure, frequently resulting in deficient height. Once epiphyseal closure is complete bone growth ceases and excessive bone is not produced. Indeed in the adult who develops this syndrome no bony change is seen. The children may show some slight growth in height after long bone epiphyses have shut and this is due to vertebral growth which may persist for many years.

This acceleration of endochondral growth and lack of excessive endosteal or periosteal bone closely resemble the effects produced by testosterone and it is in this syndrome that the excretion of 17-ketosteroids in the urine is always markedly increased.

The primary disturbance in Cushing's syndrome is still a matter of argument but there is no doubt that there is a gross derangement of the adrenal cortical function. The urinary excretion of 17-ketosteroids may be somewhat increased but this is inconstant and seldom of any magnitude. The excretion of corticosteroid substances is always increased and often remarkably so, both by biological and chemical assay.

In Cushing's syndrome in contrast with the adrenogenital syndrome, bone growth is remarkably retarded and epiphyseal growth may cease altogether. In addition there develops a remarkable thinning of the spine and often of the pelvis. The structure of such bone shows a failure of osteoblastic activity, the condition of osteoporosis.

From the experimental observation that both corticosteroid-like substances and the adrenocorticotrophic hormone can prevent bone growth in animals, and indeed can abolish the effects of injected growth hormone, it seemed reasonable to assume that the bone disorder in Cushing's syndrome might be brought about by an excessive production of corticosteroid substances which we know to be occurring. This effect is in direct contrast to the action of the sex hormones and is thrown into contrast even more by the persistent negativity of the nitrogen balance, independent of the nitrogen intake. This effect can only be overcome by a gross excess of testosterone.

With this osteoporosis the calcium and phosphorus in the blood are normal and the alkaline phosphatase is usually stated to be normal. Such findings are usual in osteoporosis. In Cushing's syndrome, however, it is not invariably true and in the patient I have chosen to illustrate this disease a high alkaline phosphatase was constantly found during the time the vertebrae were markedly deteriorating.

Osteoporosis in the spine and pelvis are the bony features of this disease and appear to be explained by an excessive production of corticosteroid-like hormones from the adrenal cortex. These substances interfere with, or prevent, osteoblastic activity as part of the general interference with tissue anabolism and in consequence no bony matrix is formed. This process is especially marked in the spine and pelvis and growth of the epiphysis is also inhibited. If therefore it is accepted that these changes in Cushing's syndrome are the result of over-production of corticosteroid products the adrenal is capable of inhibiting both endochondral and endosteal bone formation.

lobe are deficient. Untreated, such patients grow at a very slow rate but growth persists indefinitely since they do not reach complete sexual or skeletal maturity. Under treatment with testosterone and thyroid, growth may be markedly accelerated provided over-enthusiastic use of testosterone does not lead to epiphyseal closure. Over-dosage, however, does not lead to excessive bone formation and the effect of the treatment is shown almost entirely in epiphyseal growth, that is endochondral bone formation, and may be akin to the effect seen in animals in whom after hypophysectomy, treatment with testosterone prevents the cessation of bone growth and enhances the action of injected growth hormone.

The syndromes produced as a result of increased growth hormone production occur with eosinophilic hyperplasia or neoplasia of the anterior lobe. Acromegaly occurs when this process begins after skeletal maturity. The osseous manifestations are produced by an excessive periosteal bone formation but in certain sites further endochondral bone is stimulated. The cartilaginous end-plates of the vertebræ start to undergo hyperplasia and this, together with periosteal bone formation, produces the remarkable changes in the vertebræ which seem to be always most marked in the region of the lower thoracic vertebræ.

Gigantism results when the disease begins before skeletal maturity but the stimulation of endochondral and periosteal bone is uniform and disproportion is not evident as in the restricted response of acromegaly. Growth can proceed indefinitely if epiphyseal closure does not occur.

It is clear that in the early stages of gigantism, before pituitary function is completely disorganized the changes of puberty may occur. If this should happen the features of pure gigantism will be clouded by a superimposition of acromegalic features, once epiphyseal closure has occurred in the long bones under the influence of puberty.

Lastly I would like to draw attention to a syndrome which has received little attention. It has no name and I will therefore refer to it as adolescent gigantism. Sometimes there is evidence of a pituitary tumour and sometimes not. Growth occurs rapidly for a short and limited time but usually ceases before the condition can reasonably be termed gigantism. Commonly sexual maturity fails to develop but often failure is incomplete. In man such a syndrome is commonly overlooked and appears to be compatible with reasonable health at least for many years until revealed later in life by complaints of maldevelopment, impotence or infertility. Further examination often shows, however, signs suggestive of pituitary failure. The testes are usually atrophic and show lack of spermatogenesis. Anaemia, though often mild, is intractable, and cardiac disease may later supervene and prove fatal, frequently with arrhythmia, often auricular flutter. Union of epiphyses in the long bones is often delayed but eventually occurs.

In view of the identity of these cases whether evidence of pituitary enlargement is demonstrated or not it seems reasonable to suppose that they represent a comparatively transient phase of eosinophilic adenomatous enlargement of the anterior lobe and the ultimate fate of such a patient is dependent on the degree of pituitary destruction which may occur during this time. Many such cases seem to masquerade later in life under the titles, in bad cases, of chromophobe adenoma, or in milder cases of Klinefelter's syndrome.

I have not seen in such patients evidence of osteoporosis in contrast with many cases of acromegaly who eventually show decalcification of the skeleton.

The osseous manifestations of these diseases show that in man the growth hormone has a stimulating effect on both endochondral and membranous, including periosteal, bone formation. There is little to suggest a direct effect on endosteal bone. The decalcification sometimes seen in acromegaly is at present unexplained. The inconstancy of its appearance, together with its absence in conditions of lack of growth hormone would suggest that it is associated with some indirect effect and related to other forms of osteoporosis which I will discuss later.

The Effect of the Sex Hormones on Osteogenesis

The skeletal effects of the testis hormone are well known and the failure of physical development as well as sexual development in eunuchs does not need elaboration here.

Since the use of testosterone, however, it has been possible to demonstrate conclusively its metabolic as well as its sex functions. I have already referred to the effects of testosterone in panhypopituitarism and the effects on bone growth in hypophysectomized animals, but at this point I would like to make it clear that such changes are not isolated but occur in association with somatic growth generally, and the development of a positive balance, not only of calcium and phosphorus, but in particular of nitrogen. These effects of testosterone are exerted in all tissues and growth is accelerated. Such growth includes epiphyseal growth and also endosteal and probably periosteal bone growth, but unlike the effects of the growth hormone the response is limited and uniform and excessive bony response cannot be produced.

The effects of the oestrogens on the bones seem to be similar to testosterone but the oestrogens lack the somatic effects and the available data is far from conclusive. Considerable work in this field has been stimulated by the demonstration of the remarkable

of the conditions show phases in which the bones exhibit first one and then the other type of reaction.

Decalcification

Osteoporosis, &c.—The most important in the radiographic diagnosis is that found in hyperparathyroidism. It has been claimed by certain workers (Snapper, 1943) that in more than half of the patients with hyperparathyroidism the predominant symptoms originate from the urinary tract and that the biochemical syndrome of the disease has been detected when the X-rays of the skeleton showed completely normal findings—Albright recorded that "in 15 of 35 consecutive cases of hyperparathyroidism no radiographic changes could be found—the symptomatology of these cases was exclusively renal in character". Yet in the cases of hyperparathyroidism submitted to me which have remained unsuspected though previously subjected to considerable clinical investigation, in some cases for three or four years, the radiographs have shown the typical distinctive evidence of the disease. Consequently I regard the radiographic diagnosis of hyperparathyroidism as of great importance. The diagnosis of hyperparathyroidism was not made for the average of 4·8 years from the onset of symptoms in some 49 cases recorded in the literature. This is very important because it was often not made until the destructive bone changes had resulted in multiple deformities due to fractures and abnormal plasticity of the bone, which could not be corrected even though the causal parathyroid tumour was removed. Early diagnosis and treatment permit the skeleton to return to the normal and avoid crippling deformities. Another reason for the delay has been the belief that the characteristic radiographic feature was osteitis fibrosa cystica—a condition which may not be seen in some cases in the early years. This belief has also been responsible for a large number of erroneous interpretations of the radiographic features.

Radiographs showing localized expansion of bone with obliteration of their normal cancellous structure—the conditions now referred to as polycystic dysplasia or polyostotic fibrous dysplasia—have been interpreted as examples of hyperparathyroidism. Histological evidence of osteitis fibrosa cystica, though this is but a type of reaction found in a number of different conditions, has been sought and obtained in some cases before surgical search for a parathyroid tumour which it was thought to indicate. Fortunately the radiographic appearances of the dysplasias are characteristic and their recognition should obviate such surgical explorations. The chief distinctive feature of these dysplasias as shown in the bones of the hand is the localization of the aberrant tissue in a segment of bone which was otherwise normal in size, structure and density. On the other hand the cystic conditions of the bone which may be present in hyperparathyroidism are associated with generalized osteoporosis; further, such lesions are usually multiple and do not show the tendency to unilateral distribution which is seen in the dysplasias. Because in hyperparathyroidism every part of the skeleton shows osteoporosis of a characteristic nature there is no need, as we too often see, for radiographic examination of the whole skeleton.

Radiographs of the hands in hyperparathyroidism show general decalcification of the bones: the phalanges are without compact tissue, the periphery showing in part the crenated surface of the cancellous tissue. The terminal phalanges in particular show a great degree of decalcification, the terminal tuft may be almost invisible. One or more of the bones may show one or more small areas of cancellous destruction—the representative of the "cysts" or giant-cell tumours in the larger bones. The bones of the forearm also show lack of compact tissue and a characteristic stippled osteoporosis, with areas from which the cancellous pattern has been wiped out. There is no other condition which presents these characteristic features in combination. True, in certain grave cases of so-called renal osteodystrophia there is a near approach but in these cases the parathyroids are probably responsible, for it is found that they show general hypertrophy. The long clinical history, in particular the continued prominent evidence of renal insufficiency, assists the differentiation. A lateral radiograph of the skull would also help, for though in the old-standing renal osteodystrophy, the skull may show the features of irregular ossification and calcification, the relatively recent case of hyperparathyroidism due to tumour would show a fine stippled osteoporosis with obliteration of the outline of much of the outer table.

Radiographs of the pelvis or long bones show in addition to the general osteoporosis large areas within which all the detail of cancellous structure has been wiped out with attenuation of the compact tissue to linear dimensions. In some cases the "cysts" are more clearly defined and expanded beyond the normal. With removal of the responsible parathyroid tumour the long bones recalcify and become of normal structure except in the larger cystic areas. These may retain a multilocular cystic appearance; one or more may become densely calcified. It used to be claimed that the radiographic features of hyperparathyroidism and Paget's disease were indistinguishable, but I trust that this belief no longer prevails, for the essential features of Paget's disease, even after a duration of twenty or more years, is its localization to certain bones of the skeleton. The radiograph of the

Senile Osteoporosis

Osteoporosis in man occurs in a variety of conditions. I have already considered Cushing's syndrome and I will not now say anything about disuse atrophy, extreme senility, or chronic inanition. I would like to discuss briefly the changes which are still called senile osteoporosis, although in many such patients their general condition and actual age belie such description. I think under this title three conditions can be distinguished: (1) Menopausal or post-menopausal osteoporosis; (2) pre-senile osteoporosis; (3) an idiopathic group at present quite unexplained.

The first two conditions have many similarities but I have separated the post-menopausal cases as this condition is for obvious reasons better defined in women and seems to be an exaggeration of the normal post-menopausal state. A lack of oestrogen is present and the decline in 17-ketosteroid excretion with increasing years would suggest a decline in the production of androgenic substances.

It seemed probable that the failure of sex hormone production both gonadal and adrenal might be a precipitating factor in the failure of osteoblastic activity. The administration of both oestradiol and testosterone has confirmed this impression, both in post-menopausal and pre-senile osteoporosis in men. Both compounds can make the calcium balance positive but the combined use is more effective than the sum of the two separately. The use of oestradiol alone appears not to influence the nitrogen but testosterone profoundly affects it and will produce a positive nitrogen balance with increase in weight and strength. It is not yet clear how much change will be produced eventually in the vertebral column by this therapy but the immediate results have been very satisfactory and it remains to be seen how much radiological change will be evidenced in the years to come.

Dr. James F. Brailsford: The scope indicated by the title of this Discussion is a wide one. Unfortunately the time allowed will not permit me to deal comprehensively with any of the groups into which I have classified the diseases.

The classification I have adopted is as follows:

(1) Generalized changes in bones due to dysplasias and dystrophies of the skeleton. These are essentially laid down in foetal or infantile life in varying degrees of severity. Some at one end of the scale are incompatible with a separate existence, others of much less severity permit of apparently normal life, even to old age, and then perhaps are only discovered by radiography during investigation for fracture, &c. These are few and far between and of importance only in the differential diagnosis; they include certain cases of osteogenesis imperfecta (Brailsford, 1943) and Albers-Schönberg's disease.

(2) Generalized bone changes associated with defects in other systems. These include renal and gastro-intestinal osteodystrophies and such conditions as von Recklinghausen's neurofibromatosis. The adult members of this group are usually known to have carried the disorder from earlier years.

(3) Generalized bone changes associated with deficiencies, endocrine and blood disorders such as osteomalacia, hyperparathyroidism, leukaemia and anaemia. These, as well as those in the succeeding groups (4) and (5), are the most important and most common conditions. They appear to be initiated in adult life and produce generalized changes in the skeleton which was formerly apparently normal.

(4) Those generalized diseases of bones which represent the terminal stage of diseases, which throughout the major part of their course have appeared as localized conditions and failed to respond favourably to any form of treatment administered. They include Paget's disease, syphilis, the solitary and the endothelial myeloma (Ewing's tumour) and carcinoma.

(5) Those generalized diseases of the bones which are associated with general progressive clinical deterioration. These conditions are often associated with long latent negative radiographic periods so that radiographs for many months may fail to show any changes in the bones and even when the changes do appear they may not be distinctive. These conditions are often classified under the title of senile osteoporosis of bones but more careful examination may permit of the recognition of myelomatosis, carcinomatosis or some serious disturbance of metabolism or endocrines.

Generalized diseases of the bones can be indicated by radiographs of any and every part of the skeleton; consequently radiographs of the hand are the best for obtaining indication of generalization. Because of the intimate contact between the radiographic film and the bones of the hand the detail of the bony structure is sharp and clearly defined. As a student I was impressed with Wood Jones's "The Principles of Anatomy as Seen in the Hand" and I suggest that a companion volume "The Pathology of the Skeleton as Seen in the Bones of the Hand" could be of equal value.

Radiographically we may consider these conditions of the adult skeleton under two main distinctive radiographic features, i.e. (1) diminished density of the bone—decalcification, and (2) increased density of the bone—osteoplasticity or osteosclerosis; though some

and appearances in the cretinoid form of the hands indicating that the changes are of many years' duration, probably associated with severe metabolic disturbances rather than infiltration with tumour cells.

There are a number of conditions in the adult skeleton which are associated with osteoporosis; often revealed by radiography which is being used to ascertain the cause of pain in the back or lower extremities. Compression fractures of one or more vertebral bodies, usually in the mid-dorsal or dorso-lumbar areas, are found. Usually these have been produced without any definite trauma: the pain may have come on suddenly when the patient was bending to pick up an object of no great weight; in other cases a more definite strain has been imposed at the time. The discs are expanded and the osteoporosed bodies are compressed to accommodate them. Radiographs of the hand may show a degree of general osteoporosis of no characteristic pattern. In many of these cases the underlying cause cannot be found and they are referred to under the term *senile osteoporosis*; in others, disturbances of the gastro-intestinal tract, diffuse myelomatosis, carcinomatosis, hyperthyroidism, pituitary or adrenal tumours or even syphilis may be found to be the cause.

Myelomatosis may occur subsequent to the development of a localized myeloma, but more often the disease is revealed in radiographs by multiple, small, well-defined, circumscribed areas of cancellous structure up to the size of a pea. These may be scattered about in the expanded ends of the main bones of the extremities, and in the pelvis, ribs and skull. Near the termination of the illness these foci may be almost contiguous. In the shafts of the long bones the cancellous tissue may be destroyed, the medulla expanded and the inner border of the compact cortex may show much crescentic scalloping of the size indicated above. In some of these lesions the peripheral border of the cortex may be pushed out beyond the line of the shaft. In those cases of diffuse myelomatosis the diagnosis may depend entirely upon the finding of Bence-Jones proteose and the recognition of the typical cells in the tissue removed by sternal puncture.

Carcinomatosis producing generalized osteoporosis of the skeleton is relatively rarely diagnosed at the stage when investigations are being made, though it is not so rare as a terminal observation. More commonly the disease is shown only in the pelvis, spine, ribs and proximal bones of the extremities and in these there may be irregular distribution. Even when the disease can be recognized radiographically as generalized in the trunk and proximal extremities, the bones of the hands may show only generalized osteoporosis. In a few cases only a single metastasis in one of the bones has been found and that in one of the bones of the hand—this may be the first indication of malignant disease. A radiograph of the chest may show the primary to be an epithelioma. Other lesions of the skeleton may be revealed after a variable period.

In *leukæmia* and in certain malignant tumours we may see a generalized osteoporosis of the skeleton with periosteal accretions along the shafts of most of the long bones simulating hypertrophic pulmonary osteoarthropathy; in other cases only localized sites of periosteal reaction are shown, with perhaps some disintegration of the underlying bone. In hypertrophic pulmonary osteoarthropathy due to abscess or neoplasm of the lung, regular periosteal accretions may be found enveloping all the long bones except the terminal phalanges, which though associated with marked clubbing of the fingers often show no change.

The possibility that the generalized osteoporosis associated with one or more spontaneous fractures is due to syphilis must not be overlooked. Radiographs of the skeleton in syphilis may show generalized blurring of the detail of all bones; the details of the diploë and the cancellous structure of the bones may be completely obliterated. Considerable absorption of the bone may occur at fracture sites, and this may not show any regeneration though the other bones respond well to appropriate medication. Generalized granuloma due to lipid and other abnormal cell metabolism may produce somewhat similar changes as I have described (Brailsford, 1948a). Certain cases of osteogenesis imperfecta live to old age and they may show evidence of multiple fractures; in some cases which I have seen, fractures have remained ununited for fifty or more years. The distinctive radiographic features I have recorded (Brailsford, 1948b). Fractures and compression of multiple vertebral bodies, pressure deformities, particularly of the pelvis and lower extremities, and a skeleton lacking in normal structure and density are usually found in any extensive examination; but the clinical history usually provides the key to the diagnosis. The occurrence of extensive subperiosteal hæmatoma as a complication of osteogenesis imperfecta must not be overlooked, for such have been mistaken for sarcomata. The generalized osteoporosis which is associated with hyperthyroidism need only be mentioned for the symptoms of the latter dominate the picture.

Osteoplasticity

There are a number of terms which indicate a diminished density of the bone, but few which denote an increased density. The terms *osteosclerosis* and *osteopetrosis* suggest a bone of stony hardness, but many of the bones to which they are applied have little more than the hardness of chalk. Because such bone often shows a greater degree of

hand, even in cases exhibiting the characteristic features of Paget bone throughout the skull, spine, and the large proximal bones of the extremities, may show all the bones of the hand to be normal, or one or two small bones may show the characteristic Paget bone throughout. I have classified (Brailsford, 1938) the radiographic features of Paget's disease into three types: (1) Osteoporotic; (2) Osteoplastic; and (3) Lithocystic.

Distinctive from the fine stippling of the skull in hyperparathyroidism, in Paget's disease there may be the conditions of osteoporosis circumscripta or a localized area of the skull may show thickening of the pericranium, an osteoid development which contains multiple ill-defined deposits of greater density resembling pledgets of cotton-wool. The affected area of the skull may become an inch or more in thickness. Later the periphery of this thickened pericranial tissue and even the dura may show the density and appearance of ossification.

The Paget lesions in the long bones may begin with the appearances of a gradual deposition of calcium which obliterates the detail of the cancellous structure converting it into a so-called "ivory" bone of uniform density, but at the expense of increased fragility. Later the affected bone may show osteoporosis. When fracture occurs this osteoporosis becomes the noticeable feature. In other cases the lesion begins, as I (Brailsford, 1938) have shown, in a superficial lanceolate area of decalcification which gradually spreads along the bone in a very characteristic fashion; it produces what I have described as the V-shaped thrust of the Paget bone into the normal. The appearances can be illustrated by partially tearing the wrapper from a tightly covered journal, the end of the tear has the shape of a V. Such appearances suggest that the periosteum resists the progressive expansion of the Paget bone for a time, but eventually it yields, and strips in this fashion from the adjacent normal bone. The line of demarcation is clearly defined, the Paget side showing decalcification by its lesser opacity than the normal. As the acute phase passes, the line of demarcation may be removed and the two segments may blend or a further recurrence may occur and the Paget thrust be extended to involve a further segment or the remainder of the bone. This characteristic V-shaped demarcation between the normal and Paget bone is to be seen in no other condition. Obviously it could not be present in a condition which is generalized, yet the literature contains illustrations showing this characteristic feature of Paget's disease labelled Fluorosis. Spéder (1936) used such an illustration and labelled it "Fluorosis".

Paget's disease may remain limited to the one bone when its contrast expansion will be obvious without causing any recognizable change in the joint surfaces. One vertebra may be involved with one or both of its associated ribs but the adjacent vertebrae and ribs may be unaffected. This series of changes is characteristic of Paget's disease. It is not seen in hyperparathyroidism or any other condition which might be thought to resemble Paget's disease.

In renal osteodystrophy the bones of the hands show absence of compact tissue. The cancellous structure is regular but of a coarser pattern than normal, and because of the stunted growth and plasticity the shape of the bones does not show the exquisite form of the normal. The bones of the spine and pelvis being plastic show the deformities of stress and strain. If the disease is a continuation from adolescence plasticity rather than fragility is the essential feature, but if the condition has developed in adult life there may be deformity associated with multiple incomplete fractures. The skull shows changes which are probably associated with hyperactivity of the parathyroids (for these are all found to be hypertrophic) but it is a coarser change than that seen in hyperparathyroidism due to tumour. The detail of the diploic structure is obliterated in a general osteoporosis which appears to have begun in multiple miliary foci which in many areas have coalesced to form fairly well-defined rounded decalcified patches. These are separated from similar lesions by denser structureless bone. There is little or no marked increase in the thickness of the skull and none of the cotton-wool-pledget effect. It will be seen therefore that the resemblance to Paget's disease is very superficial and unlikely to confuse the experienced observer, particularly when in possession of the age and clinical history of the patient.

In idiopathic steatorrhœa the bones show general decalcification and absence of compact tissue. The bones of the hands may have the external form of the normal but their cancellous structure, though regular, appears to be of coarser mesh. The bones of the pelvis and spine show these characters well. Plasticity of the bone is a feature: bending, moulding and pressure deformities, and, in some cases, incomplete fractures, particularly of the pelvis and bones of the lower extremities, will be seen.

Neurofibromatosis (von Recklinghausen): Associated with the multiple skin lesions of neurofibromatosis, multiple neurofibromata may be found in the skeleton. In the skull and spine there may be large or small areas of destruction of bone, sometimes associated with diffuse osteoporosis and reactive thickening of adjacent bone: and the skull may acquire the thickness of one inch as I have illustrated (Brailsford, 1948a). In many sites the bones may be scalloped to form beds in which the tumours lie. I have also recorded that diffuse osteoporosis of the whole skeleton with multiple incomplete fractures may be found,

and appearances in the cretinoid form of the hands indicating that the changes are of many years' duration, probably associated with severe metabolic disturbances rather than infiltration with tumour cells.

There are a number of conditions in the adult skeleton which are associated with osteoporosis; often revealed by radiography which is being used to ascertain the cause of pain in the back or lower extremities. Compression fractures of one or more vertebral bodies, usually in the mid-dorsal or dorso-lumbar areas, are found. Usually these have been produced without any definite trauma: the pain may have come on suddenly when the patient was bending to pick up an object of no great weight; in other cases a more definite strain has been imposed at the time. The discs are expanded and the osteoporosed bodies are compressed to accommodate them. Radiographs of the hand may show a degree of general osteoporosis of no characteristic pattern. In many of these cases the underlying cause cannot be found and they are referred to under the term senile osteoporosis; in others, disturbances of the gastro-intestinal tract, diffuse myelomatosis, carcinomatosis, hyperthyroidism, pituitary or adrenal tumours or even syphilis may be found to be the cause.

Myelomatosis may occur subsequent to the development of a localized myeloma, but more often the disease is revealed in radiographs by multiple, small, well-defined, circumscribed areas of cancellous structure up to the size of a pea. These may be scattered about in the expanded ends of the main bones of the extremities, and in the pelvis, ribs and skull. Near the termination of the illness these foci may be almost contiguous. In the shafts of the long bones the cancellous tissue may be destroyed, the medulla expanded and the inner border of the compact cortex may show much crescentic scalloping of the size indicated above. In some of these lesions the peripheral border of the cortex may be pushed out beyond the line of the shaft. In those cases of diffuse myelomatosis the diagnosis may depend entirely upon the finding of Bence-Jones proteose and the recognition of the typical cells in the tissue removed by sternal puncture.

Carcinomatosis producing generalized osteoporosis of the skeleton is relatively rarely diagnosed at the stage when investigations are being made, though it is not so rare as a terminal observation. More commonly the disease is shown only in the pelvis, spine, ribs and proximal bones of the extremities and in these there may be irregular distribution. Even when the disease can be recognized radiographically as generalized in the trunk and proximal extremities, the bones of the hands may show only generalized osteoporosis. In a few cases only a single metastasis in one of the bones has been found and that in one of the bones of the hand—this may be the first indication of malignant disease. A radiograph of the chest may show the primary to be an epithelioma. Other lesions of the skeleton may be revealed after a variable period.

In leukaemia and in certain malignant tumours we may see a generalized osteoporosis of the skeleton with periosteal accretions along the shafts of most of the long bones simulating hypertrophic pulmonary osteoarthropathy; in other cases only localized sites of periosteal reaction are shown, with perhaps some disintegration of the underlying bone. In hypertrophic pulmonary osteoarthropathy due to abscess or neoplasm of the lung, regular periosteal accretions may be found enveloping all the long bones except the terminal phalanges, which though associated with marked clubbing of the fingers often show no change.

The possibility that the generalized osteoporosis associated with one or more spontaneous fractures is due to syphilis must not be overlooked. Radiographs of the skeleton in syphilis may show generalized blurring of the detail of all bones; the details of the diploë and the cancellous structure of the bones may be completely obliterated. Considerable absorption of the bone may occur at fracture sites, and this may not show any regeneration though the other bones respond well to appropriate medication. Generalized granuloma due to lipid and other abnormal cell metabolism may produce somewhat similar changes as I have described (Brailsford, 1948a). Certain cases of osteogenesis imperfecta live to old age and they may show evidence of multiple fractures; in some cases which I have seen, fractures have remained ununited for fifty or more years. The distinctive radiographic features I have recorded (Brailsford, 1948b). Fractures and compression of multiple vertebral bodies, pressure deformities, particularly of the pelvis and lower extremities, and a skeleton lacking in normal structure and density are usually found in any extensive examination; but the clinical history usually provides the key to the diagnosis. The occurrence of extensive subperiosteal hæmatoma as a complication of osteogenesis imperfecta must not be overlooked, for such have been mistaken for sarcomata. The generalized osteoporosis which is associated with hyperthyroidism need only be mentioned for the symptoms of the latter dominate the picture.

Osteoplasticity

There are a number of terms which indicate a diminished density of the bone, but few which denote an increased density. The terms osteosclerosis and osteopetrosis suggest a bone of stony hardness, but many of the bones to which they are applied have little more than the hardness of chalk. Because such bone often shows a greater degree of

hand, even in cases exhibiting the characteristic features of Paget bone throughout the skull, spine, and the large proximal bones of the extremities, may show all the bones of the hand to be normal, or one or two small bones may show the characteristic Paget bone throughout. I have classified (Brailsford, 1938) the radiographic features of Paget's disease into three types: (1) Osteoporotic; (2) Osteoplastic; and (3) Lithocystic.

Distinctive from the fine stippling of the skull in hyperparathyroidism, in Paget's disease there may be the conditions of osteoporosis circumscripta or a localized area of the skull may show thickening of the pericranium, an osteoid development which contains multiple ill-defined deposits of greater density resembling pledgets of cotton-wool. The affected area of the skull may become an inch or more in thickness. Later the periphery of this thickened pericranial tissue and even the dura may show the density and appearance of ossification.

The Paget lesions in the long bones may begin with the appearances of a gradual deposition of calcium which obliterates the detail of the cancellous structure converting it into a so-called "ivory" bone of uniform density, but at the expense of increased fragility. Later the affected bone may show osteoporosis. When fracture occurs this osteoporosis becomes the noticeable feature. In other cases the lesion begins, as I (Brailsford, 1938) have shown, in a superficial lanceolate area of decalcification which gradually spreads along the bone in a very characteristic fashion; it produces what I have described as the V-shaped thrust of the Paget bone into the normal. The appearances can be illustrated by partially tearing the wrapper from a tightly covered journal, the end of the tear has the shape of a V. Such appearances suggest that the periosteum resists the progressive expansion of the Paget bone for a time, but eventually it yields, and strips in this fashion from the adjacent normal bone. The line of demarcation is clearly defined, the Paget side showing decalcification by its lesser opacity than the normal. As the acute phase passes, the line of demarcation may be removed and the two segments may blend or a further recurrence may occur and the Paget thrust be extended to involve a further segment or the remainder of the bone. This characteristic V-shaped demarcation between the normal and Paget bone is to be seen in no other condition. Obviously it could not be present in a condition which is generalized, yet the literature contains illustrations showing this characteristic feature of Paget's disease labelled Fluorosis. Spéder (1936) used such an illustration and labelled it "Fluorosis".

Paget's disease may remain limited to the one bone when its contrast expansion will be obvious without causing any recognizable change in the joint surfaces. One vertebra may be involved with one or both of its associated ribs but the adjacent vertebrae and ribs may be unaffected. This series of changes is characteristic of Paget's disease. It is not seen in hyperparathyroidism or any other condition which might be thought to resemble Paget's disease.

In renal osteodystrophy the bones of the hands show absence of compact tissue. The cancellous structure is regular but of a coarser pattern than normal, and because of the stunted growth and plasticity the shape of the bones does not show the exquisite form of the normal. The bones of the spine and pelvis being plastic show the deformities of stress and strain. If the disease is a continuation from adolescence plasticity rather than fragility is the essential feature, but if the condition has developed in adult life there may be deformity associated with multiple incomplete fractures. The skull shows changes which are probably associated with hyperactivity of the parathyroids (for these are all found to be hypertrophic) but it is a coarser change than that seen in hyperparathyroidism due to tumour. The detail of the diploic structure is obliterated in a general osteoporosis which appears to have begun in multiple miliary foci which in many areas have coalesced to form fairly well-defined rounded decalcified patches. These are separated from similar lesions by denser structureless bone. There is little or no marked increase in the thickness of the skull and none of the cotton-wool-pledget effect. It will be seen therefore that the resemblance to Paget's disease is very superficial and unlikely to confuse the experienced observer, particularly when in possession of the age and clinical history of the patient.

In idiopathic steatorrhœa the bones show general decalcification and absence of compact tissue. The bones of the hands may have the external form of the normal but their cancellous structure, though regular, appears to be of coarser mesh. The bones of the pelvis and spine show these characters well. Plasticity of the bone is a feature: bending, moulding and pressure deformities, and, in some cases, incomplete fractures, particularly of the pelvis and bones of the lower extremities, will be seen.

Neurofibromatosis (von Recklinghausen): Associated with the multiple skin lesions of neurofibromatosis, multiple neurofibromata may be found in the skeleton. In the skull and spine there may be large or small areas of destruction of bone, sometimes associated with diffuse osteoporosis and reactive thickening of adjacent bone; and the skull may acquire the thickness of one inch as I have illustrated (Brailsford, 1948a). In many sites the bones may be scalloped to form beds in which the tumours lie. I have also recorded that diffuse osteoporosis of the whole skeleton with multiple incomplete fractures may be found,

and one or more of the bones may show localized surface destruction or even fine spicular formation.

(The radiographs used to illustrate this paper are to be found in Brailsford, 1948a.)

Sir Thomas Fairbank: I propose to refer to a few somewhat unusual cases.

Occasionally osteogenesis imperfecta may be a matter of real interest in an adult patient. It is well known that some cases, particularly the milder ones, tend to improve gradually, till the fragility of the bones disappears. Occasionally recovery may take place even after adult life is reached.

A rather severe pre-natal case never walked till 12 years of age, and was laid up with many more fractures later. There was an element of softening of the bones or mollities present, in addition to the fragility. At 20 there was still considerable generalized osteoporosis and an incomplete fracture of one femur. This young woman, although a deformed dwarf of 31, is able to get about and has worked as a secretary in a London office for some years. One brother, in a family of four, was also affected: he died at 17, never having walked.

There is a rare and little-known complication of osteogenesis imperfecta which may occur in the adult. It is not only of considerable interest but is important from the diagnostic point of view.

A boy aged 14 in 1937 had had multiple fractures early in life but none for the preceding six years. When 7 the right thigh had been contused, and at 8 thickening of the thigh was noticed. Amputation of the leg had been seriously considered. Radiographs taken in 1937 showed a large amount of open mesh bone surrounding the lower two-thirds of the femur. Now at 24 recent films show the additional bone still present. At 14 there were signs of a fracture of the shaft of the left femur, united with no excess of callus. Ten years later he suddenly complained of pain and swelling of his left thigh. A radiograph five weeks later showed a shadow measuring at least five inches across in the film, and its shape and texture suggested the possible presence of a sarcomatous growth. Fortunately we have experience of other cases that have developed similar masses of hyperplastic callus.

Dr. Brailsford, in a paper on osteogenesis imperfecta (1943) referred to four cases complicated by what he took to be superiosteal hæmorrhages, and he suggested an element of scurvy to account for these. His cases include the one now referred to, copies of the early records and films having been also sent to me by Dr. W. Mackenzie, to whom I am indebted for the recent history and further radiographs.

In 1946 Professor S. L. Baker published a paper on "Hyperplastic callus simulating sarcoma in two cases of fragilitas ossium". We now have records of six other cases (Fairbank and Baker, 1948). Most, but not all, of the eight cases have a background of osteogenesis imperfecta.

The femur is the bone most frequently affected. The hyperplastic callus, with or without a provocative fracture, may, as in this case, extend the whole length of the shaft of the bone. Sometimes the early callus is excessively dense and structureless. Another feature of these cases is the presence of multiple bony excrescences on the shafts of the long bones, particularly along the interosseous borders of the bones of the forearm and leg. Professor Baker has informed me that one of his cases in which, as a result of fractures four years ago, both femora were surrounded throughout their entire length by enormous masses of callus, has also recently flared: at the age of 19 he has developed, quite spontaneously on this occasion, great swelling of one thigh and a new mass of callus. For various reasons we cannot agree with the suggestion of scurvy: histological examination of biopsy specimens in Baker's two cases revealed no sign of old hæmorrhage. Sections showed infiltration of the muscles by oedema and chondroid tissue, while in the deeper layers of the mass there was calcified cartilage and woven bone. Similar histological features were found by Professor Baker after a recent biopsy in Dr. Mackenzie's case. The callus in this case increased still further in thickness and extended the full length of the bone, but now the swelling has begun to subside. It seems highly probable this femur also will remain permanently enlarged. But for the curious behaviour of his two femora, this case seemed to have recovered from his generalized osseous dysplasia.

X-ray films were then shown of an old lady of 73 suffering from osteopetrosis or "marble bones". On admission to hospital (under Dr. Wallace J. Gill) with a minor head injury, the extreme density of the bones and an old fracture of one femoral neck were discovered. Though the generalized osteopetrosis was very severe, there was no anæmia, and no optic neuritis. Spleen not palpable. The

moulding than the normal and for the want of a better term, I have used the term osteoplastic. Generalized osteoplastic change throughout the entire adult skeleton recognizable by radiography, is rare. From time to time one sees a case of Albers-Schönberg's disease in an adult. Such cases are recognized from radiographs taken in the course of investigation of fractures or other conditions. Though the condition may not be recognized until middle or late life it has been present since infancy and would have been detected at an earlier age if radiographs had been taken. In some cases the condition can be recognized in the fœtus *in utero*, in others the dystrophic bone commences to be laid down in infancy. As with other general dysplasias and dystrophies of the skeleton it may be so severe as to affect the fœtal skeleton seriously and be incompatible with survival; such cases can be detected by radiographs of the pregnant woman. In other cases severity permits of life for a variable period—even to old age—and the dystrophic bone maintains its characters. In the severe degrees of the dystrophy, the dystrophic bone laid down is expanded beyond the normal, giving the long bones club-shaped extremities and the vertebral bodies an expanded denser superior and inferior third. All detail of the structure of the skull may be obliterated so that the radiographs suggest an earthenware skull. In the lesser degrees, and it is these which are discovered accidentally only by radiography, some of the bones may show little departure from the normal shape, though they show little true compact bone and bands of dense bone running parallel to the growth cartilage with little or no evidence of a medulla. Such bones fracture like chalk—the fibrous element being apparently deficient. The nature of the condition may be brought to light because of such a fracture or because of a progressive anæmia or cranial nerve involvement. The radiographic features are distinctive but apparently not generally understood for when Flemming Møller (1934) published his account of the appearances of the bones in fluorosis a number of papers followed on the subject in which the authors used illustrations of such conditions as Paget's disease and carcinomatosis, and some authors went to the length of stating that Albers-Schönberg's disease was not a rare condition but one which could be produced at will by the ingestion of fluoride.

Flemming Møller showed that the workers in cryolite develop after ten or more years an increased density of the bones—the trabeculae appeared to grow thicker with the deposition of denser material until all their cancellous spaces were obliterated. There was no change in the form of the bones to indicate abnormal osteogenesis or plasticity. Associated with this there was ossification of the tendinous insertions and interosseous fascia. The morbidity and mortality of these affected workers showed little difference from the normal population of Copenhagen (Roholm, 1937). The teeth showed irregularity in opacity and structure; whitish patches were readily detected on examining them.

Paget's disease in the osteoplastic form is never seen throughout the entire skeleton. One side or both sides of the pelvis, one or more vertebrae, perhaps one or more ribs, a part or the whole of the skull, sometimes without changes in the mandible, one or more of the long bones or bones of the hand or foot may show uniform density, all the other bones having a completely normal appearance. Some of the bones may present the appearances described under osteoporosis. Abnormal fragility of the bone which shows the transverse fracture of a stick of chalk may be revealed and this may be followed by the V-shaped extension and osteoporosis. The Paget bone in spite of its density is of increased plasticity; bending and pressure deformities are produced; best seen in the pelvis and the long bones of the lower extremities because the disease at this stage is compatible with normal life.

In the polycythaemias, anæmias and leukaemias of long duration, the bones acquire the so-called osteomyelosclerosis. They become unduly hard and heavy. The cancellous trabeculae are thickened and the interstices filled in with bone. The change in density is not associated with any change in nature or form, i.e. there is no indication of undue plasticity, so that unless of a severe degree, as in the case recorded by Landoff (1944) it may pass unnoticed by the inexperienced observer. It is best seen in radiographs of the pelvis. The changes are uniform throughout the bones, and distinct from fluorosis, there is no concomitant ossification in the tendinous insertions.

Carcinomatosis producing increased density of the affected bones of the skeleton may be seen following carcinoma of the prostate, œsophagus, stomach, &c. These changes are apt to be described erroneously as indicating Paget's disease but they are usually distinctive. In the early stage of development multiple rounded areas of increased density, not very clearly defined, will be seen in the affected bones. These expand and gradually coalesce. The whole pelvis, spine and ribs may show this detail, but the skull and limb bones may show it at this stage only an indication of osteoporosis. This is distinct from Paget's disease in which you may get the pelvis and the whole spine showing the characteristic change but non-uniformity with obliteration of all normal cancellous bone. The whole of the ribs or just isolated ones, and only one or more isolated limb bones may be changed from the normal; further, Paget's disease is a slowly progressive condition in a patient with the deformities due to pressure on plastic bone, whereas the dense bones in carcinomatosis are for they are associated with a very sick patient

and one or more of the bones may show localized surface destruction or even fine spicular formation.

(The radiographs used to illustrate this paper are to be found in Brailsford, 1948a.)

Sir Thomas Fairbank: I propose to refer to a few somewhat unusual cases.

Occasionally osteogenesis imperfecta may be a matter of real interest in an adult patient. It is well known that some cases, particularly the milder ones, tend to improve gradually, till the fragility of the bones disappears. Occasionally recovery may take place even after adult life is reached.

A rather severe pre-natal case never walked till 12 years of age, and was laid up with many more fractures later. There was an element of softening of the bones or mollities present, in addition to the fragility. At 20 there was still considerable generalized osteoporosis and an incomplete fracture of one femur. This young woman, although a deformed dwarf of 31, is able to get about and has worked as a secretary in a London office for some years. One brother, in a family of four, was also affected: he died at 17, never having walked.

There is a rare and little-known complication of osteogenesis imperfecta which may occur in the adult. It is not only of considerable interest but is important from the diagnostic point of view.

A boy aged 14 in 1937 had had multiple fractures early in life but none for the preceding six years. When 7 the right thigh had been contused, and at 8 thickening of the thigh was noticed. Amputation of the leg had been seriously considered. Radiographs taken in 1937 showed a large amount of open mesh bone surrounding the lower two-thirds of the femur. Now at 24 recent films show the additional bone still present. At 14 there were signs of a fracture of the shaft of the left femur, united with no excess of callus. Ten years later he suddenly complained of pain and swelling of his left thigh. A radiograph five weeks later showed a shadow measuring at least five inches across in the thigh, and its shape and texture suggested the possible presence of a sarcomatous growth. Fortunately we have experience of other cases that have developed similar masses of hyperplastic callus.

Dr. Brailsford, in a paper on osteogenesis imperfecta (1943) referred to four cases complicated by what he took to be subperiosteal hæmorrhages, and he suggested an element of scurvy to account for these. His cases include the one now referred to, copies of the early records and films having been also sent to me by Dr. W. Mackenzie, to whom I am indebted for the recent history and further radiographs.

In 1946 Professor S. L. Baker published a paper on "Hyperplastic callus simulating sarcoma in two cases of fragilitas ossium". We now have records of six other cases (Fairbank and Baker, 1948). Most, but not all, of the eight cases have a background of osteogenesis imperfecta.

The femur is the bone most frequently affected. The hyperplastic callus, with or without a provocative fracture, may, as in this case, extend the whole length of the shaft of the bone. Sometimes the early callus is excessively dense and structureless. Another feature of these cases is the presence of multiple bony excrescences on the shafts of the long bones, particularly along the interosseous borders of the bones of the forearm and leg. Professor Baker has informed me that one of his cases in which, as a result of fractures four years ago, both femora were surrounded throughout their entire length by enormous masses of callus, has also recently flared: at the age of 19 he has developed, quite spontaneously on this occasion, great swelling of one thigh and a new mass of callus. For various reasons we cannot agree with the suggestion of scurvy: histological examination of biopsy specimens in Baker's two cases revealed no sign of old hæmorrhage. Sections showed infiltration of the muscles by œdema and chondroid tissue, while in the deeper layers of the mass there was calcified cartilage and woven bone. Similar histological features were found by Professor Baker after a recent biopsy in Dr. Mackenzie's case. The callus in this case increased still further in thickness and extended the full length of the bone, but now the swelling has begun to subside. It seems highly probable this femur also will remain permanently enlarged. But for the curious behaviour of his two femora, this case seemed to have recovered from his generalized osseous dysplasia.

X-ray films were then shown of an old lady of 73 suffering from osteopetrosis or "marble bones". On admission to hospital (under Dr. Wallace J. Gill) with a minor head injury, the extreme density of the bones and an old fracture of one femoral neck were discovered. Though the generalized osteopetrosis was very severe, there was no anæmia, and no optic neuritis. Spleen not palpable. The

moulding than the normal and for the want of a better term, I have used the term osteoplastic. Generalized osteoplastic change throughout the entire adult skeleton recognizable by radiography, is rare. From time to time one sees a case of Albers-Schönberg's disease in an adult. Such cases are recognized from radiographs taken in the course of investigation of fractures or other conditions. Though the condition may not be recognized until middle or late life it has been present since infancy and would have been detected at an earlier age if radiographs had been taken. In some cases the condition can be recognized in the fetus *in utero*, in others the dystrophic bone commences to be laid down in infancy. As with other general dysplasias and dystrophies of the skeleton it may be so severe as to affect the fetal skeleton seriously and be incompatible with survival; such cases can be detected by radiographs of the pregnant woman. In other cases severity permits of life for a variable period—even to old age—and the dystrophic bone maintains its characters. In the severe degrees of the dystrophy, the dystrophic bone laid down is expanded beyond the normal, giving the long bones club-shaped extremities and the vertebral bodies an expanded denser superior and inferior third. All detail of the structure of the skull may be obliterated so that the radiographs suggest an earthenware skull. In the lesser degrees, and it is these which are discovered accidentally only by radiography, some of the bones may show little departure from the normal shape, though they show little true compact bone and bands of dense bone running parallel to the growth cartilage with little or no evidence of a medulla. Such bones fracture like chalk—the fibrous element being apparently deficient. Anterior Synechia following Perforating Injuries

By P. MCG. MOFFATT, F.R.C.S.

On 20.8.44 the patient, aged 35, was standing in his office on the top floor of the building when a bomb exploded, as he says, about 10 yards away. He finally came to rest in the next room but two, the intervening walls having parted conveniently to allow his transit. He was lowered to the ground on a stretcher by ropes and taken to hospital. On examination, according to report, his general condition was good. His injuries were laceration of the left knee, right forearm, scalp, prolapse of iris of left eye and injury to the lens, cuts in the lower lid, foreign body in the right eye with laceration of the cornea. Immediate treatment consisted of stitching the skin lacerations, abscission of prolapsed uveal tissue and stitching a conjunctival flap over the wound, stitching of the lower lid, removal of the foreign body from the right eye and instillation of atropine and antiseptic drops into both conjunctival sacs. He was transferred to a Base Hospital next day.

He remained at the Base Hospital for nearly seven weeks. The patient states that during that period no operations were performed, but discussions took place regarding an operation for releasing the iris from the wound in the right cornea. It was decided that the eye was too inflamed to allow operative interference.

About 15.9.44 he complained of marked irritation in the right eye, causing a certain amount of pain and watering. This recurred once or twice a week. On October 4 his wife noticed that there was a blister-like swelling over the scar in the cornea. It subsided and on October 7 he left the hospital. During the next five weeks there were repeated "blisters".

January 7, 1945, admitted to the Royal Westminster Ophthalmic Hospital, and the upper two-thirds of the synechia depicted in fig. I (1) were divided on January 8 (2). Two days later the tension in the eye rose but was controlled by eserine and heat until January 12 when the tension rose further and reached its peak on the evening of January 13. It then subsided, possibly as the result of the development of a large blister (3). Thereafter the eye settled down, but blisters occurred at regular intervals and with increasing severity. Short-wave diathermy appeared to cause some improvement, but suddenly in one week he had four large blisters, bigger than any previous ones, lasting four, six, five and eight hours respectively (3). He again entered the R.W.O.H. on March 22 when the scar was treated with iodine and four days later with carbolic, but blisters continued to appear, and the remainder of the synechia was divided on April 3. Rather more than a week elapsed before the blisters appeared (4 and 5), and about this time the patient noticed that he was seeing haloes. The tension measured by Schiötz tonometer was 40 mm. It was decided to decompress the eye, as the sight in this, his only effective eye, was in serious danger. A corneo-scleral trephine

bones of the hands, as usual, showed much less density than the rest of the skeleton. She died at 75. A cross section of the femoral shaft was solid, the medullary cavity having completely disappeared. Microscopic section (Professor W. G. Barnard) showed multiple spherical foci of ossification.

Another similar case died at the age of 63.

In contrast to these, the X-ray film of the hands of another woman, a very mild case of osteopetrosis, shows faint dense transverse bands in the phalanges, and a dense band at the lower end of the femur, the only other part radiographed. There seemed no reason to doubt the diagnosis, since this woman's daughter, aged 6, was unquestionably suffering from osteopetrosis of moderate severity.

Osteopoikilosis or osteopathia condensans disseminata has been seen at all ages from foetal life to over 60 years, and is always discovered by chance, since it produces no symptoms. The dense spots consist of closely packed trabeculae. The appearance of the pelvis with many dense spots, in a man of 24, may be compared with Paget's disease, in which there may be some mottling, but the dense spots are not nearly as discrete as in osteopoikilosis and are mixed with streaks or striations and clear areas, while the surface of the bone is distorted. The skull bones, so commonly showing gross mottling and thickening in Paget's disease, are among the limited number of bones not affected in osteopoikilosis.

Dense mottling of the pelvis may be caused also by metastatic growth from carcinoma of the prostate.

Paget's disease may affect so many bones that it becomes practically generalized.

Hypertrophic osteoarthropathy has resulted from a large number of different affections: it is not always remembered that it may result from an osteogenic sarcoma and this before there is evidence of pulmonary metastases.

A young woman of 19 had had a leg amputated three years before for a spindle-celled sarcoma, with much calcification in it, growing from the tibia. Well-marked signs of generalized osteoarthropathy and clubbing of the fingers. Large secondary retroperitoneal growth but no signs, clinical or radiographic, of metastases in the chest. Subperiosteal shadows were seen on the shafts of all the long bones. Two months later she died and at autopsy secondary growths were found in the lungs. Another similar case, a young man with an osteogenic sarcoma of the lower end of the radius, was treated by amputation. In the following nine months before he died he developed well-marked changes typical of osteoarthropathy.

Endocrine errors.—Most of the epiphyses were still ununited in one case (radiographs shown)—that of an intelligent perfectly proportioned dwarf of 46. His height was 4 feet; his voice high-pitched. The condition was regarded as due to hypopituitarism as the radiographs of the skull show a calcified cyst of the pituitary with enlargement of the pituitary fossa. (By courtesy of Mr. St. J. D. Buxton.)

With regard to thyrotoxic osteoporosis I can remember seeing only one case in which the osteoporosis was severe enough to result in more or less spontaneous fractures.

In senile osteoporosis the spine seems to suffer much more than the rest of the skeleton. Multiple collapse or crushes of the vertebral bodies are, of course, common. After a period of recumbency, preferably in a plaster shell when the pain is sufficiently severe, one likes to make use of some form of spinal jacket or brace. My experience, however, has been that many of these old ladies refuse to put up with a brace and prefer to suffer a certain amount of discomfort. In many such cases the ordering of a brace means wasting their money.

I would like to refer briefly to:

One case with multiple pseudo-fractures (Milkman's syndrome) since the sex of the patient is unusual. A man of 34, a miner, had broken his right leg (tibia and fibula) five years before. Union did not take place and a bone-grafting operation was necessary. He had not walked for the past four years. A year ago his neck had been explored but no parathyroid tumour was found. Biochemical investigations revealed nothing abnormal. Radiographic examination showed many typical pseudo-fractures and some general osteoporosis but the latter was not very marked.

Was the condition of this man simply due to prolonged inactivity? Owing to the war the later history of the case is unknown.

Lastly a point mentioned by Snapper (1943) is worthy of attention.

When multiple cyst-like lesions are present in the bones and the diagnosis of xanthomatosis versus fibrocystic changes is under consideration, he strongly advises the selection of a small young lesion for biopsy. He points out the typical cells of xanthoma are associated with a good deal of fibrosis in the lipid granulomatous tissue, and in an old lesion the xanthoma cells may have disappeared completely, leaving nothing but fibrous tissue. This he maintains has often led to an erroneous diagnosis.

Anterior Synechia following Perforating Injuries

By P. MCG. MOFFATT, F.R.C.S.

ON 20.8.44 the patient, aged 35, was standing in his office on the top floor of the building when a bomb exploded, as he says, about 10 yards away. He finally came to rest in the next room but two, the intervening walls having parted conveniently to allow his transit. He was lowered to the ground on a stretcher by ropes and taken to hospital. On examination, according to report, his general condition was good. His injuries were laceration of the left knee, right forearm, scalp, prolapse of iris of left eye and injury to the lens, cuts in the lower lid, foreign body in the right eye with laceration of the cornea. Immediate treatment consisted of stitching the skin lacerations, abscission of prolapsed uveal tissue and stitching a conjunctival flap over the wound, stitching of the lower lid, removal of the foreign body from the right eye and instillation of atropine and antiseptic drops into both conjunctival sacs. He was transferred to a Base Hospital next day.

He remained at the Base Hospital for nearly seven weeks. The patient states that during that period no operations were performed, but discussions took place regarding an operation for releasing the iris from the wound in the right cornea. It was decided that the eye was too inflamed to allow operative interference.

About 15.9.44 he complained of marked irritation in the right eye, causing a certain amount of pain and watering. This recurred once or twice a week. On October 4 his wife noticed that there was a blister-like swelling over the scar in the cornea. It subsided and on October 7 he left the hospital. During the next five weeks there were repeated "blisters".

January 7, 1945, admitted to the Royal Westminster Ophthalmic Hospital, and the upper two-thirds of the synechia depicted in fig. I (1) were divided on January 8 (2). Two days later the tension in the eye rose but was controlled by eserine and heat until January 12 when the tension rose further and reached its peak on the evening of January 13. It then subsided, possibly as the result of the development of a large blister (3). Thereafter the eye settled down, but blisters occurred at regular intervals and with increasing severity. Short-wave diathermy appeared to cause some improvement, but suddenly in one week he had four large blisters, bigger than any previous ones, lasting four, six, five and eight hours respectively (3). He again entered the R.W.O.H. on March 22 when the scar was treated with iodine and four days later with carbolic, but blisters continued to appear, and the remainder of the synechia was divided on April 3. Rather more than a week elapsed before the blisters appeared (4 and 5), and about this time the patient noticed that he was seeing haloes. The tension measured by Schiötz tonometer was 40 mm. It was decided to decompress the eye, as the sight in this, his only effective eye, was in serious danger. A corneo-scleral trephine

(6) was performed on April 12. Recovery was uneventful and from that time he has never had another blister.

The best vision before the operation was 6/18 with -5.0 D.S., $+7.0$ D.Cyl Ax 60° , but one month after the vision had improved to 6/9 with -1.25 D.S., $+3.0$ D.Cyl Ax 65° .

He returned to work and was without complaint in this eye until February 1946 when he suddenly noticed haloes. The tension was 45 mm. and the trephine was filtering poorly. The operation was repeated a little to the outer side of the first (7) on March 14. Convalescence was uneventful and since then he has had no further trouble. The vision when last recorded on June 9, 1948, was 6/5 with -4.0 D.S., $+2.5$ D.Cyl Ax 65° . The trephine

FIG. I (1 to 9).—Flying bomb injuries, 20.8.44.

was filtering well, the tension normal, the field of vision to $\frac{1}{4}^\circ$ white test object almost full, but there was slight enlargement of the blind spot. The disc is a little pale and shows some pathological cupping. He experiences no handicap except when driving a car at night.

The left eye (8 and 9) was never a source of physical discomfort and gradually settled, some of the lens matter absorbing after some months. The eye was always regarded as a doubtful asset although the projection was accurate. There was a history of hypotonia for some weeks after the injury. However it was felt that no harm would be done by attempting to make a hole through the remains of the lens, and it would increase the field of vision on the left side and possibly provide a useful spare part should anything happen to the right eye. The result was rather disappointing because, although a small gap was achieved (9) through which the fundus can be seen, changes at the macula and in the lower half of retina were found. The best vision is 3/60 with correction and there is loss of the upper portion of the field of vision.

So far as the right eye is concerned, I think the chief factor in the development of the glaucoma was probably delayed formation of the anterior chamber. It is probable with a wound of this size which was uncovered, that leakage of aqueous was considerable and there had been time for peripheral synechiae to form. Whether this could have been avoided by covering the wound by a conjunctival flap at the earliest opportunity is a matter for speculation, but it would seem to be rational treatment in such cases. An alternative explanation might be that the anterior synechiae caused a rise in tension by mechanical and reflex irritation of the ciliary body with increased output of aqueous in the first place, and later on the development of peripheral anterior synechiae and gradual occlusion of the filtration angle. If so, the early division of the synechia might have prevented the onset of secondary glaucoma. It is, however, easy to understand the reluctance to do this in an only eye which was inflamed. The final choice of trephining as the most suitable operation for decompressing the eye was made on the assumption that a permanent filtering scar was necessary, and this operation was the one that gave the best consistent results.

The full significance of the blisters was not realized until the patient began to complain of haloes. Except for the attack of acute glaucoma following the first operation for division of the synechia, the tension was thought to have been normal. The scar appeared to be well healed although there were particles of pigment incarcerated in it, and it was difficult to believe that such a scar could be leaking. I think that the resistance of the scar to the passage of aqueous was overcome from time to time when the tension rose above a certain level and blisters formed. At any rate no more blisters occurred after the eye was decompressed. Fluorescein did not give any useful information.

The following is a brief account of 12 cases of anterior synechiæ following perforating injuries which have come my way.

The first group (fig. II) consists of four cases which did not have any injury to the lens.

- (1) An injury with glass in which the iris was not prolapsed, but was caught in the wound. The iris was separated from the scar about a week after the injury and no complications ensued.
- (2) An injury with a pebble in which the iris was incarcerated in the wound. Mydrine was injected subconjunctivally but the anterior chamber was not formed twenty-four hours later so a conjunctival flap was sewn over. The iris was not free. The A.C. formed on the fifth day. Subsequently four attempts were made to divide the synechia with Lang's twin knives. The A.C. was lost on each occasion and there still remains a fine thread adhering to the scar. The tension is normal but the vision is only 6/36 due to retinal changes.
- (3) Slice with a chisel. Prolapse of iris was abscised and the cornea was covered by a purse-string conjunctival flap. Synechiæ were present at each end of the scar. These were divided by Lang's twin knives within eight weeks of the injury. There were no complications.
- (4) Puncture wound with a fine wire. This patient attended Mr. Gayer Morgan's outpatient department at Guy's Hospital when I was Registrar. There was a history of injury some weeks before which was regarded as trivial. The symptoms were pain in the eye and misty vision. The tension was raised, the cornea steamy and a fine adhesion existed between a punctate scar and the surface of the iris. The synechia was divided by a knife needle and the symptoms subsided. There was no further trouble.

The second group (fig. II) comprises 4 cases in whom there was no injury to the lens but who had had a complete iridectomy. In this group glaucoma was not likely to develop. (1) An intraocular foreign body had been removed by magnet and a complete iridectomy performed at the same time. There were symptoms of irritation, photophobia and pain. A fine synechia

FIG. II (Groups 1, 2, 3).—Anterior synechiæ following various types of perforating injuries.

stretched from the wound of entry of the foreign body and one pillar of the coloboma. This was divided by a knife needle and the symptoms were relieved. (2) Injury with glass from a broken door. Prolapsed iris was abscised and the wound covered by a hood of conjunctiva. Synechiæ extended from the edges of the coloboma in the iris to the corneal scar. There were symptoms of irritation, aching of the eye and photophobia. At operation it was possible to divide only the synechia between the lower pillar of the coloboma and the scar. The symptoms persisted to some extent until the upper synechia was divided. (3) Motor accident in which a corneal injury occurred due possibly to flying glass. (4) Slice with a chisel. Both cases had a fine adhesion between one pillar of the coloboma and the scar left after abscission of prolapsed iris. There were no symptoms of irritation so the synechiæ were not divided.

The third group (fig. II) consists of cases in which the lens had been damaged at the time of the injury. (1) Perforation with a spicule of metal which the patient had removed himself. A

small synechia was attached to the scar in the cornea. There was a stellate opacity in the posterior cortex of the lens. The synechia was divided by knife needle without losing the anterior chamber. The lens opacity continued to spread and it was intended to remove the cataract but the patient ceased to attend the hospital. (2) Injury with a piece of concrete. Wound was covered by a purse-string conjunctival flap, after abscission of prolapsed iris. The lens gradually absorbed, but there was an extensive adhesion of iris to the back of the corneal scar. This was divided completely and the eye has remained quiet ever since. (3) Injury with a piece of broken spectacle lens. The wound involved cornea and sclera. This was covered by a conjunctival flap. The iris became firmly attached to the scar. The lens partly absorbed. Fine "K.P." appeared but the eye settled down after some weeks. Division of the synechia was attempted after about eighteen months but hyphæma developed and the tension rose. As the blood absorbed the tension came down and the eye became quiet. Projection of light was found to be very defective and it was decided to do nothing further. (4) Injury with a stick which had produced a large-stellate wound in the cornea. Prolapsed iris was abscised and the wound covered by a purse-string conjunctival flap. The eye settled down but extensive adhesions between the iris and the scar remained. The lens appeared to be absorbing satisfactorily, when the patient was evacuated to the country. He was not seen again for over a year and then was found to have the iris knotted to the centre of the scar. The eye, which was blind, painful and hard, was excised.

The following comment is tentative only:

Where there is a corneal wound, unless it be small, it should be covered by a conjunctival flap, care being taken that it does not exert undue pressure on the cornea. Not only does it prevent infection from entering the eye, but it promotes closure of the wound, favours anterior formation of the anterior chamber, and lessens the likelihood of peripheral synechia. Anterior synechia should, as a rule, be divided because of the risks of secondary glaucoma arising later. If a complete iridectomy has been done, this risk is probably much less. Professor Goldman of Berne states that the tension does not begin to rise until 270 degrees of the circumference of the filtration angle have been occluded, so it would seem that other factors are involved in the production of secondary glaucoma in some of these cases.

The presence of anterior synechia does appear to be a cause of symptoms which may be disabling to the patient, and division of the synechia is indicated.

Unfortunately no gonioscope was available for examining the cases, but it is hoped that this will be remedied in the near future and more complete observation will then be possible.

Mr. H. Neame said that anterior synechia were sometimes very difficult to separate, particularly the long linear type. With regard to the occlusion of 270 degrees, three-quarters of the circumference, surely there must be variation with the age of the patient. He had seen middle-aged or elderly people who had had a relatively small anterior synechia after injury develop glaucoma fairly soon. Admittedly, one had not examined them with the gonioscope, but young people with extensive synechia did not develop glaucoma, though he had always felt doubtful as to whether it was wise to leave them alone, because of the possibility of their developing glaucoma in twenty or thirty years' time as a result of the reduced angle of the anterior chamber. He could not accept Professor Goldman's statement—as quoted by Mr. Moffatt—without some corollary as to the age of the patient.

Mr. M. H. Whiting thought that the possibility of dealing with penetrating wounds by a corneal suture might be considered. In the *British Journal of Ophthalmology* some months ago there was a description of the anatomical results obtained by the use of a conjunctival flap, and the writer showed how inaccurate the apposition of the corneal surface usually was in such a case (Levykoieva, E. Th., 1947, *Brit. J. Ophthalm.*, 31, 336). There was no reason why with sutures one should not get apposition as accurately as in suturing wounds in the skin.

Anterior synechia should be divided as early as possible, and if the eye happened to be inflamed that was an indication for dealing with the synechia without delay. There were various methods of dealing with anterior synechia following perforating injuries; probably the most difficult were those which were close in to the angle. In Case 3 of the last series described by Mr. Moffatt there was an example of synechia with which the speaker had found it useful to deal by making a broad needle incision on either side of the synechia and pulling the iris out with an iris hook and then cutting it through so that the synechia were not actually removed but successfully isolated from the rest of the eye.

Mr. Whiting agreed with Mr. Neame that to talk of 270 degrees of synechia being necessary in order to produce glaucoma was nonsense. It was not merely the anatomical condition of the angle; it was the fact that the iris was continually contracting and dilating, and the pupil doing likewise, so that there was a constant irritation to the eye from the adhesion of a portion of the iris, which ought to be mobile, fixing it. That had a considerable effect not only on the irritation but also on the rise of intraocular pressure.

Dr. N. Pines contended that for the formation of an anterior synechia three conditions were necessary: the wound in the cornea must have the membrane of Descemet turned in such a way that it could not be reconstructed so that the endothelium would commence to proliferate. Secondly, the wounding of the iris was done in such a way that the epithelium of the iris was injured and commenced to proliferate. A third and consequently important factor was the delayed formation of the anterior chamber. This was why it was necessary to follow the original idea of Kuhn and to apply, in the first place, scleral or corneal stitches in the gaping wound of the cornea. A conjunctival flap in itself did not bring the edges of the wound together. Secondary glaucoma, according to Levkoieva, was formed by proliferation of the endothelium of the cornea or the epithelium of the eyes or both of them forming a thin line across the corner of the anterior chamber.

Dr. Pines submitted that Mr. Whiting was right in saying that synechiæ should be dealt with as early as possible. He had just reviewed a book on the subject from Russia in which it was emphasized that to avoid complications it was well to suture the cornea as early as possible so as to prevent any proliferation.

Mr. A. S. Philips said that, besides allowing re-formation of the anterior chamber, if the suture was used it also allowed the surgeon to inspect the anterior chamber day by day to see what was going on inside. That was impossible when there was a conjunctival flap.

With regard to Lang's twin knives, clearly if the anterior synechia was to be divided successfully it was essential not to lose the anterior chamber, and that could only be achieved if Lang's twin knives were exactly a twin set; the area of the cross-section of the shaft of the two instruments should be identical. Often they became transposed and the only way to check whether one had a true twin set was to use a gauge. Unless the knives were a pair it was safer not to use the second Lang's twin knife but to do the whole operation with the first. That did just as well because the side of the perforating instrument was also sharp and would cut the synechiæ as well as did the cutting instrument.

Mr. F. W. Law said he had hitherto believed that the essential part of the twin knives was that the blunt one was fatter than the sharp one. Therefore was Mr. Philips right on this important point?

Mr. Affleck Greeves put in a plea for complete anaesthesia, either local or general, before division of an anterior synechia was performed. In his experience if anaesthesia was complete and great care taken and proper time given to the operation, then one instrument was all that was necessary. It was all-important that as far as possible no aqueous should be lost.

The President did not think the value of corneal suture in such injuries had been appreciated to the full extent. It was not difficult to do. Good apposition of the wound edges could be obtained, and a flap became unnecessary. In any case, there were always cases that gave rise to anxiety.

Mr. Moffatt thanked Mr. Whiting for his description of a method of isolating a peripheral synechia, a method of which he had not hitherto thought. He had, however, thought of using a keratome to divide the synechia.

Mr. Moffatt had not, so far, sutured any of the perforating wounds because of the risk of increasing the damage already done.

With regard to Dr. Pines' remarks as to proliferation of epithelium, it might be that when members became more familiar with the gonioscope they would be able to see how much peripheral anterior synechiæ actually existed in cases which developed glaucoma, or even in those which had not developed glaucoma but had had a synechia for some considerable time.

Mr. Neame had queried the correctness of Professor Goldman's statement as to 270 degrees. Mr. Moffatt had gathered that Professor Goldman had been taking that figure as the amount of peripheral anterior synechiæ, excluding other complications, required to produce glaucoma.

Mr. Moffatt added that he had not said very much in regard to the methods he had used for division of anterior synechiæ. He mostly used the Lang's twin knives, sometimes he used the sharp pointed knife only or a knife needle. He believed that a stout synechia could be more easily divided with a Graefe knife though he had always been afraid he might damage the cornea in the attempt.

Mr. Moffatt agreed with Mr. Greeves that complete anaesthesia was essential; certainly in the case of young people he personally had always had them under a general anaesthetic before attempting to divide the synechia.

Mr. Philips, in reply to Mr. Law, said that he thought that Lang's twin knives were made not with a constant uniform shaft but that the shaft became thicker as the handle was reached. The perforating needle, the first one, was only just put inside the anterior chamber and so the narrow section of the shaft was engaged, the following knife was pushed through into the anterior chamber, so that as the shaft became much thicker, the thicker portion of the shaft engaged in the hole.

Exfoliation of the Lens Capsule in Each Eye.—P. MCG. MOFFATT, F.R.C.S.

W. A. H., aged 52. Has spent most of his life in India. Shortsighted from boyhood. Five years ago he noticed blurring of vision and coloured haloes round naked lights. He has been examined many times under suspicion of glaucoma, but the Schiötz measurements have always been within normal limits, and the fields of vision show no deterioration.

R.V. 6/18 with -5.5 D.S.

L.V. 6/18 with -4.5 D.S., -1.0 D.Cyl. Ax 180° .

Examination shows exfoliation of the lens capsule, particles floating in the anterior chamber and frost-like deposits on the margin of the pupil and elsewhere.

Mr. F. A. Williamson-Noble thought Mr. Moffatt would remember that when they were in Switzerland together and Professor Goldman demonstrated the use of the gonioscope he had said it was possible when using the instrument to see flakes lying in the region of the angle and that these flakes gave rise to the glaucoma. Could that apply to the exfoliation under discussion?

Mr. H. Neame asked if any member had any knowledge of what happened to those with exfoliation of lens capsule if they were operated on for glaucoma. Did the drainage become obstructed again? He presumed it would be no use to wash out the anterior chamber because that washing-out would have to be repeated several times. Had any member watched such cases following operation for glaucoma?

Mr. Moffatt said there had been a paper on the subject (Gradle, H. S., and Sugar, H. S., 1947, *Amer. J. Ophthal.*, 30, 12); and the point as to operation for glaucoma had been mentioned "... Since there is a tendency for the drainage path to be closed by further exfoliated shreds carried there from the lens surface by the newly diverted current of the aqueous, any glaucoma operation must be followed by the constant use of miotics to prevent further exfoliation from the capsule..." Removing the lens did not relieve the glaucoma if it was already present. Gradle and Sugar had reviewed 77 cases in their paper.

Section of Dermatology

President—J. E. M. WIGLEY, F.R.C.P.

[April 15, 1948]

Modern Conceptions Concerning the Compulsory Isolation of Lepers

Contagious Malignant Morbus Hansen versus Non-contagious Benign Hansenide

By R. D. G. PH. SIMONS, M.D.

*Privat docent at the University of Leiden
Dermatologist of the Civilian Hospital Amsterdam*

It is deplorable that even to-day some dermatoses may be diagnosed as leprosy, thus leading to wrong and inadequate treatment. The patient too, may abandon all medical care in fear of compulsory isolation as a leper.

Syphilis and leprosy are often confused. Because the Wassermann test may sometimes be positive in leprosy it may also happen that syphilis is not diagnosed in a leper. This unfortunate occurrence (which only happens in rare forms of malignant leprosy) has been the cause of the erroneous opinion that a positive Wassermann reaction is only a freak of leprosy, instead of the coincidence of syphilis being suspected *a priori*.

The classification of leprosy is highly important.

There is one point, however, which invariably appears in all classifications, even in that of the Second Pan-American Conference of Leprosy in 1946¹, namely that there is a non-contagious and benign form of leprosy.

Morrow in 1854 and Stelwaggon in 1910 divided leprosy into two groups: (1) *Lepra tuberosa*; (2) *lepra maculo-anæsthetica* or *lepra nervorum*.

In 1931, at the Congress of Manila, a new division was made: (a) Neural leprosy; (b) cutaneous leprosy.

This classification, however, was misleading, as "neural" did not imply neurological, and "cutaneous" did not exclude an involvement of the nerves. The latest international classification was made in Cairo in 1938, and it is still in official use. It divided leprosy into two main groups: (a) Lepromatous leprosy (L) which is leprosy of the skin, nerves, glands and internal organs; (b) Neural leprosy (N) which corresponds approximately to the former maculo-anæsthetic leprosy.

The meaning of both terms has more or less altered with the advance of time. Nowadays lepromatous leprosy (L) implies the multibacillary, malignant, and contagious type, whereas neural leprosy (N) implies a paucibacillary, non-progressive, benign and non-contagious form. The so-called lepromine test is negative in the former (L) and positive in the latter (N), because of the abundance of antibodies. The (N) leprosy is again subdivided into Na, mainly anæsthetic, Ns the more visible form and Nt, the tuberculoid form. The Havana Congress, 1948, classified leprosy as lepromatous, tuberculoid and indeterminate (not intermediate) leprosy.

Another very important factor in classification is Virchow's globus or leper cell. This consists of a great number of vacuoles ("foam cell") containing a fat or lipid, as well as a multitude of leprosy bacilli. In those cases where leprosy bacilli are seen in "cigar bunches", one can assume the presence of a rudimentary globus. Leper cells or "cigar bunches" are characteristic of lepromatous leprosy, they are absent in N-leprosy.

This is an important point, as the nose has been regarded as the "porte d'entrée" of leprosy, or the positive nose-smear as the first symptom. However, in the majority of lepers (nearly all N-leprosy) the discharge from the nose is negative. A positive nose-smear, therefore, is not an initial symptom of leprosy, but a symptom of degree, since it indicates

¹This is not the international conference. The international Cairo classification is still the official one. In the Havana Congress (1948) the same opinion was expressed.

malignant lepromatous leprosy. A positive nose-smear generally only contains "cigar-bunches" thus indicating leprosy L. Just as in tertiary syphilis, lepromatous leprosy has a predilection for the nose.

A transformation of N into L leprosy (compare the transformation of a tuberculide into lupus vulgaris) is very rare (Schujman, Rodriguez, Plantilla and Wade). In fact, N and L leprosy should be regarded as "polar forms", separated from each other by a "no man's land" in which a true transmission from N into L leprosy is most improbable (Cochrane).

A diagnosis of the different types of leprosy is a difficult task and calls for specialized knowledge. For instance the infiltrative process in N-leprosy can be so pronounced that induration can be felt and N-leprosy seems to simulate L-leprosy (Davey), which is also infiltrative. When a similar picture of tuberculoid is found in tuberculosis, it is called "sarcoid".

Thus tuberculoid leprosy (a histological concept), will rarely be tubercous (a clinical or morphological concept), though tubercous leprosy usually implies the malignant lepromatous leprosy, whilst tuberculoid leprosy (also called lepride) implies the most benign leprosy.

Rogers, who traced the source of infection of his patients, found that 94.7% of it was due to L-leprosy. In the remaining 5.3% a new infection was traced to contact with a nerve case; probably a mixed type with preponderance of nerve symptoms.

To summarize, there are two main types of leprosy: (1) The contagious malignant form. (2) The non-contagious benign form.

It should therefore be quite possible to find a terminological solution, which according to my mind lies in the *name* of the disease.

If, however, the misleading habit of calling all types of leprosy Morbus Hansen should persist, it will be a definite regression and we shall labour under the same misapprehensions and difficulties as our colleagues in the Middle Ages. We shall class the lepride with leprosy or Morbus Hansen and thus condemn 80% of those suffering from the benign type of the disease with the 20% suffering from malignant leprosy.

It is not generally realized that the majority of patients formerly called lepers are not leprosy in the old sense of the word, but suffer from a benign disease. Their segregation is unscientific, unreasonable and inhuman: "The whole weight of modern, competent opinion is that such cases (i.e. 80% of all (Rogers)) are no danger to the public and that their segregation only encourages false and misleading fear" (Brit. Emp. Lep. Relief Assoc.).

The new term "Hansen's disease" has been explained in a non-medical magazine, thus instructing the public as to its real meaning. That is another reason for separating the benign form from the Hansen terminology.

In the case of treponematoses a similar incidence arose accidentally. Yaws and syphilis are caused by spirochetes which cannot be differentiated, though nobody will ever mistake the one disease for the other. And so to my point: just as some benign forms of tuberculosis, i.e. Boeck's sarcoid and Bazin's erythema are called *tuberculide*, so should the term Morbus Hansen or leprosy be differentiated from the term Hansenide. This new terminology should give the N or T patients a new lease of life and the *ghastly alternatives of either no medical treatment or barbed wire for life would no longer confront them*.

Muir and Rogers therefore suggest using the term "neuritis" in such cases, "thus excluding difficulties due to unreasoning prejudice". In Surinam such cases are called "suspect".

If, therefore, such Hansenide patients are still in leper homes, they should (provided a well-established diagnosis is made) immediately be released, sent home or to a sanatorium for treatment. Treatment should be mainly directed towards a general improvement of health and increase in resistance. Too active treatment should be avoided.

Much money will be saved this way, which in turn "can be well devoted in increasing the attraction and treatment in leper homes for the *infective* cases" (B.E.L.R.A.).

As to the contagiousness of leprosy: The origin of infection is still open to argument. Many people in fact claim to have demonstrated a direct contact infection, whereas others insist on having found an inanimate medium.

Hundadze, Pefard, Mitchell, Marchoux, Ehlers and others, have described cases in which physicians were contaminated following an injury during treatment of a leper. Blanchard, Blanquier, Mitsuda, Kensuke, &c., described incidents of leprosy primarily due to the custom of tattooing. Hildebrandt tells of a child which had infected itself by pricking its skin with a needle with which another child had demonstrated the analgesia of its leprosy skin. Strain found the beginning of leprosy in the wound of a breast excision in a woman, whose son had been suffering for three years from manifest leprosy. De Lange reviews an infection from a morphine syringe. Infection by clothes has been described by Arning, Looft, Romer, Hansen, Lorand, and many others. Bergmann observed that 20% of female hobsies working in leper colonies sooner or later acquire the disease. Broers van Dort, Gougerot, Giordano, Muir and Simons among others described the origin of infection,

or probable infection from soil, i.e. from walking with bare feet. It is a well-known fact that the slightest injury of the leprous skin of a lepromatous leper exudes bacilli. This in turn finds its practical use in the examination of the serum from leprous earlobes.

Leprous bacilli may be present in all layers of the skin, but it is by no means certain that normal scaling of the skin does expose bacilli. According to des Essarts, bacilli in the hair follicles may "grow out" with the hair and furthermore bacilli from the sweat glands may be brought to the surface by the action of these glands.

It is, however, still questionable whether the infection is due to direct or indirect (intermediary) contact. What is certain is the fact, that the disease is epidemic in some areas, and it is practically certain the "contact" (direct or indirect) for infection must be close and of long duration. The disease is not only confined to certain countries, but is, in fact, found in particular areas, or even particular houses. Should there exist an intermediary factor, such as an insect, it is bound to have a short "action radius".

Since the disease is neither waterborne (occurring in towns and villages along rivers), nor airborne (occurring in disseminated areas due to mosquitoes and the like), it must be assumed that it is, like scabies, a "familial disease".

As infection usually only occurs after long-continued intimate contact with the source, I am of the opinion that the disease is not highly contagious and that the risk of infection is relatively small, though one should never be exposed to this small risk for any length of time.

Moiser found acid-fast bacilli, similar to those of leprosy, in 69% of cockroaches from leper colonies. Although it is possible that these bacilli may also exist in cockroaches that do not come from leper homes, it is an important feature, which requires serious hygienic measures.

An even more likely carrier of infection is the common bed bug, particularly as it is, in contrast to cockroaches, a blood-sucking insect. Goodhue, Ehlers, Bourret, Sandes, Lebœuf, Skelton, Perham, Thomson, Johnston, Da Buen and many others (Rogers) have detected acid-fast bacilli, similar to leprosy bacilli, in bed bugs.

But quite apart from the *mode* of infection, one can assume from all investigations that L-leprosy is infectious. The danger of infection should neither be exaggerated nor underestimated.

Rogers, Muir, Cochrane and others claim that children are particularly prone to infection. Manalang goes so far as to state that only children can be infected, whereas adults are immune. Children are usually taken early from leprous environments, and, should they happen to be born in it, they are removed as soon as possible.

Of great value for the demonstration of the epidemiology of L-leprosy and the non-infectiousness of N-leprosy is the so-called *Nauru epidemic*. In 1912, a leper woman from the Gilbert Islands was allowed to enter Nauru, a Pacific (South Sea) Island. This happened against the advice of the quarantine physician. In 1925, 368 new cases, i.e. one-third of the whole of the population, were found to be infected: an infection which could be traced to this one case. In spite of the panic caused by this epidemic, Rogers, in fighting it, advised the isolation of only the 189 L cases. A decrease of infected cases was noticeable in 1933, and in 1937 there remained only 57 L and 102 N cases. "Thus one of the most serious epidemics in history had been got under control" (Rogers). (Unfortunately no further developments can be reported, as the Japanese drowned all surviving patients during the occupation.)

The dangers of compulsory measures are the following: patients dare not report the disease. This not only leads to wrong statistics, but in addition patients cannot be treated and hidden cases form a great potential unchecked danger. Still worse, thousands of people suffering from diseases wrongly regarded as leprosy do not report for medical treatment.

"Total segregation therefore spreads leprosy" (B.E.L.R.A.).

"Where it becomes known that patients are to be shut up for life, lepers will conceal themselves outside and keep on—those are the L cases—spreading the disease" (B.E.L.R.A.).

When a house-to-house investigation was carried out in India, it became evident that for 102,000 known cases, over one million were hidden, of which one-quarter were of contagious type. Only 14,000 cases are isolated, of which 5,000 are non-contagious (Rogers).

In 1925, the South African Government ordered an examination of 3,501 patients who were "immured in prison-like asylums"; 800 were found to be non-contagious and were released. The result was striking; from that moment twice as many cases (about 4,000) reported voluntarily. Of a total of 6,769 cases, 60% (4,052) could be released again after having received adequate treatment. 61% remained free of any symptoms for the next five years. For this reason nobody to-day will advise the obsolete method of "hunting down hidden lepers like wild beasts" (Rodriguez).

"Millions have been spent on segregation, without any effective good and millions more will be wasted on it" (Moiser).

"Segregation is a regrettable necessity in the case of infective lepers. But we have no right on humanitarian grounds to separate a man from his wife and family, unless there are adequate public grounds for doing so" (B.E.L.R.A.).

Hansenide—i.e. N-leprosy—patients should not be isolated.

"It is therefore imperative that the line of demarcation as far as segregation is concerned, should rest not on the diagnosis of leprosy but on the differential diagnosis between the infectious and non-infectious leper!" (Rogers and Muir.)

"Let us change our methods: We know that compulsory segregation has proved worse than useless" (Moiser).

"The whole concept of total segregation is out of date" (B.E.L.R.A.).

Conclusions.—"As long as we had no treatment of material value there was some excuse for recourse to the crudities of the Middle Ages: lifelong segregation of lepers" (Rogers and Muir). To-day, however, there remains no doubt that one can save energy and money by isolating only the malignant lepromatous and not the Hansenide patients.

The Hansenide patients who leave leper colonies, will in their turn encourage others to undergo adequate treatment, since they will see by this example that leprosy is no longer a crime for which the only punishment is imprisonment for life, but that it is curable and certainly in two-thirds of all cases not even contagious. Lepers and sufferers from disease classified as leprosy will no longer fly from the police and . . . the doctor!

The answer to the question what should be done with the isolated patients is twofold.

(a) All patients with L-leprosy should remain in isolation. Leper homes should be called "clinic" or some such name. Diagnosis should be negative for at least two years without the appearance of new symptoms before the patient's discharge is considered. This period of two years has been decided upon, as any shorter interval has resulted in too many relapses (Culion).

(b) All Hansenide patients (N or tuberculoid leprosy) should be discharged immediately, though they would have to remain under regular supervision of a skin specialist.

The following should be cared for by the public health authorities: Those Hansenide patients who suffer from general poor health, or who return to unhealthy and poor environment, also patients who are likely to turn to prostitution or to contract tuberculosis—24% to 32% of all lepers die from tuberculosis and many more suffer from it (Faget).

In conclusion I would say again that segregation should depend not on the diagnosis of leprosy, but on the differential diagnosis between infectious malignant leprosy and the non-infectious Hansenide.

Schamberg's Disease.—H. W. BARBER, F.R.C.P.

Miss I. W., aged 62.

History.—In December 1944, she stated that she had been subject to attacks of *follicular tonsillitis* all her life, and that at the age of 18 she had a particularly severe one which was followed by *chorea*. Although there is no valvular disease of the heart, she had at one time frequent extrasystoles, but these diminished, and a report by Dr. Peter Miles (19.7.39) on her cardiovascular system revealed no organic changes, only occasional extrasystoles.

The eruption appeared first in August 1944 on the inner side of the left knee. Later the anterior surfaces of the legs and the skin between the toes became affected. The eruption continued to spread, eventually involving the legs, particularly over the knees, the elbows and forearms, the palms and soles and the skin between the fingers and toes. Patches also appeared on the abdomen, shoulders, and inner thighs.

The tonsils were clearly infected, and she was admitted to Guy's Hospital in August 1945 for their removal; afterwards she was given a five-day course of sulphamezathine, during which there was an exacerbation of the eruption. This was followed by a general subsidence.

December 14, 1945: The eruption was still present on the legs, over the patellæ and elbows, and on the forearms and palms, but was much less active. Small new patches appeared from time to time. She continued, however, to have sore throats, particularly in the left tonsillar fossa, where periodically a remaining portion of lymphoid tissue became inflamed and ulcerated.

In July 1946 there was an exacerbation on the hands and wrists and in August 1946 she was again admitted. An ulcer in the left tonsillar fossa was present, but cultures from this revealed only *Streptococcus viridans* and no B-hæmolytic strains.

Summary of investigations by Dr. R. L. Waterfield: Slightly raised B.S.R.; slight simple anæmia with slight lymphocytosis. Blood clotting time was normal.

Intramuscular injections of penicillin—300,000 units twice daily for ten days—were given and she was then discharged.

From then onwards the active eruption has gradually disappeared, and there has been great improvement in her general health. Occasionally, however, there have been recurrences of the inflammation with ulceration in the remaining portion of infected lymphoid tissue in the left tonsillar fossa. When this occurs she feels unwell and *new active lesions always appear on the left forefinger.*

When last seen, April 2, 1948, even the pigmented remains of the greater part of the eruption had disappeared. These, however, were still present as brown patches on the fronts of the knees, on the palms, and on the left forefinger where the eruption recurs with her sore throats.

She has for long noticed that bruises appear on slight trauma of the skin, and formerly pressure and tension exerted on the skin of the palms, e.g. by wringing out clothes, produced linear hæmorrhagic streaks. These no longer occur.

Comments.—I have long held the view that Schamberg's dermatosis, in view of its histopathology, is probably caused by a hæmolytic toxin acting both on the blood cells and the walls of the capillaries. I have had many cases in which a chronic streptococcal infection, as in this case, proved to be responsible, and a few in which the eruption appeared suddenly after an acute infection, such as tonsillitis.

Dr. Barber then showed some coloured photographs of one of his early cases—an elderly man in whom the legs were extensively involved. He had been having injections of an autogenous hæmolytic streptococcal vaccine for a chronic throat infection. After his first visit he was evidently given an overdose of vaccine, which was followed by a rigor, high temperature, and the acute outbreak of his eruption on the back shown in the second photograph.

In another patient, seen during the past few years, the eruption, which became widespread, appeared when he was on active service after a septicæmic infection complicated by thrombophlebitis migrans. The point of interest in his case is that the organism responsible would seem to have been a strongly hæmolytic *Staphylococcus aureus*. He is now well.

The striking clinical resemblance of the eruption provoked in some persons by adalin to Schamberg's dermatosis would suggest that this drug may have an action on the red blood-corpuscles or capillaries comparable to that of certain bacterial toxins, but I have not seen microscopical sections of an adalin eruption. Dr. Yorke has recently had a patient who some years previously had had the characteristic adalin rash and in whom an acute outbreak of Schamberg's dermatosis had recently followed the extraction of infected teeth.

Parapsoriasis en Plaques Treated with Calciferol.—H. W. BARBER, F.R.C.P., and DAVID ERSKINE, M.D.

A. T. F., male. The eruption, which was extensive, involving the trunk and limbs, appeared gradually four or five years ago. There were no subjective symptoms. It improved under the influence of sunbathing in the summer. It was a characteristic example of parapsoriasis en plaques, of the type that resembles in its zoniform distribution pityriasis rosea. Some of the patches enclosed islets of normal skin, and the margins of others formed peninsulas and bays.

In the experience of one of us (H. W. B.) the only treatment that has had any lasting effect on this eruption has been exposure of the skin to sunlight or ultraviolet radiation. For this reason, one of us (D. E.) suggested that the patient should try the effect of calciferol. He had a course of twelve ampoules of sterogyl-15 (Roussel), and after a month's rest, a further course of six ampoules.

The effect has been remarkable, and when seen on March 31, 1948, the patches had faded leaving recognizable traces which appeared to show slight atrophy.

POSTSCRIPT.—On my advice, the patient took no more calciferol and the eruption gradually recurred.

I have had three other cases of parapsoriasis en plaques, all of which have responded to calciferol, but they will probably relapse when the treatment is discontinued.—H. W. B.

Parapsoriasis en Plaques—Treated with Vitamin D₂.—ALLAN YORKE, M.R.C.S., L.R.C.P. J. M., aged 28. Stoker.

Family history.—1940: Sister recovered from pulmonary tuberculosis.

History of present condition.—Eruption first appeared about June 1945 whilst he was serving in Italy, and involved parts covered by his trunks. Ardent sun-bather. It remained localized until return to this country in July 1946, when it spread centrifugally to abdomen, chest and then to the extremities, avoiding palms and soles. Moderate pruritus. Treated at several hospitals for "ringworm" with a variety of local applications.

On examination (September 1947).—Discrete, mobile, non-tender cervical glands of rubbery consistence. Multiple well-defined plaques or patches varying in colour from

red to fawn, and in size from a silver shilling to inches in diameter. The surfaces showed fine desquamation.

Blood-count within normal limits.

X-ray of chest: No evidence of organic disease.

Treatment (November and December 1947).—(1) Thorium X 1,000 units/c.c. was applied to the lesions of the upper arms on two occasions without significant change.

(2) As the initial lesions only involved the parts covered by the trunks, whilst sun-bathing freely in Italy, and as the lesions rapidly spread when these conditions were denied him on his return to this country, it was decided to give him vitamin D₂ 600,000 units orally at weekly intervals for four weeks.

The patient himself noticed regression at the end of two weeks, and when examined at the end of four weeks, (a) some lesions, i.e. the most recent, had disappeared completely. (b) Others showed significant regression, i.e. on the forearms. (c) The oldest lesions were involuting with hyperpigmentation.

The dark staining on the upper arms is an effect of thorium X.

Comment.—This patient was probably a tuberculous contact. His response to oral vitamin D₂ was rapid and definite. Even so, it may well be that parapsoriasis in this patient represents a tuberculide, which would accord with Civatte's opinion.

Multiple Atrophic Lesions: Case for Diagnosis.—C. D. EVANS, M.B.

Boy, aged 6 years.

History.—In January 1948 this boy had an attack of nocturnal delirium and pyrexia, lasting for a week. On the second day a bullous rash appeared. For the first two days he was given a medicine to reduce the temperature, but no other drugs were used except argyrol drops for a nasal discharge. When first seen on February 20 the condition was as follows:

On the arms and legs there were dark bluish plaques, 1 to 2 cm. in diameter, slightly raised above the surface and of irregular outline. On the trunk there were sharply defined bluish circular or oval lesions varying in size from $\frac{1}{2}$ to 3 cm. These were slightly depressed below the surface and showed some superficial atrophy and slight scaling. Many of the lesions had minute flesh-coloured papules scattered over their surface (fig. 1). Since

FIG. 1.—Photograph of lesions on the trunk.

February the lesions on the trunk have changed colour to a light red, those on the extremities remain dark blue but have tended to return to normal in the centre.

Past history.—Measles, whooping-cough and pneumonia at 2 years of age. A nasal discharge which started in infancy has persisted ever since in spite of treatment. He has had frequent chest trouble and has always been thin until recently.

In January 1947 he attended hospital and was diagnosed as suffering from a tuberculous hilar gland causing partial bronchial obstruction and collapse of the right middle and lower lobes, with bronchiectasis. He spent eight months in bed and then three months at a convalescent home.

Family history.—There is no history of tuberculosis. His mother died of "colitis".

Investigations.—Histology of lesion on back (Dr. Freudenthal): "The cutis shows a cellular scar tissue, probably rather a fresh scar, but there is no hint as to what the previous lesion may have looked like. The elastic fibres are thoroughly destroyed, with the exception of a few small spots where a number of thick fibres have survived. The epidermal changes, I suppose, are secondary".

Chest X-ray: The right hilar shadow is dense and enlarged, suggesting enlarged glands. There is partial deflation, with possible bronchiectatic changes in the right middle lobe and congestive or bronchiectatic changes in the posterior basal segment of the left lower lobe.

Blood-count.—R.B.C. 5.37 million; Hb 86%; C.I. 0.81; W.B.C. 9,600 (polys. 50%, eosinos. 2%, lymphos. 36%, monos. 12%).

Patch test with argyrol nasal drops was negative.

Mantoux test positive 1 : 10,000.

Note.—A further biopsy was done on a lesion from the left thigh on 22.4.48 when most of the induration had subsided. Section showed no microscopical evidence of tuberculous infection and the inflammatory reaction was minimal.

On 23.4.48 the child was admitted to hospital with a temperature of 101.5° F. A number of vesicles appeared in the lesions on the trunk which subsided in a day or so. The temperature returned to normal in three days and he returned home to rest in bed after fourteen days in hospital.

Dr. H. W. Barber: My opinion of this case is tentative as I could not examine the child as carefully as I should have wished. He reminded me of cases that were at one time not uncommon in which multiple patches of tuberculosis of the skin (disseminated lupus vulgaris) appeared after an acute infection, e.g. measles or whooping-cough. In such cases there is clearly bacillæmia, no doubt due, as Dr. Adamson suggested, to the breaking down of an old tuberculous focus with dissemination of the bacilli in the blood-stream. Dr. Cranston Lowe emphasized the fact that during and for some time after an attack of measles a von Pirquet reaction, which was previously positive, becomes negative, presumably due to antibodies disappearing from the skin. Hence, should a tuberculous bacillæmia occur, multiple patches of lupus are apt to appear instead of one or other of the tubercles in which the circulating bacilli are destroyed.

Fox-Fordyce Disease in a Young Girl.—R. T. BRAIN, M.D.

E. G., girl, aged 10.

History of a rash in the axillæ, on the breasts and on the pubic area of about twelve months' duration. The lesions irritate when she gets warm. Menstruation has not yet started but she has some secondary sexual changes indicating its imminence.

On examination.—She is a well-developed, intelligent girl, with pale pink papules in each axilla, a few pinkish papules on the areolæ of her breasts and a few papules on the mons veneris.

Since the clinical appearances are characteristic a biopsy has not been performed.

I have nothing to add to this case report except to point out the unusual feature of its early onset.

The President: Do you propose to use any hormonal treatment?

Dr. Brain: Not yet.

Necrobiosis Lipoidica Diabeticorum following Pyoderma.—F. RAY BETTLEY, F.R.C.P.

Mrs. H. H., aged 27.

History.—A known diabetic for seven to eight years. For the last four years recurrent sore throats.

October 1947: Attended the skin department of Middlesex Hospital with a slowly growing purple nodular area on the inner aspect of the left thigh, present for over six months. Thick yellowish pus exuded from a single small sinus.

Cultures: Coagulase positive *Staphylococcus pyogenes*.

Diagnosis: Chronic staphylococcal granuloma.

November 1947: Granuloma healed following local application of penicillin cream. Seen by Mr. Monkhouse, who advised tonsillectomy.

February 1948: Tonsillectomy. Urine showed sugar ++; acetone bodies ++.

Left thigh: Healed scar resulting from pyoderma now surrounded by an annular zone of typical necrobiosis lipoidica varying from 2 to 4 mm. wide.

March 6, 1948: Biopsy of left thigh showed typical necrobiosis.

March 7, 1948: Discharged from hospital. Diabetes balanced on diet and insulin.

April 1, 1948: Early patch of necrobiosis 1 cm. in diameter on left shin.

Comment.—I brought this patient because the occurrances in diameter. The surfaces showed injury has been mentioned many times and was recently I am not aware that it has been previously recorded as developing an infective lesion.

Sarcoidosis following Injury.—F. RAY BETTLEY, F.R.C.P.

Mrs. H. C., aged 37.

History.—1927: Road accident involving grazes and cuts of varying conditions were denied him 1943: Small sores began to appear in the scars. Seen in June 1943 by a D₂ 600,000 units orally when there were present irregular scars on the forehead with considerable and when examined at of dust in the scars. Scars excised July 1943. Healed satisfactorily. appeared completely. oldest lesions were

September 1947: Red nodules appeared on the scars, starting near the outer corner of the right eye.

November 1947: Similar nodule right pre-auricular. About the same time swelling of lymph glands in the neck was first noticed by the patient.

January 1948: Further yellow nodules appearing in the scar on the right side of the forehead. General health is fairly good. No loss of weight. No specific complaint.

On examination.—Irregular scarring, mainly linear, on the right side of the forehead around the orbit. Purplish and yellow-brown nodules are scattered in the scars. Large of these in the right upper eyelid measures 1½ cm. across while many are of pinhead size. In the right pre-auricular region is a similar nodule which has arisen without a preceding scar. There are many soft, not tender, lymph glands palpable on both sides of the neck.

Investigations.—X-ray: Chest—no hilar enlargement; lung fields normal; hands and feet normal.

Blood-count.—Hb 97%; W.B.C. 6,100. Differential normal.

Plasma proteins.—Albumin 4.2 grammes%; globulin 3.2 grammes%; fibrinogen 0.19 gramme %. Mantoux 1:1,000 positive. Blood Wassermann negative.

Histology.—Biopsy of nodule (right upper lid) shows well-formed typical sarcoidosis. (Section shown.)

Comment.—The original injuries resulted in scarring with a fair amount of tattooing of dust. Four years after these were excised nodules of sarcoid began to appear in the scars. After this there seems to have been a progress of the disease, starting in the scars and then appearing on the previously unaffected skin within the lymphatic drainage area, followed by involvement of the regional lymph glands. There are at present no other signs of sarcoidosis.

I would like to mention a similar occurrence in two previous cases. The first is a man whom I now have under treatment with sarcoidosis of the pernio type on the nose. In 1944 he had a car accident in which he grazed his nose against the windscreen. This resulted in a superficial injury which healed, leaving a small red scar. In May 1947 the scar started to become thickened, and ultimately changed into a typical sarcoid covering an area two or three inches across. The diagnosis was confirmed by biopsy and there are no other lesions.

The third case of this kind is a medical student who had superficial scars on the tip of the nose resulting from a slight injury. When I saw him in April 1946 the scars were becoming red and nodular and a small nodule had appeared on the upper lip. Biopsy showed typical sarcoidosis. Dr. Leonard Howells saw this patient, and found radiological evidence of enlarged hilar glands with a fine nodulation in the lung parenchyma compatible with sarcoidosis. The Mantoux test 1/1,000 was positive; blood-count, E.S.R., skiagram of the feet, were all normal. I have not seen him since, but Dr. Leonard Howells kindly informs me that the skin lesions have not appeared; the radiological appearances in the chest are unchanged but no other sarcoidosis has appeared.

These cases are of importance because the cause of sarcoidosis remains unknown. It is usually assumed that the disease has been able to discover any information or evidence as to its origin.

Those who have assumed the disease is developing at remote sites. These followed, in the time of injury. Other possible

Family history.—There is no history as determined the onset of sarcoidosis in these particular sites.

Investigations.—Histology of cellular scar tissue, probably of a few small spots where lesion may have looked like Bloch and Sulzberger).—HENRY HABER, M.D.

I suppose, are secondarily a rash on right arm, which became generalized on the fourth day.

Chest X-ray: The r. Eruption on the trunk consisting of tense vesicles arranged in some There is partial degeneration forming a reticular pattern. Warty lesions on the proximal segments of congestive or bronchial. Blue scleræ. Twitches occasionally. Otherwise nil.

Blood-count.—Eosinophils. 2%. Lymphocytes. Blood-count normal.

Patch test was given sulphapyridine tablets for pneumonia when seven months pregnant.

Mantoux negative. No similar skin trouble in the family. The rash has undergone changes during the last ten months.

Note.—The changes during the last ten months.

Examination.—The vesicular eruption has disappeared entirely. It has been replaced by a peculiar pigmented rash of a characteristic grey-brown colour, shape, and arrangement.

On individual lesion is an atrophic macule or a bizarre line which does not follow any reticuli or nerves, the whole pattern suggests something artificial or arbitrary, never seen in history, and is characteristic for the dermatosis.

The warty lesions have undergone considerable involution and there are only a few lesions on the left thigh present.

Incontinentia pigmenti is a well-defined histological dermatological entity described by Bloch and Sulzberger. It is characterized by the following features:

- (1) Presence of lesions at birth or first days of life.
- (2) Obscure inflammatory condition of skin, such as bullous erythema, urticaria, precedes pigmentation.
- (3) Associated with the pigmentary anomaly there are sometimes other ectodermal defects.
- (4) Dermatoses may show a familial occurrence.
- (5) It has a characteristic histology. There is only slight epidermal change confined to the basal-cell layer, which shows various degrees of irregularity and hydrops of individual cells, and some smaller cells with pyknotic nuclei. In general, the pigment in the epidermis is not increased, and only slightly increased in certain areas. The stratum papillare and subpapillare show the presence of coarse melanin granules, situated within phagocytic cells. Bloch and Sulzberger forwarded a hypothesis that there is a congenital pigmentary anomaly due to a pathological permeability of the melanoblasts by which the pigment instead of being discharged into the epidermis is directed into the corium, leading to an autochthonous tattoo of the corium. This tattoo is responsible for the peculiar pattern.
- (6) The pigmentation is of such striking appearance that once seen it can never be missed again.

Dr. W. N. Goldsmith: Is the pigmentation always preceded by the various inflammatory conditions described? If so, the name is very inadequate for the clinical disorder as a whole. It only expresses a histologically diagnosed pigmentary aberration. Do the patches all look brown rather than grey or blue, in spite of the masses of pigmentation being fairly deep in the dermis, the epidermis being practically empty of it?

Dr. Haber: Bloch and Sulzberger labelled their case *Incontinentia Pigmenti* because they thought that the melanoblasts of the basal layer are unable to keep their pigment within the cell membrane. Siemens, who was not prepared to accept the Bloch-Sulzberger theory, labelled his case as a "melanotic degeneration of the corium" and Naegeli regarded the condition as a chromatophore nevus. The colour of the pigmentation is similar to that of arsenical and tar melanosis because the chromatophores are situated in the upper layers of the corium, whereas in the blue nevus the melanoblasts are to be found in the mid-cutis.

The following cases were also shown:

Case for Diagnosis. ? Leiomyoma.—Dr. G. B. DOWLING.

Riehl's Melanosis (Type Civatte).—Dr. E. J. MOYNAHAN (for Dr. L. FORMAN).

Pityriasis Rubra Pilaris.—Dr. D. I. WILLIAMS.

(1) *Erythema Figuratum Perstans*. (2) *Atrophoderma Vermiculata*.—Dr. THERESA KINDLER.

(These cases may be published later in the *British Journal of Dermatology*.)

Comment.—I brought this patient because the occurrence of injury has been mentioned many times and was recently. I am not aware that it has been previously recorded as developing an infective lesion.

Sarcoidosis following Injury.—F. RAY BETTLEY, F.R.C.P.

Mrs. H. C., aged 37.

History.—1927: Road accident involving grazes and cuts of varying dimensions on the trunks, whilst sun-bathing. Conditions were denied him. 1943: Small sores began to appear in the scars. Seen in June 1943 by Dr. D. 600,000 units orally when there were present irregular scars on the forehead with considerable dust in the scars. Scars excised July 1943. Healed satisfactorily. September 1947: Red nodules appeared on the scars, starting near the outer corner of the right eye. When examined at the oldest lesions were

November 1947: Similar nodule right pre-auricular. About the same time swelling of lymph glands in the neck was first noticed by the patient.

January 1948: Further yellow nodules appearing in the scar on the right side of the forehead. General health is fairly good. No loss of weight. No specific complaint.

On examination.—Irregular scarring, mainly linear, on the right side of the forehead around the orbit. Purplish and yellow-brown nodules are scattered in the scars. Large of these in the right upper eyelid measures $1\frac{1}{2}$ cm. across while many are of pinhead size. In the right pre-auricular region is a similar nodule which has arisen without a preceding scar. There are many soft, not tender, lymph glands palpable on both sides of the neck.

Investigations.—X-ray: Chest—no hilar enlargement; lung fields normal; hands and feet normal.

Blood-count.—Hb 97%; W.B.C. 6,100. Differential normal.

Plasma proteins.—Albumin 4.2 grammes%; globulin 3.2 grammes%; fibrinogen 0.19 gramme %. Mantoux 1:1,000 positive. Blood Wassermann negative.

Histology.—Biopsy of nodule (right upper lid) shows well-formed typical sarcoidosis. (Section shown.)

Comment.—The original injuries resulted in scarring with a fair amount of tattooing of dust. Four years after these were excised nodules of sarcoid began to appear in the scars. After this there seems to have been a progress of the disease, starting in the scars and then appearing on the previously unaffected skin within the lymphatic drainage area, followed by involvement of the regional lymph glands. There are at present no other signs of sarcoidosis.

I would like to mention a similar occurrence in two previous cases. The first is a man whom I now have under treatment with sarcoidosis of the pernio type on the nose. In 1944 he had a car accident in which he grazed his nose against the windscreen. This resulted in a superficial injury which healed, leaving a small red scar. In May 1947 the scar started to become thickened, and ultimately changed into a typical sarcoid covering an area two or three inches across. The diagnosis was confirmed by biopsy and there are no other lesions.

The third case of this kind is a medical student who had superficial scars on the tip of the nose resulting from a slight injury. When I saw him in April 1946 the scars were becoming red and nodular and a small nodule had appeared on the upper lip. Biopsy showed typical sarcoidosis. Dr. Leonard Howells saw this patient, and found radiological evidence of enlarged hilar glands with a fine nodulation in the lung parenchyma compatible with sarcoidosis. The Mantoux test 1/1,000 was positive; blood-count, E.S.R., skiagram of the feet, were all normal. I have not seen this patient since, but Dr. Leonard Howells kindly informs me that the skin lesions have now disappeared; the radiological appearances in the chest are unchanged but no other sign of sarcoidosis has appeared.

These cases are of importance so long as the cause of sarcoidosis remains unknown. It is usually assumed to be an infection, but I have not been able to discover any information or evidence as to the portal of entry.

Those who lean to the view that sarcoidosis is tuberculous in origin will presumably assume the usual portals of entry for that disease, with sarcoidosis developing at remote sites. These three cases, however, suggest the inoculation of infection at the time of injury followed, in the first patient, by a progressive spread via the lymph channels. Other possible

tissue in the corium. There is no obvious decrease in the amount of elastic tissue present.

The interest of this case lies in the fact that up till three months ago when his son developed the condition he would by many have been labelled as a case of epidermolysis bullosa acquisita, a not very happy name.

II.—B. E., male, aged 4 months. Only child.

History.—At the aged of 1 month the mother noticed that blisters were developing on the hands and fingers after the baby had sucked them. Later it was realized that slight knocks also produced blisters. "White little lumps" were first noticed on the backs of the hands at the age of 6 weeks.

The baby is otherwise thriving.

Family history.—Apart from the father no other relatives are known to be affected. The parents are not related.

On examination.—Clusters of milium-like bodies are present on the backs of the hands, identical with those on the father's hands. The remains of blebs are seen and on two occasions unbroken blebs containing clear fluid were observed on the fingers and on the palm of one hand.

Tropical Lichenoid Dermatitis.—K. GREENWOOD, M.B., M.R.C.P., Major R.A.M.C.

The eruptions due to idiosyncrasy to mepacrine have been described by, among others, Nisbet (1945) Schmitt, Alpins and Chambers (1945), and Singh (1948).

Nisbet described the condition as accounting for 80% of total dermatological cases received at his hospital from New Guinea. He says that certain characteristics help in its identification. A tendency to pigmented, flat, or hypertrophic lichenoid lesions, the production of persistent circumscribed erythematous areas, the characteristic distribution, extreme chronicity, a decided tendency to secondary infection, a tendency to progress to an exudative eczematous eruption, and peculiar pigmentary changes.

He describes three types: The patchy eczematoid type, the hypertrophic lichenoid type, and a generalized exfoliative type.

This second type, as in the present case, is very similar to hypertrophic lichen planus. Lesions on the eyelids are particularly common. The patients may be profoundly ill.

The blood picture is essentially normal, but shows sometimes a leucocytosis and an eosinophilia.

 Dr. R. C. E. Brodie (Melbourne): I have seen about 400 of these cases. The variety shown this afternoon is the true hypertrophic type. One case which I saw recently had persisted for four years. I myself have now seen it for three years and there have been no signs of regression. The case is symptomless, but there is often intense pyrexia on exertion on a warm day. I was interested in seeing the case now shown because it corresponds to the general experience. I am sorry I cannot help in the matter of treatment.

Dr. H. Haber: I have seen a case with moth-eaten alopecia, which at first I thought to be due to syphilis.

Precocity in a Girl Aged 5 : Due to Stilbæstrol Inunction.—C. H. WHITTLE, M.D., and A. LYELL, M.B.

Patient S. H. This child had total alopecia from 1 year of age after chickenpox and otitis media.

In December 1947 she was given stilbæstrol ointment 0.5% to rub into the scalp, and the mother continued to use this for thirteen weeks. After about ten weeks' treatment vaginal bleeding was noticed and was fairly heavy for a week, and continued for about four weeks, for the last week of which she was under observation in hospital.

For the last two or three months there has been deep pigmentation of the areolæ of the breasts, and the breasts have developed and become prominent. There is deep pigmentation also of the trunk.

Investigation in hospital showed a healthy well-grown child, with rather a deep voice. The scalp hair appears to be growing: eyebrows present, eyelashes present but scanty on lower lids. No pubic or axillary hair.

Dosage: 2 ounces of ointment (emulsifying base) yield 240 mg. of stilbæstrol, or approximately 2.7 mg. daily if *all* were absorbed.

Special examinations.—(1) 17-ketosteroid output 1.7 mg. *per diem*, i.e. normal. (2) X-ray of the skull—sella turcica normal.

Comment.—Dr. Laurence Martin saw the child and stated that he thought this was a pure stilbæstrol effect. He suggested as an alternative diagnosis a true constitutional precocious puberty. If the first alternative is rejected, the second may be the correct one, the stilbæstrol either drawing attention to or accentuating the condition. But the bleeding has ceased and the breasts are getting smaller since the stilbæstrol was stopped.

POSTSCRIPT (3.7.48).—Dr. H. W. Barber writes (personal communication): "As compared with the effects of oral administration of tablets in usual dosage, there is no doubt that inunctions are far more active, and must be used with the greatest care. The explanation, no doubt, is that some of the œstrogen, when rubbed into the skin, is absorbed into the blood-stream and exerts its effects before being altered by the liver, whereas when given by mouth all of it, of course, has to pass through the liver before reaching the blood-stream. I have had many cases in which uterine bleeding and pigmentation of the nipples have followed in a short time the inunction of dienœstrol ointment into the scalp or face of women long past the menopause, and it is extremely rare for pigmentation of the nipples to result even from high doses of œstrogen *by mouth* after the menopause, the excess of pituitary gonadotrophins being supposed in some way to check pigmentation. Stilbæstrol is many times more potent than dienœstrol, so I am not surprised at the effects in this case."—C. H. W.

Epidermolysis Bullosa, Two Cases (Father and Son).—DAVID I. WILLIAMS, M.R.C.P.

I.—J. E., male, aged 22.

History.—In 1943 when he was a stoker in the Royal Navy he began for the first time in his life to develop an eruption involving the hands, the feet and the knees. He was seen by several dermatologists, who diagnosed chronic dermatitis and prescribed various ointments with no avail. In August 1946 X-rays, 200 r, were applied to the hands and repeated in three weeks.

On 16.11.46 the following report was made: "Teeth adequate: the skin of both elbows and knees shows hyperkeratosis and pigmentation. Both legs from knees to ankles show marked pigmentation with several small ulcers covered by scabs. Diagnosis: 'Dermatitis'."

A further report on 20.10.47 states: "There are patches of dermatitis on ankles, knees, back of hands, across the shoulders and on the front of the chest. Lesions consist of small milky-white papules which break down and form superficial ulcers; a few blood cysts are present on the hands. There is progressive loss of the toe-nails and a similar condition is beginning on the hands."

He receives a 25% disability pension.

Past history.—Uneventful.

Family history.—Until his son, now aged 4 months, developed the condition at the age of 1 month, no member of his family was known to suffer from a similar complaint.

On examination.—He shows the typical scars of the condition on the knees, hands and feet. Bullæ containing clear fluid have been seen from time to time. He has lost his toe-nails and is losing the finger-nails. He has multiple milium-like bodies on the backs of the hands.

Histological report (Prof. H. A. Magnus).—Section shows the typical histological picture of epidermolysis bullosa dystrophica with some increase in the amount of fibrous

Biopsy (Dr. A. M. Barrett).—Section taken from these circular and oval pale scars shows gross abnormality of the superficial layer of the corium. The delicate inter-papillary zone with its tree-like branching elastic fibres is almost absent and instead there is a dense feltwork of elastic fibres slightly below the bases of the poorly developed papillae with only a few twigs sprouting up towards the epidermis. The interpapillary layer is thus thinner, denser and less rich in elastic tissue than normal.

Blood: Wassermann and Kahn reactions are negative.

Dr. Whittle: This is obviously a case of epidermolysis bullosa of the dystrophic type, but we have been specially interested in the white circular areas on the lower part of the trunk. All the activity appears to have been on the shoulders and the legs. We therefore tried to find out whether the atrophic lesions were really part of the disease picture. Sections showed considerable thinning of the skin, chiefly in the papillary layer. The normal elastic layer is completely absent and instead, in the thinned corium, there is a coarse feltwork of broken-up elastic tissue.

Cockayne (1933) mentions a *typus maculatus* which occurred in non-familial cases in Holland: there were two sisters similarly affected. Cerutti (1933) also described two cases of epidermolysis bullosa with an "albo-papuloid dystrophy"—white wrinkled areas of 2 cm. diameter scattered all over the trunk and surrounded by hyperpigmentation. We would welcome suggestions as to the cause of these lesions, and whether their pathology is linked with that of epidermolysis bullosa.

Dr. G. B. Dowling: I would like to refer Dr. Whittle to the report of an identical case (Degos, R. et al. (1948) *Bull. Soc. Dermat. Syph.*, p. 164) under the name of Epidermolyse bulleuse congénitale dystrophique, type albo-papuloides de Pasini.

Dr. R. T. Brain: I have seen several cases of the atrophic type of epidermolysis bullosa; with them we have seen the nails atrophy without receiving bullosus damage to the matrix.

Dr. Dowling: The principal feature of this condition is the presence of firm white papules seen mainly on the trunk and not preceded by bullae.

Hyperkeratosis Follicularis et Para-follicularis in Cutem Penetrans (Kyrle).—RONALD SCUTT, M.B. (for R. M. B. MACKENNA, M.D.).

Mrs. M. C., aged 60.—Non-irritating spots on the legs for two years, slowly increasing in size. No history of relevant illnesses nor of intake of drugs.

Scattered over lower legs are numerous reddish-brown papules varying in size from pinhead to split pea. Smaller lesions show central horny plugs, leaving small craters on removal. Larger lesions show irregular greyish-yellow horny crusts, with an inflammatory halo of the surrounding skin. Some of the older lesions have healed, leaving small depressed scars. No lesions elsewhere.

Investigations.—W.R., Kahn, negative. Blood-count: Mild normocytic anaemia, otherwise within normal limits. Vitamin-A value—Carotenoids 233 i.u./100 ml., vitamin A 79 i.u./100 ml.

Histology report (Dr. H. Haber).—"The section shows two lesions, both of which represent a parakeratotic plug pressing heavily on the underlying epidermis, which forms broad shallow grooves on which the horny masses rest. In no place is there any tendency for these plugs to penetrate the cutis, which shows a mild inflammatory reaction."

Comments.—This case, only the second to be published in this country, shows the clinical characteristics as originally described by Kyrle (*Arch. Derm. Syph. Chicago*, 1916, 123, 466). Until 1947, when Arnold reviewed the literature, only about 12 cases had been written up, practically all in the German and Danish journals, though Benedek and Oreo then stated that they had seen several cases, all in negro soldiers. When Dr. J. R. Simpson showed his case in December 1946 (*Proceedings R. Soc. Med.*, 40, 262), Dr. Hohmann said that he had seen cases in Holland in which the serum vitamin-A values had been low, and in which improvement had occurred after prolonged administration of the vitamin. In this case, the vitamin-A values are within normal limits.

The non-penetration of the cutis indicates either that the excised lesion is an early one, or that Kyrle's conception of the pathology was not entirely accurate. Also, there appears to be no definite relationship to hair follicles. Arnold described a case in which lesions were present in the palms only, where, of course, there are no hair follicles. These minor differences are possibly sufficient, as Arnold pointed out, to reduce the unwieldy name of this disease to "hyperkeratosis penetrans".

[June 17, 1947]

Pretibial Myxomatous Degeneration.—C. D. CALNAN, M.B. (for I. MUENDE, M.R.C.P.).

Miss L. W., aged 47.

History.—1941: Partial thyroidectomy for Graves' disease.

1943: Kicked on right shin.

1944: In the course of a few days the skin on the front of the legs became tense and swollen as it appears at present.

1947: Normal menopause.

February 1948: Began to complain of giddiness and palpitation, feeling hot and cold, and was referred by her doctor who found her in an emotional state with a tachycardia of 120/min.

On examination.—Somewhat obese. Outer third of eyebrows thin. Some fullness under the eyes. No exophthalmos. Heart, lungs, abdomen normal. Pulse-rate 60/min. Blood-pressure 160/80.

An "œdema-like" swelling is present on the anterior aspect of both legs between the knees and ankles, spreading on to the posterolateral surface in its lower part. The area is pale reddish-brown with prominent follicles and a few coarse hairs. The upper limit shows a gradual transition from normal skin to the swollen area. The lower margin, however, is sharply demarcated, and shows the maximum swelling of 4 to 5 mm. The area is firm and does not pit on pressure. At the side the transition to normal skin is irregular and there are many small round lesions of similar tissue. A rather more elevated area in the centre of the lesion in the right leg is at the site of injury in 1943.

Investigations.—Blood cholesterol 138 mg./100 ml. E.C.G.: Normal; no evidence of myxœdema. B.M.R. -9%.

Biopsy (Dr. H. C. Moore).—Section shows myxomatous degeneration of subepidermal tissues which occurs in masses with no intervening collagen, and stains with Southgate's mucicarmine. Mallory's stain is not taken up by the myxomatous areas.

Treatment—1944: Extr. thyroid sicc., gr. $\frac{1}{2}$ b.d. for one year.

1945: Extr. thyroid sicc., gr. $\frac{1}{2}$ t.d.s., up to present time.

No striking improvement has been noted in the condition, in spite of four years' treatment with thyroid extract.

Comment.—This is a case of extensive localized pretibial myxomatous degeneration, occurring three years after partial thyroidectomy for thyrotoxicosis.

Dr. F. Parkes Weber: This is one of those cases which should appear in an international atlas of dermatology. It is so striking and yet so typical in every way. The mucinous plaques over the shins are of extreme degree. The patient has had thyrotoxicosis and has been operated for it. A permanent record is needed for teaching purposes.

Dr. Lipman Cohen: The one atypical feature in this patient is the degree of pinkness of the lesion which is usually much more yellow, rather like pigskin.

Epidermolysis Bullosa Dystrophica (with "Albo-papuloid Dystrophy" of Pasini).—C. H. WHITTLE, M.D., and A. LYELL, M.B.

F. R. a farm labourer, aged 43.

History of sores on the back and the legs which are said to have started after vaccination at the age of 6 months. They have been present on and off ever since.

Family history (not completed).—Two sisters have similar sores though less severe.

When he was first seen nine years ago the lesions were typical on the legs and on the shoulders, with large blisters leaving sores which healed slowly. Two years ago he had superimposed sepsis which masked the picture so much that the diagnosis of epidermolysis bullosa was not considered until his original notes were turned up. There was severe chronic ulceration on the left leg and the shoulder. Hæmolytic strep. and *Staph. aureus* were obtained in abundance in cultures.

The condition has waxed and waned so that at times he has been almost completely free of blisters; in addition there are curious scars on the trunk quite different from those on the shoulders and legs. These are circular and oval, white, crinkled, rather papery areas varying from 1 to 4 cm. in diameter, of uniform consistency and occurring in large numbers. They have been present for as long as he can remember and he is positive that they are not the result of blisters. In these white areas the skin is thinner and feels soft.

Biopsy (Dr. A. M. Barrett).—Section taken from these circular and oval pale scars shows gross abnormality of the superficial layer of the corium. The delicate inter-papillary zone with its tree-like branching elastic fibres is almost absent and instead there is a dense feltwork of elastic fibres slightly below the bases of the poorly developed papillae with only a few twigs sprouting up towards the epidermis. The interpapillary layer is thus thinner, denser and less rich in elastic tissue than normal.

Blood: Wassermann and Kahn reactions are negative.

Dr. Whittle: This is obviously a case of epidermolysis bullosa of the dystrophic type, but we have been specially interested in the white circular areas on the lower part of the trunk. All the activity appears to have been on the shoulders and the legs. We therefore tried to find out whether the atrophic lesions were really part of the disease picture. Sections showed considerable thinning of the skin, chiefly in the papillary layer. The normal elastic layer is completely absent and instead, in the thinned corium, there is a coarse feltwork of broken-up elastic tissue.

Cockayne (1933) mentions a *typus maculatus* which occurred in non-familial cases in Holland: there were two sisters similarly affected. Cerutti (1933) also described two cases of epidermolysis bullosa with an "albo-papuloid dystrophy"—white wrinkled areas of 2 cm. diameter scattered all over the trunk and surrounded by hyperpigmentation. We would welcome suggestions as to the cause of these lesions, and whether their pathology is linked with that of epidermolysis bullosa.

The Management and Treatment of Psychopaths in a Special Institution in Denmark

By GEORG K. STÜRUP, M.D.

IN order to understand the unusual working conditions which have gradually been introduced in the Herstedvester Institution for Psychopaths it is necessary to explain briefly the special legislation which provides the framework for the treatment of psychically abnormal criminals and borderline cases.

The Herstedvester Institution has two main purposes: To protect society and maintain public security by means of the preventive detention of the inmates of the Institution, and secondly, to treat these inmates psychologically in order to fit them for a normal life as free citizens.

In a number of cases, therefore, detention may be of short duration. It is not a punishment, but a security measure. By far the majority of the detainees are relapsed criminals who have committed serious crimes—murder, robbery, incendiarism, rape, indecency towards boys or girls or both, theft, embezzlement, crimes of violence—but we have also drug

addicts who forge prescriptions and similar cases where other forms of treatment have proved ineffective (Tables I and II). Most of them have been in prison again and again. Only a few outstandingly psychiatric cases reach the Institution for Psychopaths after the first or second court sentence. The detainees vary in age from about 18 to 70 years.

In sentencing persons to detention in the Institution the courts do not prescribe any definite period and the same court which has passed sentence decides whether the detainee may be released. Release is always subject to parole the period of which is likewise not defined. During parole the prisoner is subjected to supervision directly from the institution. This supervision is carried out by officers specially trained by the institution, and the paroled person may not change his place of residence or employment without obtaining the prior approval of the institution. Final release is likewise only obtainable on application to the same court which ordered detention and parole.

There must therefore be an intimate co-operation between the court and the psychiatrist responsible for the treatment which is given during detention. The first Act dealing with this question came into force in 1925. This Act provided for the internment of certain abnormal criminals who constitute a palpably serious danger to the public safety, defined in the Act as including sexual offences, gross acts of violence, incendiarism or other serious crimes. A new criminal law of 1930 which, since 1933, is still in force to-day affords a sub-

Dr. Haber: Kyrle's first case of *Hyperkeratosis follicularis et parafoollicularis in cutem penetrans* was a woman, aged 22, who developed a generalized rash in the course of a few weeks. The primary lesion consisted of a pinhead hyperkeratosis, partly follicular and partly parafoollicular. As the lesion grew it became indurated, and there was an inflammatory halo round it. The lesions tended to coalesce to larger plaques and the colour became dirty green-brown similar to that seen in psoriatic rupia. On removal of a plaque bleeding occurred and a depressed scar was left after healing. The head, hands and feet were free from lesions. Kyrle performed many biopsies on the case and found follicular and parafoollicular hyperkeratotic plaques extending deep to the pallisade layer and sometimes perforating the latter, producing a foreign-body reaction. He regarded the condition as a dyskeratosis.

Many more cases were described after Kyrle's paper, but some authors stressed the point that penetration does not always take place. In this case one can see that the hyperkeratosis is pressing on the epidermis causing thinning of the latter, but actual penetration does not take place. Another section showed almost penetration with an inflammatory reaction in the cutis, so that penetration is not obligatory and the downgrowth of the hyperkeratosis only a matter of degree.

The clinical picture combined with the histological findings justify the title given to the disease.

Dr. W. Lemberger: Further biopsies should be done to demonstrate other peculiar features of this condition in an earlier stage. The prickle cells are in some places strikingly small and packed so closely together that the intercellular spaces almost disappear. There are also marked degenerative changes in the cytoplasm and the cell nuclei.

Dr. John C. Belisario (Sydney): In a case presented in America with the same diagnosis only the palms and soles were affected. The opinion was that the condition was allied with keratosis punctata or lichen pilaris, which in turn is considered by many to be linked with ulerythema ophryogenes and keratosis follicularis ulerythematosus.

Dr. John C. Belisario (Sydney) read a paper on *Cutaneous Cancer and Precancer* (to appear later in the *British Journal of Dermatology*).

The following cases were also shown:

Case for Diagnosis.—**Dr. C. H. WHITTLE.**

Nævus Syringadenomatosus Papilliferus.—**Dr. JAMES OVERTON.**

Papulonecrotic Tuberculide with Acne Scrofulosorum.—**Dr. J. R. SIMPSON.**

Reticulosis.—**Dr. W. G. TILLMAN.**

(These cases may be published later in the *British Journal of Dermatology*.)

follows a period of bitter disappointment, the indeterminate sentence begins to get on his nerves and very often there ensues a feeling of hopelessness. At this juncture the detainee, under suitable guidance, most frequently begins to realize the important part which his own active co-operation can play in determining the date of his release.

Psychotherapy may be said to be applied from the first interview in the institution. We try at this stage to build up a certain feeling of confidence towards the authorities. A complete life-history is prepared shortly after admittance to the institution, a complete psychiatric-neurological examination is carried out, and a genealogical table drawn up. The Danish Marriage Law lays down that any person who is insane, mentally deficient, psychopathic to a serious extent or a chronic alcoholic shall be forbidden to marry without the permission of the Ministry of Justice, provided that such permission may be granted conditionally upon prior sterilization. As early as possible it is important to inform the detainee as to whether he can expect to get permission to marry without prior sterilization. Only a very few express a wish to be sterilized—about 4 or 5 a year.

In the day-to-day treatment we attach great importance to inculcating in the detainee the feeling that he himself is responsible for his future. We therefore make a point of providing opportunities for developing occupational interests such as market gardening, printing, book-binding, joinery, toy-making, and tailoring; all building repairs in the institution are carried out by the detainees. In the half-open department there are opportunities for working in general farming on neighbouring farms, and in the open department there is intensive market gardening with mushroom production as a speciality. The detainees are paid for their work if possible by "piece method". They may use half of their income for tobacco, stamps, books, extra food, and whatever they like.

Because of his psychical abnormalities, which can to some extent be suppressed or corrected, but which very often continue to manifest themselves, the detainee often finds it difficult to hold down a good job in the world outside. It is therefore important that he should be made a diligent worker.

There is besides a lively club life where sport, stamp collecting, chess and bridge, and domestic crafts are widely developed. There is a marionette theatre and a simple stage where classical plays and reviews featuring the daily life of the institution are performed. Education proper is catered for in study circles, and in certain occupations correspondence courses are available.

What I have mentioned so far is perhaps not very different from what may be used in other similar correctional institutions. Perhaps it is elaborated rather differently in Hersted-vester, where the emphasis is always on the psychiatric aspect. As regards direct psychotherapy, however, the working methods differ radically from what is used in a prison or in a hospital. It may be stated, as a fundamental rule, that psychotherapy in general cannot be conducted in the same way in a closed institution as in a private consultation, and especially not if the person in charge of the psychotherapy has a substantial say in the duration of detention. In a few special cases it is of course possible to carry out a regular consultation practice within the scope of the institution, but such cases are always the exception. All too many will feel tempted to exploit such a situation and try to deceive the doctor and themselves. It is a question, above all, of treating not merely the immediate mental symptoms, but also of preventing their recurrence, i.e. to prevent recidivism. The psychotherapy must therefore be carried out in such a way that there is always particular regard to the permanent effect on the patient's personality development. I have already said that, to a large extent, we leave the psychotherapy to the patient himself. This implies, among other things, that we exploit moments of particularly strong emotion and situations when passions are aroused to explain to the detainee his reactions in such situations and so draw analogies with previous, especially criminal, situations in which he has found himself. We call him in, to reason with him and discuss the trouble, and we are often able, from our intimate knowledge of the man's past history, to point out to him the factors which cause him to react in this way. As a rule they come in sooner or later and thank us for our explanations and often tell us that, having thought the matter over, they agree with our interpretation. The time comes when the discussion can be continued so that one is sometimes able to explain to him how he has landed himself in criminal activities in the world outside through such distortions of realities. In other cases, involving fights and so on, as a rule there is a useful opportunity of showing him how to keep his violence under control until a more appropriate occasion for exercising it, when it will not be at the expense of other people; pointing out at the same time that he does not usually behave in this fashion when he is brought before the doctor. It cannot be due merely to the doctor's behaviour, since the doctor often tells him some unpleasant things—things to which his reaction could well be extremely violent.

In a few cases we have applied hypno- or narco-analysis, but in most cases we have confined ourselves to the methods mentioned, partly because just at the present time we are not in a position to go further.

stantially increased scope for the application of psychopath detention treatment. The Danish Criminal Law of 1930 does not resort to the McNaghten rules, but says in section 16 that no person shall be subject to any punishment in respect of any act on his part if, at the time of the deed, he was irresponsible because of insanity or a condition of mind similar thereto or a high degree of mental deficiency.

Section 17, subsection 1, provides for the treatment to be adopted towards any person who, at the moment of perpetration of any crime, was, owing to underdevelopment, weakness or derangement of the mind, including sexual abnormality, in a mental state of a more permanent nature but not of a character for which provision is made in section 16 (above). In cases of this kind the court, after consideration of a medical certificate, in addition to all other relevant circumstances, decides whether the accused can be adjudged as a person who is likely to benefit from punishment.

Subsection 2 provides that in certain cases the sentence may be served in a specially constituted institution, thus originating the so-called psychopath's prison.

Section 70 lays down the course to be followed in cases exempt from punishment under section 16, or in respect of which punishment has been adjudged inappropriate under section 17.

Provision is made, *inter alia*, for admission to mental hospitals, institutions for inebriates, or a "special place of detention" (forvaringsanstalt). The Psychopath Institutions at Herstedvester were brought into use as such special places of detention in 1935. Experience gained in these institutions provides the background for the considerations which follow.

These provisions have so far been used with the greatest caution. In the period 1933-43, the first ten years in which this penal code has been in force, between 1% and 2% of those sentenced were referred for special treatment.

The psychopath institutions in Herstedvester are:

(1) The main one, a detention institution for men, houses about 175 persons. This is the group which is detained on indefinite time.

(2) A corresponding institution for women, appreciably smaller and housing at the present time 13 persons, should have accommodation for 20.

(3) A psychopath prison for men, intended as a general prison, but where the prisoners are under continual surveillance of psychiatrists. In practice it has proved difficult for the courts to determine in advance which criminals should be sent to a psychopath prison, and it is now rarely used and accommodates only 15 persons.

(4) In recent years there has been attached to the institution a special psychiatric observation department which can receive prisoners from all other criminal institutions for observation and treatment. This department can accommodate 35 persons and is officially quite independent of the other departments.

The treatment in this observation department is similar in principle to that given in the main detention institution but suffers from the drawback that the patients are serving a definite time sentence, like the few persons in the psychopath prison who now receive the same treatment as the detainees in the main detention institution. Clinical experience shows that the predetermined term of sentence creates certain difficulties: the need for treatment is less obvious to the patient than when he is serving an indefinite sentence.

The number of inmates in the institutions has grown steadily, and when there was no more room we bought an ordinary farm in a village near Copenhagen and fitted it up as a market garden with accommodation for 20 detainees. These detainees consist partly of castration cases, who are waiting until the effects of castration are sufficiently manifest to justify their release on parole, partly of others who anticipate parole within the near future and of a few older detainees who have made something of a home there.

Later a half-open department was established in an old manor house in South Zealand with accommodation for 40 persons. The small department already mentioned with accommodation for 20 persons is completely open without fencing and locked doors, the detainees working freely in the open fields but keeping within the grounds which comprise only about 6 acres. The department in South Zealand, on the other hand, is surrounded with a light wire fence. There is a permanent night watch, and the detainees work in teams under supervision.

The institution is under the direction of a senior psychiatrist with three assistant psychiatrists and two nurses. A teacher is in charge of the detainees' education and spare time activities, and the library. Welfare work is in the hands of a trained sociologist who has three assistants. The supervising staff are prison officers with special mental hospital training and further training in the institution. The total staff is rather big, nearly one for each two detainees.

The pervading atmosphere and tone of these institutions—determined under purely psychiatric direction—arouses most frequently in the new detainee an immediate awareness that he is in an institution of quite another character than a prison. Later there frequently

DISCUSSION ON CEREBRAL VASCULAR DISEASE IN THE YOUNG [Summary]

Sir Charles Symonds (*Abstract*): These observations will not include any discussion of migraine or subarachnoid hæmorrhage but will be confined to structural lesions of the brain. In older persons the common causes of a cerebral vascular lesion are hæmorrhage and thrombosis associated with arterial hypertension or atheroma. Hypertension may also occur in the young, but a cerebral vascular lesion in this setting presents no diagnostic problem. Atheroma in the young is so uncommon that it is one of the last causes to be suspected for a cerebral vascular lesion. If the discussion is limited to patients under the age of 35 and without hypertension the problems of ætiology will be of greater interest.

Cerebral embolism from bacterial endocarditis or mitral stenosis is easily recognized, as also cerebral thrombosis from congenital heart disease or syphilitic arteritis. Cerebral hæmorrhage in the young is usually derived from a ruptured aneurysm. Hæmorrhage into an angioma is another cause and may be provoked by minor injury. Two unverified cases of this kind were described with lesions in the brain-stem. Delayed traumatic cerebral hæmorrhage deserves comment. Leukæmia and purpura may also present with cerebral hæmorrhage. Injury to the carotid artery in the neck may cause cerebral embolism; a case was described. Cerebral embolism may also result from compression of the subclavian artery by cervical rib. Fat embolism and air embolism are also of interest.

Disease of the cerebral arteries in the young, apart from syphilis, is rare. The syndromes which result comprise on the one hand the acute hemiplegias, and on the other hand cases in which the symptoms are scattered, progressive or remittent. Polyarteritis nodosa may cause either syndrome. Atheroma in the young may result in cerebral thrombosis; a case was described with post-mortem findings. There are many cases of what appears to be cerebral arterial thrombosis in the young without explanation. The ætiology of these cases was discussed and a case described in which extensive thrombosis of the larger cerebral arteries was found post mortem without arterial disease. Thromboangitis obliterans of the cerebral vessels may also occur, involving either peripheral branches or main trunks. The differential diagnosis of progressive cerebral thrombosis from cerebral tumour is often difficult and may require air pictures. Thrombosis of the intracranial veins causes symptoms which may be divided into those of increased intracranial pressure, which are due to obstruction of venous outflow from the skull; focal epilepsy or paralysis resulting from local congestion; and cranial nerve palsies from compression.

The pathology and mechanism of these syndromes was discussed.

Professor Geoffrey Jefferson: *Intracranial hæmorrhage*.—Intracranial bleeding in the young must be classified first as intra- or extra-cerebral. Much interest has been shown recently in subdural hæmatoma in infancy. I shall consider two different causes, (a) congenital cerebral angiomas, (b) congenital aneurysms, as sources of hæmorrhage.

(a) *Congenital cerebral angiomas* frequently bleed into the subarachnoid space or ventricle giving rise to recurrent attacks of so-called "meningitis". There may have been several such attacks before the diagnosis is arrived at. These angiomas furthermore usually cause epileptic attacks; Jacksonian focal epilepsy in the young

The co-ordination of the direct psychotherapy and the ordinary day-to-day work is most essential and we consider it to be essential to keep the staff informed about the more important happenings. This takes place at weekly meetings where all interested members of the staff have an opportunity of being present, though none is obliged to come.

The detainees are kept informed about the world outside by means of newspapers and wireless. Every detainee may buy himself a crystal set and there is a loud speaker in each assembly room. Finally, what is most important, they can go out. Detainees, who have proved themselves diligent and have conducted themselves well throughout one year, can get permission to go out once a month for eight hours, accompanied by one of the welfare officers in civilian clothes.

Since 1929 Denmark has had a law which permits voluntary castration, subject to permission being obtained from the Ministry of Justice. The law was amended and extended in 1935. Professor Sand (1939) has given an account of the results of the first ten years. A very substantial number of the persons who are sent to the psychopath detention institution because of sexual crime themselves express the wish to undergo the operation, which has long shown itself to be particularly effective. So far, 161 castrations have been performed in the institution. The law admits in theory the possibility of compulsory castration, but this provision has never been used and presumably never will be used. Looking at the question from a psychiatric point of view, I have no doubt whatever that compulsory castration is less beneficial than the voluntary operation. Castration involves in practice a distinct reduction of sexual desire—so great a reduction in fact, that the man who has hitherto been oversexed in relation to his powers of control, or whose sexual needs took an unlawful form for their satisfaction, is able after the operation to steer clear of further criminal activities. Of the 161 cases so far, there have been 4 sexual recidivists, all of whom were homosexuals. None of the cases has relapsed into the more serious crimes, one has been only biologically recidivated (i.e. he has engaged in homosexual activities with adults, which is not punishable in Denmark), but we have naturally taken prompt and serious action in all these cases and retained the recidivist several years before he was again released. Three of them are again released and are doing well, the fourth has recently relapsed.

The physical consequences of castration with adults have proved to be only minor things of no practical importance. In any case they are considerably less striking than those produced by the change of life in women. For psychological reasons glass prostheses are inserted, so that the patient can go to swimming baths and in general can strip before others without arousing attention.

There is no time to go into details about the effects of castration, but I can sum it up by saying that in Denmark we are all agreed that we cannot consider abandoning castration as a method of treatment for sexually abnormal criminals. This unanimity embraces the castrated themselves, who often regret that they have taken so long in deciding to undergo the operation. Time after time they refer to the sense of peace and confidence in their behaviour which follows the operation. Some marry after a time, and there are cases of men who are worried about their inability to give their wives sexual satisfaction, but most are of such an age when they marry that this question is of no great importance. Since we always insist that the woman must be informed about the position before marriage, the matter in the great majority of cases is of no importance.

I would emphasize that the hormonal effects of castration should not be relied upon without some attempt at psychotherapeutic treatment, since I am of the opinion that only in very exceptional cases can we be satisfied with mere castration. As a rule castration cases should be referred for institutional treatment.

As regards the general results of treatment in the institution, we can fairly say that they are promising. We have managed to get the detainees to take part in their own rehabilitation with the necessary enthusiasm.

The detailed elaboration of the material from different points of view is not yet completed, but we can say that more than 50% of the detainees after some years go back to normal life in the community.

AT L'HÔPITAL STE. ANNE, PARIS

DISCUSSION ON INTRACRANIAL HYPOTENSION [Abstract]

Dr. P. Puech: *I. Introduction.*—Intracranial hypotension comes into the framework of disturbances of cerebromeningeal hydrodynamics, that is, it is one of the hydraulic reactions of the brain and its envelopes to the most diverse processes: a vast chapter in general and nervous pathology.

Professor Leriche will show how, while studying the clinical manifestations formerly attributed to post-traumatic intra-cranial hypertension, he was led to identify hypotension.

Following this, Doctors P. Puech, P. Guilly, J. Morice and M. Brun will consider the principal forms of hypotension, some of which are associated with other disturbances of cerebromeningeal hydrodynamics. Their discussion will be based on 238 cases of hypotension, confirmed at operation.

Finally, Professor Petit-Dutaillis, with Doctor G. Guiot, will describe the therapeutic indications in hypotension.

Professor R. Leriche: *II. Post-traumatic hypotension of the cerebrospinal fluid.*—The existence of hypotension was established in 1915–16 as a result of the following observations in minor head wounds and in trephined patients with depressed scars:

- (1) Hypotension shown by the manometer after lumbar puncture.
- (2) Restoration of pressure by subcutaneous or intravenous injections of artificial serum.
- (3) Disappearance of headache and other symptoms at the same time, with
- (4) Bulging of the depressed scars.

A little later, in 1920, it was observed in closed fractures of the skull that hypotension might develop primarily or secondarily as well as hypertension, and with almost identical symptoms which disappeared immediately after the intravenous injection of 40 c.c. of distilled water. This led to the interpretation of the symptoms of fracture of the petrous portion of the temporal bone or of the lamina cribrosa with loss of fluid as being due to hypotension. The injection of distilled water caused all the symptoms (coma, hyperthermia, slow pulse) to disappear at the same time as fluid escaped in jets through the ear or nose. Similar observations were made in Jacksonian epilepsy during fits, when hypotension is perhaps as frequent as hypertension.

During the same period it was observed that secondary fistulization of the ventricle after the removal of splinters in the brain, followed by abundant loss of fluid, was accompanied by hyperthermia (39–40° C.), cyanosis and peripheral coldness. The intravenous injection of distilled water caused all the symptoms to disappear in a few moments.

An analysis of what had been seen (collapse of the walls of the ventricle) led to the supposition that in severe hypotension there was a disturbance of ventricular form, a collapse which affected the function of the vegetative centres.

This hypothesis fitted a case which had been observed in 1915, of great loss of ventricular tissue, with coma and hyperthermia. Filling of the ventricle with an iodoform paste liquefied by heat had brought about a temporary recovery of the

is not infrequently due to cortical angiomas. Although they may bleed they do not cause cranial nerve palsies nor very often intracerebral bleeding, though they can do so. Surgical treatment does little good unless the angioma is small.

(b) *Congenital aneurysms*.—These are much commoner than angiomas. My youngest patient was 9 months old. There are three possible ways in which a congenital aneurysm can show itself, (1) by subarachnoid leakage, (2) by compressing the second, third, fourth or (rarely) other cranial nerves, and (3) by intracerebral bleeding. I have almost exhausted my interest in (1) and (2) having seen a great number, but I have found a new interest in intracerebral bleeding, which is the especial feature of aneurysms of the anterior and middle cerebral arteries. In some instances in which a bloody fluid is found on lumbar puncture the blood has arrived there by the intraventricular route: this is especially true of anterior cerebral aneurysms. Stupor is a sign of intracerebral and *scarcely at all* of purely subarachnoid bleeding. Surgical treatment is sometimes possible.

Dr. J. Purdon Martin: In addition to arterial hæmorrhage, thrombosis and embolism we must think of venous hæmorrhage, venous thrombosis and venous embolism; I shall also refer to some cases of venous hæmangioma. Venous thrombosis is much the most common of these conditions; venous hæmorrhage is frequently secondary to venous thrombosis and the cases in which it occurs independently are usually traumatic; venous embolism (if it occurs) may be one cause of venous thrombosis. The most important groups of cases of venous lesions are:

(a) Those occurring in association with childbirth. (b) Those occurring in young children. (c) Those due to trauma.

(a) In the cases that are associated with childbirth thrombosed veins are found on the surface of the brain and blood clot may be found in the superior longitudinal sinus, or other of the cranial sinuses. At our Meeting in London last year Dr. Garcin described a most interesting case in which the straight sinus and the great veins of Galen were thrombosed. The thrombosis of the veins is associated with an effusion of blood on the surface of the brain, with discrete hæmorrhages into its substance extending to a variable depth and with a variable degree of softening. Subsequently gliosis occurs in the affected area and a depressed scar is left on the surface of the brain. The usual clinical history comprises convulsions of sudden onset, hemiplegia and, eventually, good functional recovery. The cause of the thrombosis in these cases is still unknown, but the possibility of embolism from the veins of the pelvis, or of the lower limbs, must be closely considered. Some embolic material, e.g. a bubble of air, might pass either by way of the right auricle and jugular veins, or by way of the vertebral veins, but it is doubtful whether the former route could be traversed by a solid embolus, since it would be more likely to be diverted into the lungs.

(b) Cases of venous embolism in young children seldom come to autopsy, but a number have been confirmed, e.g. two cases associated with heart disease described a number of years ago by Lhermitte and his co-workers, and studies have also been made by others. The pathological anatomy and the clinical features of these cases in children are very similar to those in the cases already referred to. It is possible that the condition of lobar sclerosis found in later life in subjects of infantile hemiplegia is a consequence of thrombosis of veins with hæmorrhage and subsequent gliosis.

(c) The traumatic cases are of different types. Thrombosis of the superior longitudinal sinus consequent upon superficial gunshot wounds of the brain and its clinical features were described by Holmes and Sargent, and in rare instances a similar syndrome may result in cases of closed head injury. It is now generally agreed that chronic subdural hæmatoma results from venous hæmorrhage and there are cases of subarachnoid hæmorrhage following trauma (with or without concussion) in which the bleeding is probably of venous origin.

As special instances of venous thrombosis (confirmed by autopsy) I will refer to a

are described. Sometimes the patients are in a state of coma with perhaps hemiplegia, or status epilepticus. These appearances often lead to a diagnosis of softening of the brain or of cerebral hæmorrhage. Again the patient may show from the first hemiplegia, monoplegia, oculomotor paralysis. Yet again, he may be brought in because of local or generalized convulsions. Hypothalamic symptoms are the rule. If they are accentuated a true hypothalamic form is seen.

Mental type.—Cases of the principal forms of mental disease due to hypotension are also reported. We have described a form of the depressive melancholic type, a form of the confusional type, forms with manic attacks and narcoleptic forms. Thiébaud and Daum (1945) have isolated a form resembling general paralysis. We have also observed forms producing states of a schizophrenic type. For some years Professor Delay has stressed the effect of "cerebral pneumotherapy" in intracranial hypotension, but he also emphasizes its important action on the intellectual and the emotional sphere.

Modes of progression.—The condition of intracranial hypotension may be acute or chronic, but in either case the course generally follows a definite pattern. The prodromal period, which may last from a few days to several months, is characterized by headache, loss of weight, emotional changes and often diabetes insipidus. The symptoms of this stage are often recognized only retrospectively, in the established phase, when the serious nervous and mental symptoms have appeared. These may develop insidiously or suddenly, after a severe attack of headache, often fronto-temporal resembling facial neuralgia. Questioning then reveals the fact that the earliest symptoms occurred mainly in the morning, appeared a long time after meals and were relieved by taking food or drink and by lying with the head low. If "re-inflation of the ventricles" is not carried out as an urgent measure the patient falls into coma and dies. In other cases the hypotensive syndrome lasts for months or years in the chronic state, and the diagnosis is mistaken until the day when ventricular puncture reveals the "ventricular collapse" of Clovis Vincent.

Anatomical forms.—Both isolated and associated forms of intracranial hypotension exist. The diagnosis is again difficult, but it is always made clear by trephine puncture of the ventricle, which is also the first stage of treatment.

Isolated intracranial hypotension.—There were 135 cases, of which 24 were post-traumatic, 25 were post-operative, 19 were secondary to various diseases, and 67 were apparently primary.

Whatever its cause may be, isolated hypotension shows all the clinical and evolutionary characteristics already described. The neurosurgeon observes that the dura mater does not pulsate; when this membrane is incised, the brain is seen to be shrunken, collapsed and pulseless. This state of cerebral dehydration is confirmed by ventricular puncture. No fluid escapes when the trocar penetrates it, and one hears the sound of air being sucked into the ventricle. If any ventricular fluid is found, it cannot be removed except by aspiration or by swinging the head backwards or compressing the jugular veins.

Hypotension associated with other disturbances of cerebromeningeal hydrodynamics.—There were 71 cases, of which 16 were post-traumatic, 46 secondary and 9 apparently primary.

It often happens that hypotension verified by trephine puncture is, nevertheless, associated with (1) a certain amount of more or less diffuse cerebral œdema (gelatinous, grey, hypotensive brain); or (2) ventricular dilatation in spite of hypotension of the fluid; or (3) serous meningitis or subdural hydroma with hypotension.

The cerebral mass and the space it occupies in the cranial casing are sufficient to make it easy to realize the possibility of such associations, which we have confirmed at operation. Any one of the disturbances of cerebromeningeal hydrodynamics may be primary or secondary. It has seemed to us that the so-called localizing symptoms were related sometimes to cerebral collapse, especially marked in the

vegetative functions and of consciousness. There was therefore reason to attach great importance to ventricular form in the interpretation of the symptoms. The observed facts, as a whole, made it possible in 1922 to relate hypotension to three conditions:

(1) Loss of fluid into the soft parts (lumbar puncture in which the hole leaks, resulting in headaches) or to the outside (fractures of the petrous bone, ventricular fistula, operative losses).

(2) Insufficiency of dialysis in the choroid plexus as a result of acute or chronic vasomotor disturbances (closed fracture of the skull with vaso-constriction in the basal arteries—surgical shock) or inflammation or sclerosis.

(3) Enlargement of the subarachnoid spaces in patients trephined in the past.

The symptoms resemble those of hypertension—but less marked—and those of meningism. The hyperthermia of severe cases suggests infection. In minor cases (after lumbar puncture in Jacksonian epilepsy) headache and vertigo occur.

Treatment has consisted in intravenous injections of 40–50 c.c. of distilled water. The results have been striking. For chronic cases resembling those described by Puech in 1942 the following have been suggested: ligation of the inferior longitudinal sinus, ligation of the internal jugular vein, and peri-carotid sympathectomy. This last has been done four times. It causes cranio-cerebral hyperæmia seen in the fundus of the eye, and makes depressed scars bulge. Patients were doing well after one year, and one patient was followed up for 20 years.

Drs. P. Puech, P. Guilly, J. Morice and M. Brun: *III. The principal forms of intracranial hypotension.*—Professor Leriche has just described how, having isolated intracranial hypotension, he determined its morbid physiology and treatment.

[The literature of the subject was then reviewed.]

According to our statistics, verified intracranial hypotension represents 7.2% of all cases of cerebral neurosurgery. In a series of 3,284 intracranial affections operated upon in the Neurosurgical Department of the Hôpital Sainte-Anne there were 238 cases of hypotension which were verified by trephine puncture or by direct exploration of the brain. We have not included cases diagnosed by lumbar or sub-occipital puncture, as these methods quite often give a poor idea of what is happening in the ventricles, and the conception of a uniformly lowered pressure in the cerebro-spinal system as a whole is an over-simplification and must be revised.

We are therefore considering mainly the neurosurgical forms of intracranial hypotension which justify “re-inflation of the ventricles”.

The abortive forms which recover after “cerebromeningeal rehydration” are much more frequent than our statistics show.

In this series of 238 cases of intracranial hypotension 68 per cent. were secondary (18.8% followed accidental trauma, 10.5% were post-operative complications and 38.7% were secondary to a medical or surgical disease), and 32% apparently primary. This means that sometimes the physician and sometimes the surgeon must anticipate and prevent or detect and treat intracranial hypotension. The clinical diagnosis is often difficult, but must be considered on many occasions.

Clinical forms.—Intracranial hypotension, related to more or less acute cerebro-meningeal dehydration, can produce symptoms like those of intracranial hypertension. In both, the patients complain of headache and vomiting; there may be undoubted papillœdema, at least in our experience, though we are aware that certain authors have stated that the disc remains normal in hypotension. The electroencephalogram may show diffuse or more localized changes in either condition.

We have stressed the three main clinical aspects of intracranial hypotension: the neurological, the psychiatric and the neuropsychiatric which are about equally frequent.

Neurological type.—Typical cases showing the principal neurological symptoms

are described. Sometimes the patients are in a state of coma with perhaps hemiplegia, or status epilepticus. These appearances often lead to a diagnosis of softening of the brain or of cerebral hæmorrhage. Again the patient may show from the first hemiplegia, monoplegia, oculomotor paralysis. Yet again, he may be brought in because of local or generalized convulsions. Hypothalamic symptoms are the rule. If they are accentuated a true hypothalamic form is seen.

Mental type.—Cases of the principal forms of mental disease due to hypotension are also reported. We have described a form of the depressive melancholic type, a form of the confusional type, forms with manic attacks and narcoleptic forms. Thiébaud and Daum (1945) have isolated a form resembling general paralysis. We have also observed forms producing states of a schizophrenic type. For some years Professor Delay has stressed the effect of "cerebral pneumotherapy" in intracranial hypotension, but he also emphasizes its important action on the intellectual and the emotional sphere.

Modes of progression.—The condition of intracranial hypotension may be acute or chronic, but in either case the course generally follows a definite pattern. The prodromal period, which may last from a few days to several months, is characterized by headache, loss of weight, emotional changes and often diabetes insipidus. The symptoms of this stage are often recognized only retrospectively, in the established phase, when the serious nervous and mental symptoms have appeared. These may develop insidiously or suddenly, after a severe attack of headache, often fronto-temporal resembling facial neuralgia. Questioning then reveals the fact that the earliest symptoms occurred mainly in the morning, appeared a long time after meals and were relieved by taking food or drink and by lying with the head low. If "re-inflation of the ventricles" is not carried out as an urgent measure the patient falls into coma and dies. In other cases the hypotensive syndrome lasts for months or years in the chronic state, and the diagnosis is mistaken until the day when ventricular puncture reveals the "ventricular collapse" of Clovis Vincent.

Anatomical forms.—Both isolated and associated forms of intracranial hypotension exist. The diagnosis is again difficult, but it is always made clear by trephine puncture of the ventricle, which is also the first stage of treatment.

Isolated intracranial hypotension.—There were 135 cases, of which 24 were post-traumatic, 25 were post-operative, 19 were secondary to various diseases, and 67 were apparently primary.

Whatever its cause may be, isolated hypotension shows all the clinical and evolutionary characteristics already described. The neurosurgeon observes that the dura mater does not pulsate; when this membrane is incised, the brain is seen to be shrunken, collapsed and pulseless. This state of cerebral dehydration is confirmed by ventricular puncture. No fluid escapes when the trocar penetrates it, and one hears the sound of air being sucked into the ventricle. If any ventricular fluid is found, it cannot be removed except by aspiration or by swinging the head backwards or compressing the jugular veins.

Hypotension associated with other disturbances of cerebromeningeal hydrodynamics.—There were 71 cases, of which 16 were post-traumatic, 46 secondary and 9 apparently primary.

It often happens that hypotension verified by trephine puncture is, nevertheless, associated with (1) a certain amount of more or less diffuse cerebral œdema (gelatinous, grey, hypotensive brain); or (2) ventricular dilatation in spite of hypotension of the fluid; or (3) serous meningitis or subdural hydroma with hypotension.

The cerebral mass and the space it occupies in the cranial casing are sufficient to make it easy to realize the possibility of such associations, which we have confirmed at operation. Any one of the disturbances of cerebromeningeal hydrodynamics may be primary or secondary. It has seemed to us that the so-called localizing symptoms were related sometimes to cerebral collapse, especially marked in the

region corresponding to the localizing signs, and sometimes to local serous meningitis or local cerebral œdema associated with the hypotension.

These forms should be distinguished from cerebral collapse related to direct compression of the brain, which is accompanied by intracranial hypertension. The compression may be due to a subdural hæmatoma or to predominant serous meningitis. Hypotension occurs only if the hæmatoma has been evacuated or the serous meningitis drained.

It must be noted that the various hydraulic disturbances of the cerebromeningeal system (cerebral œdema, serous meningitis, ventricular hydrocephalus, cerebromeningeal dehydration) may not only be combined, but may follow each other in the same patient. This may be a fortunate or normal event, or, on the contrary, a grave, and very often fatal, complication. In either case, the degree of disturbance shown by the electroencephalogram is of indisputable prognostic value.

If a fatal issue is feared, it is of the highest importance to recognize the dominant disturbance so that it may be suitably treated. Drainage for serous meningitis, dehydration for œdema, and restoration of the ventricular balance for hydrocephalus may follow each other or be combined in one and the same case.

Hypotension associated with other intracranial lesions.—The lesions may be post-traumatic or non-traumatic. They may be diffuse or local, tumoral, vascular, atrophic or infectious. All may be accompanied by other disturbances of cerebromeningeal hydrodynamics. J. Lebeau (1947) has shown that temporal hernia may be associated with intracranial hypotension and hypertension. In every case the primary lesion must be treated first, and the hydrodynamic disturbance dealt with afterwards if necessary.

Causes.—The cause of hypotension is sometimes obvious, but often very difficult to detect. There are secondary forms and clinically primary forms.

A study of the patient's history, clinical investigation, a search for the biological signs of hypotension, and especially a systematic study of the ventricular fluid, which often shows ventricular hæmorrhage, hyper-albuminosis and sometimes, on the contrary, a predominant leucocytic reaction, a comparison of the fluid of serous meningitis and of the ventricular fluid, and a complete humoral examination often give useful information.

The authors then dealt with:

- (1) *Post-traumatic hypotension*, on the basis of 45 cases. Recent and late forms, with or without leakage of fluid to the outside or into the subdural space.
- (2) *Post-operative hypotension*, on the basis of 25 cases.
- (3) *Secondary hypotension*, after many surgical or medical affections, on the basis of 87 cases.
- (4) *Therapeutic hypotension*, following radiotherapy (Stuhl, Bordet and Thiébaud, 1938) or drug therapy, on the basis of 5 cases.
- (5) *Clinically primary hypotension*, on the basis of 76 cases.

The type of hypotension which follows lumbar puncture, spinal anæsthesia, ventricular puncture or drainage of the ventricles in hydrocephalus is well known and will not be considered except to mention that hypotension left to itself is often the immediate cause of death in diverse conditions (traumatic, operative, circulatory, infectious, toxic or due to malnutrition). The surgeon is sometimes able to avoid this occurrence, and also secondary hæmorrhage or secondary softening of the brain. We have had the opportunity of observing a certain number of patients showing the classical symptoms of cerebral apoplexy in whom we have been able to prevent the hæmatoma by re-establishing the disturbed balance of the cerebrospinal circulation.

Morbid physiology.—This is easy to conceive. There may be a leakage of fluid, defective secretion or excessive absorption. Schaltenbrand and Wolf have tabulated it thus: "Hypotension of the cerebrospinal fluid may be due either to diminished

secretion of fluid with constant absorption, or to increased absorption with constant secretion. These disturbances may occur:

- (1) If the flow of blood towards the plexus is diminished or interrupted.
- (2) If the secretion of the plexus is diminished by nervous influences.
- (3) If lesions in the cells of the plexus prevent the secretion of cerebrospinal fluid.

The absorption of cerebrospinal fluid may be increased if: (a) The cerebrospinal fluid goes elsewhere—perforation of the dura mater. (b) The osmotic pressure of the blood increases and allows the cerebrospinal fluid to enter the blood stream."

We would point out that the problem of intracranial hypotension is a special case in the problem of water metabolism in the tissues and is related to that of œdema. It is well known that this is at present the object of very active research and we refer the reader to the work of Mach on states of dehydration, in which the still very incomplete data collected so far are summed up. This problem is further complicated in that we are dealing with the brain working in its rigid cranial casing. Reversible and irreversible forms of hypotension exist, such as the recurrent and finally incurable forms connected with atrophic lesions of the choroid plexuses.

In the patients we are considering, where death seems imminent, direct action on disturbances of the blood circulation (cardiovascular drugs, sympathetic surgery) are of little use, even if these disturbances are primary. On the other hand, neurosurgical procedures designed to restore the water balance of the brain and its envelopes directly are often efficacious. These operations, which first of all constitute urgent neurosurgery, act, in their turn, on the disturbances of the blood circulation.

238 cases of serious intracranial hypotension were operated upon with 43 deaths (18%). There are practically no sequelæ in isolated hypotension; these only occur after combined forms.

Professor D. Petit-Dutaillis and Dr. G. Guiot: IV. Therapeutic indications in intracranial hypotension.—The therapeutic indications are dominated by three considerations: the variable difficulties of diagnosis, the facts observed on direct examination of the brain and on exploration of the ventricles, and the possibility that intracranial hypotension and hypertension may alternate or succeed each other in the same patient.

The diagnosis cannot be established without complementary investigations. For a long time it was believed that the diagnosis could be based on a single spinal manometric test. This may be sufficient in conditions due for instance to lumbar puncture in patients not suspected of tumoral diseases, complications of spinal anaesthesia, hypotension in patients trephined in the past. But in head injuries, or in the interpretation of post-operative complications in neurosurgery, this method only leads to serious diagnostic and therapeutic mistakes.

In neurosurgery, it is above all the exploration of the brain through simple trephine holes, and the results of puncture of the ventricles, which allow the diagnosis of intracranial hypotension to be clearly established.

The chief fact is the diminution of the volume of the brain as a result of complete or relative emptiness of the ventricles (ventricular collapse of Clovis Vincent). In pure cases this collapse is bilateral and symmetrical, but it may be unilateral especially in forms of traumatic origin. This unilateral collapse may be associated with some aspects of serous meningitis, especially with a subdural sheet of fluid on the same side. The other hemisphere may be normal or changed (serous meningitis, mild œdema, atypical forms of intracranial hypotension according to Puech). In the pure forms, injection of fluid or air into the ventricles is enough to restore the brain to its original volume and to make all the symptoms disappear. In other cases, though the consistency may be normal, the brain does not remain filled, because of a leak in the pools at the base of the brain. In the most serious cases, the collapse of the walls of the ventricles is accompanied by disturbances of the cerebral tissues, which have lost all their elasticity and the flaccid brain allows the fluid to leak out through

region corresponding to the localizing signs, and sometimes to local serous meningitis or local cerebral œdema associated with the hypotension.

These forms should be distinguished from cerebral collapse related to direct compression of the brain, which is accompanied by intracranial hypertension. The compression may be due to a subdural hæmatoma or to predominant serous meningitis. Hypotension occurs only if the hæmatoma has been evacuated or the serous meningitis drained.

It must be noted that the various hydraulic disturbances of the cerebromeningeal system (cerebral œdema, serous meningitis, ventricular hydrocephalus, cerebro-meningeal dehydration) may not only be combined, but may follow each other in the same patient. This may be a fortunate or normal event, or, on the contrary, a grave, and very often fatal, complication. In either case, the degree of disturbance shown by the electroencephalogram is of indisputable prognostic value.

If a fatal issue is feared, it is of the highest importance to recognize the dominant disturbance so that it may be suitably treated. Drainage for serous meningitis, dehydration for œdema, and restoration of the ventricular balance for hydrocephalus may follow each other or be combined in one and the same case.

Hypotension associated with other intracranial lesions.—The lesions may be post-traumatic or non-traumatic. They may be diffuse or local, tumoral, vascular, atrophic or infectious. All may be accompanied by other disturbances of cerebromeningeal hydrodynamics. J. Lebeau (1947) has shown that temporal hernia may be associated with intracranial hypotension and hypertension. In every case the primary lesion must be treated first, and the hydrodynamic disturbance dealt with afterwards if necessary.

Causes.—The cause of hypotension is sometimes obvious, but often very difficult to detect. There are secondary forms and clinically primary forms.

A study of the patient's history, clinical investigation, a search for the biological signs of hypotension, and especially a systematic study of the ventricular fluid, which often shows ventricular hæmorrhage, hyper-albuminosis and sometimes, on the contrary, a predominant leucocytic reaction, a comparison of the fluid of serous meningitis and of the ventricular fluid, and a complete humoral examination often give useful information.

The authors then dealt with:

(1) *Post-traumatic hypotension*, on the basis of 45 cases. Recent and late forms, with or without leakage of fluid to the outside or into the subdural space.

(2) *Post-operative hypotension*, on the basis of 25 cases.

(3) *Secondary hypotension*, after many surgical or medical affections, on the basis of 87 cases.

(4) *Therapeutic hypotension*, following radiotherapy (Stuhl, Bordet and Thiébaud, 1938) or drug therapy, on the basis of 5 cases.

(5) *Clinically primary hypotension*, on the basis of 76 cases.

The type of hypotension which follows lumbar puncture, spinal anæsthesia, ventricular puncture or drainage of the ventricles in hydrocephalus is well known and will not be considered except to mention that hypotension left to itself is often the immediate cause of death in diverse conditions (traumatic, operative, circulatory, infectious, toxic or due to malnutrition). The surgeon is sometimes able to avoid this occurrence, and also secondary hæmorrhage or secondary softening of the brain. We have had the opportunity of observing a certain number of patients showing the classical symptoms of cerebral apoplexy in whom we have been able to prevent the hæmatoma by re-establishing the disturbed balance of the cerebrospinal circulation.

Morbid physiology.—This is easy to conceive. There may be a leakage of fluid, defective secretion or excessive absorption. Schaltenbrand and Wolf have tabulated it thus: "Hypotension of the cerebrospinal fluid may be due either to diminished

Urethrostomy Drainage of the Bladder? ¹

By JOHN G. SANDREY, F.R.C.S.

URETHROSTOMY drainage of the bladder has been carried out for many years at Saint Peter's Hospital in the treatment of urethral stricture. Harrison (1878) recommended the introduction of a tube along the posterior urethra to drain the bladder after external urethrotomy or perineal section as a means of preventing post-operative febrile reactions. It was not until 1885, however, that Harrison described the operation of combined internal and external urethrotomy with urethrostomy drainage with which his name is now associated. Originally recommended for "impassable or very extensive strictures which will not dilate" the operation was also used in "cases of peri-urethral abscess, fistula or extravasation" and eventually came to be employed exclusively in the latter group. The value of combined perineal drainage of both the bladder and the subcutaneous tissues in cases of stricture complicated by gangrenous cellulitis ("perineal phlegmon") was emphasised by both Freyer and Thomson-Walker in their writings and it is, I believe, still to be regarded as the method of choice in these cases, for, in addition to providing for the direct escape of urine from the bladder by the most dependent route, it avoids opening up fresh planes of cellular tissue. Most of us have looked on helplessly while a spreading gangrenous cellulitis of the abdominal wall or a gas-infection has developed after suprapubic cystostomy in cases of this kind, yet how easily this could have been prevented by drainage from below! Fortunately the so-called perineal phlegmon is becoming less common nowadays but in the half-dozen cases I have treated by combined perineal section and urethrostomy in the past few years it has always been very gratifying to watch the rapid recovery of patients who, as a rule, when admitted to hospital exhibited all the signs of the profound toxæmia so characteristic of this form of urinary suppuration. Furthermore, the infection both in the urinary tract and the cellular tissues has cleared up rapidly and completely, and incidentally the divided stricture has become more amenable to dilatation afterwards.

Apart from its occasional use in urethral stricture urethrostomy drainage of the bladder has never been popular with urologists in this country although it appears to have been extensively used for a long time in the United States. Young and his associates (1926) recommended this procedure for diverting the urine when operating for hypospadias and other deformities of the penis and I believe the majority of British plastic surgeons now follow this example. Young (1934), discussing the treatment of the obstructed bladder, advised the substitution of the urethral catheter for suprapubic drainage because of the high mortality of the latter. Where the urethra did not tolerate a catheter well, however, he also

¹This paper will appear *in extenso* in the *Post-Graduate Medical Journal*. The author discusses first, those methods of bladder drainage now in common use, secondly, personal experiences of drainage of the bladder by urethrostomy and lastly he evaluates the various procedures in order to determine under what circumstances they should be employed. The present paper deals with urethrostomy drainage of the bladder.

the trephine holes. The pathogenesis of these tissue changes is still under discussion.

The treatment may aim at direct replacement of the missing fluid (intravenous injections of distilled water, massive injections of serum repeated as required). Treatment with drugs capable of acting on the arterial blood-pressure, the capillary permeability or the secretion of the plexuses (perfusion of adrenaline or ephedrine in physiological or hypotonic serum, syncortil, pitressin). Some authors have recommended vitamin P.

Air can be injected into the ventricles. The quantity of air varies, and it must be injected prudently, until the ventricles are "reinflated". This air has a twofold action: it re-establishes the intraventricular pressure, and it causes irritation of the choroid plexuses, which tends to re-establish secretion.

In severe cases direct replacement of the fluid mass by injecting physiological serum or, better, Ringer's solution into the ventricles is the method of choice because of its rapid effect. In severe cases of collapse of the ventricles which do not respond to this treatment, the indirect methods are indicated, combined with the Trendelenburg position. This favours blood stasis, and, by relieving the nuclei at the base of the brain, sometimes gives better results than one dares to hope for.

Finally, the prevention of hypotension is most important to neurosurgeons. Repletion of the ventricles is a wise practice at the end of operations to prevent passive collapse (compression by a hæmatoma or a tumour), and also after operations on the posterior fossa to restore a normal cerebrospinal fluid pressure. All operations, even those on the nerve roots or the spinal cord, demand a reduction in the loss of cerebrospinal fluid during operation, and its replacement in order to simplify the immediate post-operative course.

Dr. W. Ritchie Russell: During the late war the British neurosurgeons came to recognize what they call a *low-pressure state* which seems to be identical with *l'hypotension intra-crânienne*. We are now more aware of this condition, but it must be admitted that our conceptions with regard to it are somewhat vague.

Patients who, after operation or injury, develop unexplained coma are suspected of developing this low-pressure state, and if on lumbar puncture or exploratory trephine the pressure is low, treatment is instituted to raise the intracranial pressure—the foot of the bed is raised and fluids are forced. This treatment is also followed in cases of subdural hæmatoma where, after operation, the brain remains retracted and the patient drowsy. The patient's condition usually improves, but why? Are these patients just suffering from water depletion or does intracranial hypotension cause coma by some mechanical displacement of the brain? Cases also occur of negative intracranial pressure in which there is no obvious disturbance of cerebral function.

With regard to intracranial hypotension following injury the position is complex. There is no doubt that in many cases of prolonged post-traumatic stupor a stage develops in which the intracranial pressure may become very low or even negative so that on exploratory trephine the brain falls away when the dura is opened. These cases are often severely dehydrated and the difficulty is to assess how much of the patient's coma is due to water depletion and how much to some other factor. Further, is the dehydration the result merely of inadequate fluid intake or of a biochemical disorder due to hypothalamic dysfunction? The hypothalamus and pituitary mechanisms control water metabolism to a profound extent. It seems possible and indeed probable that this mechanism should sometimes become disordered by trauma. I feel that the mechanism underlying intracranial hypotension can perhaps be unravelled by detailed biochemical studies.

Urethrostomy Drainage of the Bladder? ¹

By JOHN G. SANDREY, F.R.C.S.

URETHROSTOMY drainage of the bladder has been carried out for many years at Saint Peter's Hospital in the treatment of urethral stricture. Harrison (1878) recommended the introduction of a tube along the posterior urethra to drain the bladder after external urethrotomy or perineal section as a means of preventing post-operative febrile reactions. It was not until 1885, however, that Harrison described the operation of combined internal and external urethrotomy with urethrostomy drainage with which his name is now associated. Originally recommended for "impassable or very extensive strictures which will not dilate" the operation was also used in "cases of peri-urethral abscess, fistula or extravasation" and eventually came to be employed exclusively in the latter group. The value of combined perineal drainage of both the bladder and the subcutaneous tissues in cases of stricture complicated by gangrenous cellulitis ("perineal phlegmon") was emphasised by both Freyer and Thomson-Walker in their writings and it is, I believe, still to be regarded as the method of choice in these cases, for, in addition to providing for the direct escape of urine from the bladder by the most dependent route, it avoids opening up fresh planes of cellular tissue. Most of us have looked on helplessly while a spreading gangrenous cellulitis of the abdominal wall or a gas-infection has developed after suprapubic cystostomy in cases of this kind, yet how easily this could have been prevented by drainage from below! Fortunately the so-called perineal phlegmon is becoming less common nowadays but in the half-dozen cases I have treated by combined perineal section and urethrostomy in the past few years it has always been very gratifying to watch the rapid recovery of patients who, as a rule, when admitted to hospital exhibited all the signs of the profound toxæmia so characteristic of this form of urinary suppuration. Furthermore, the infection both in the urinary tract and the cellular tissues has cleared up rapidly and completely, and incidentally the divided stricture has become more amenable to dilatation afterwards.

Apart from its occasional use in urethral stricture urethrostomy drainage of the bladder has never been popular with urologists in this country although it appears to have been extensively used for a long time in the United States. Young and his associates (1926) recommended this procedure for diverting the urine when operating for hypospadias and other deformities of the penis and I believe the majority of British plastic surgeons now follow this example. Young (1934), discussing the treatment of the obstructed bladder, advised the substitution of the urethral catheter for suprapubic drainage because of the high mortality of the latter. Where the urethra did not tolerate a catheter well, however, he also

¹This paper will appear *in extenso* in the *Post-Graduate Medical Journal*. The author discusses first, those methods of bladder drainage now in common use, secondly, personal experiences of drainage of the bladder by urethrostomy and lastly he evaluates the various procedures in order to determine under what circumstances they should be employed. The present paper deals with urethrostomy drainage of the bladder.

advised that there should be no delay in establishing urethrostomy drainage. Barney (1934) described the very simple method of performing urethrostomy with catheter and clamp which he had used for many years. Lewis (1943) advocated urethrostomy for drainage of the paralysed bladder and claimed that there was less leakage, less infection, better drainage, in fact many advantages over other methods.

Dissatisfaction with routine methods of bladder drainage by cystostomy or urethral catheter first led me to explore the possibilities of urethrostomy for this purpose early in 1946 and during the past two years I have employed it more or less exclusively, the series of cases now totalling 379.

The following table shows the various conditions treated by urethrostomy drainage:

Temporary or pre-operative bladder drainage	58 cases
Post-operative drainage	
(a) Prostatectomy, one stage (retropubic, Freyer, vesico-capsular)	157 cases
(b) Prostatectomy, after suprapubic drainage	55 cases
(c) Prostatectomy, after urethrostomy drainage	49 cases
(d) Perurethral resection	8 cases
(e) Diverticulectomy	24 cases
(f) Operations for carcinoma of the bladder (open diathermy, partial cystectomy)	16 cases
(g) Miscellaneous (excision stricture penile urethra, perineal phlegmon, calculus, &c.)	12 cases
Total	379 cases

The method used in the majority of the cases was that described by Barney and will be subsequently referred to as the "closed" method. A rubber catheter is passed along the urethra to its full length and the distal end securely clamped with a curved artery forceps (Moynihan or curved Spencer Wells pattern). The forceps is advanced until its beak reaches the bulbous urethra and by rotating the handle through 180 degrees the point is made to present in the perineum where it is cut down on. The end of the catheter is disengaged from the forceps and the instrument withdrawn through the incision to the correct length for bladder-drainage. This method is speedy, simple and requires no special equipment or gadgets. In very ill patients it can readily be performed in bed under local anaesthesia. In that group of cases (comprising about 20%) where the external meatus is stenosed or the urethra congenitally small the "open" method has been employed. An incision is made in the perineum on the curve of a small metal bougie dividing the skin, fascia, bulbocavernosus muscle, the spongy tissue and the urethral mucosa. The edges of the latter must be carefully identified and grasped with fine tissue forceps before attempting to pass the catheter, otherwise the urethra will tend to invaginate and prevent the passage of the instrument. The open is much more difficult than the closed method of urethrostomy as it requires wider dissection in an extremely vascular area. It should not be attempted under local anaesthesia.

The best position for the urethrostomy opening has been found to be in the scrotal raphe about one inch in front of the perineo-scrotal angle. The site of this opening is a matter of some importance. If placed too far back it is less accessible for nursing, contamination from the anus more readily occurs, kinking of the tube by the weight of the scrotal contents is hard to avoid and spontaneous closure of the fistula after removal of the catheter is slower. If too far forward the catheter tends to kink excessively at the subpubic angle and if it should come out replacement may be difficult.

Transfixion of the catheter was found to be unsatisfactory mainly because of leakage from the stitch-hole in the rubber and the best method of fixation so far devised has been by numerous half-hitches around the catheter and stitched to the skin in front and rear. Silk, nylon or any other non-absorbable suture material serves equally well.

For post-operative drainage after prostatectomy, partial cystectomy, &c., a whistle-tip resectoscope catheter with at least three lateral eyes has been found to be the most satisfactory. The perineal urethra will readily accommodate 22 and 24 Ch. sizes and when hæmorrhage was not well controlled size 26 Ch. has been used on several occasions. In three cases urethrostomy has been combined with suprapubic drainage and drip-irrigation when severe hæmorrhage had occurred after Freyer prostatectomy; as an alternative to the latter method of combined drip irrigation, a Foley type of catheter was introduced by open urethrostomy on one occasion and control of bleeding was complete.

The best position for nursing the patient seems to be with the tube draining over the thigh and the scrotum supported by means of an elastoplast bridge.

The chief disadvantages of this method are as follows:

First, a scrotal hæmatoma may form. This does not appear to be a matter for great concern

as rapid absorption without any tendency to infection has been the rule in all the cases observed.

Secondly, replacement of the urethrostomy tube may be difficult, especially if the attempt is delayed for more than a few hours. An opening made too far forward will further increase the difficulties of replacement.

Thirdly, slight incontinence of urine is not uncommon, especially after prolonged drainage with the larger sizes of catheters. This is never severe and full control normally returns within a few weeks. No case of permanent incontinence has been observed.

Finally, leakage of urine from the resulting perineal fistula after removal of the tube will occur with each act of micturition. This is, of course, normally under voluntary control. It ceases, in the average case, after four or five days but may persist longer if the opening has been made too far back in the perineum or if circumstances have made it impossible to get the patient out of bed immediately after removal of the tube. (In one of my cases after prostatectomy severe hæmatemesis from a duodenal ulcer necessitated three months' treatment in bed. On getting the patient up at the end of this time the perineal fistula, which had leaked intermittently all this time, closed spontaneously within a few days.) In the erect posture the weight of the scrotal contents tends to drag the external opening away from the urethra and this will accelerate the obliteration of the track. In none of my own cases has spontaneous closure of the fistula failed to occur. Leakage is undoubtedly the chief disadvantage of urethrostomy drainage but it is, after all, a small price to pay for the added safety the method confers on "closed" operations on the bladder. Unlike the leakage associated with suprapubic cystostomy it is, however, under voluntary control. It is always necessary to warn patients of leakage before removing a perineal tube and to reassure them that this will only be a temporary state of affairs, otherwise they are apt to assume that some mishap has befallen them.

Most of the advantages of urethrostomy, especially the simplicity of the procedure, have already been emphasized. Compared with suprapubic cystostomy the outstanding feature is the difference between dependent and uphill drainage and, in bladder obstructions, the striking contrast between the mortality rates of the two methods. Other features favouring urethrostomy are: first, an intact abdominal wall after pre-operative drainage instead of an infected abdominal tube track, so that a subsequent suprapubic operation is safer, easier and cleaner; secondly, post-operative drainage of the bladder is away from the suture line and allows complete closure in most instances. Compared with catheter drainage the main advantage is the avoidance of most of the ill-effects of urethritis by excluding nearly two-thirds of the entire urethra; furthermore, there is always adequate provision for free drainage alongside the perineal catheter. In addition, the larger sizes of catheter, better methods of fixation, elimination of the distal (pre-pubic) bend of the urethra, the abolition of any time-limit, are all factors which make urethrostomy preferable to catheter drainage with the possible exception of that small group of cases where the external meatus is large and where drainage will probably not be required for longer than seven to ten days. While it can be said that a stricture will almost invariably follow incision of the penile urethra it can be stated, equally dogmatically, that this complication is unlikely to occur in the perineal urethra unless the entire circumference has been divided and the ends separated. In one patient incision of the bulbous urethra for the removal of recurrent calculi revealed no tendency to contracture in spite of three previous urethrolithotomies at the same site.

SUMMARY AND CONCLUSIONS

(1) Suprapubic cystostomy offers no real solution to the relief of bladder obstructions because, in the first place, it is mechanically unsound and will always be associated with a high incidence of fatal urinary infections; secondly, permanent suprapubic drainage is worse than a sentence of death to most individuals and almost any operative risk is justified in avoiding it. In the treatment of the paralysed bladder, however, suprapubic drainage appears to be still the safest and most satisfactory method for routine use.

(2) Having regard to the severe effects of traumatic urethritis, both immediate and late, the indiscriminate use of the tied-in catheter to drain the bladder for periods exceeding two or three days is condemned. Less than 10% of the urethra examined were found to tolerate a catheter of size 22 Ch. or larger for longer than a week and only this small group can be considered as suitable for this form of drainage.

(3) Urethrostomy drainage, though not ideal by any means, goes a long way towards solving many of the defects of the other methods. When bladder drainage is required pre-operatively urethrostomy has the great advantages of mechanical efficiency, simplicity and added safety over the other methods. As an alternative to immediate prostatectomy, particularly in the "poor-risk" case with extra-urinary complications, urethrostomy will, I

advised that there should be no delay in establishing urethrostomy drainage. Barney (1934) described the very simple method of performing urethrostomy with catheter and clamp which he had used for many years. Lewis (1943) advocated urethrostomy for drainage of the paralysed bladder and claimed that there was less leakage, less infection, better drainage, in fact many advantages over other methods.

Dissatisfaction with routine methods of bladder drainage by cystostomy or urethral catheter first led me to explore the possibilities of urethrostomy for this purpose early in 1946 and during the past two years I have employed it more or less exclusively, the series of cases now totalling 379.

The following table shows the various conditions treated by urethrostomy drainage:

Temporary or pre-operative bladder drainage	58 cases
Post-operative drainage	
(a) Prostatectomy, one stage (retropubic, Freyer, vesico-capsular)	157 cases
(b) Prostatectomy, after suprapubic drainage	55 cases
(c) Prostatectomy, after urethrostomy drainage	49 cases
(d) Perurethral resection	8 cases
(e) Diverticulectomy	24 cases
(f) Operations for carcinoma of the bladder (open diathermy, partial cystectomy)	16 cases
(g) Miscellaneous (excision stricture penile urethra, perineal phlegmon, calculus, &c.)	12 cases
Total	379 cases

The method used in the majority of the cases was that described by Barney and will be subsequently referred to as the "closed" method. A rubber catheter is passed along the urethra to its full length and the distal end securely clamped with a curved artery forceps (Moynihan or curved Spencer Wells pattern). The forceps is advanced until its beak reaches the bulbous urethra and by rotating the handle through 180 degrees the point is made to present in the perineum where it is cut down on. The end of the catheter is disengaged from the forceps and the instrument withdrawn through the incision to the correct length for bladder-drainage. This method is speedy, simple and requires no special equipment or gadgets. In very ill patients it can readily be performed in bed under local anaesthesia. In that group of cases (comprising about 20%) where the external meatus is stenosed or the urethra congenitally small the "open" method has been employed. An incision is made in the perineum on the curve of a small metal bougie dividing the skin, fascia, bulbocavernosus muscle, the spongy tissue and the urethral mucosa. The edges of the latter must be carefully identified and grasped with fine tissue forceps before attempting to pass the catheter, otherwise the urethra will tend to invaginate and prevent the passage of the instrument. The open is much more difficult than the closed method of urethrostomy as it requires wider dissection in an extremely vascular area. It should not be attempted under local anaesthesia.

The best position for the urethrostomy opening has been found to be in the scrotal raphe about one inch in front of the perineo-scrotal angle. The site of this opening is a matter of some importance. If placed too far back it is less accessible for nursing, contamination from the anus more readily occurs, kinking of the tube by the weight of the scrotal contents is hard to avoid and spontaneous closure of the fistula after removal of the catheter is slower. If too far forward the catheter tends to kink excessively at the subpubic angle and if it should come out replacement may be difficult.

Transfixion of the catheter was found to be unsatisfactory mainly because of leakage from the stitch-hole in the rubber and the best method of fixation so far devised has been by numerous half-hitches around the catheter and stitched to the skin in front and rear. Silk, nylon or any other non-absorbable suture material serves equally well.

For post-operative drainage after prostatectomy, partial cystectomy, &c., a whistle-tip resectoscope catheter with at least three lateral eyes has been found to be the most satisfactory. The perineal urethra will readily accommodate 22 and 24 Ch. sizes and when haemorrhage was not well controlled size 26 Ch. has been used on several occasions. In three cases urethrostomy has been combined with suprapubic drainage and drip-irrigation when severe haemorrhage had occurred after Freyer prostatectomy; as an alternative to the latter method of combined drip irrigation, a Foley type of catheter was introduced by open urethrostomy on one occasion and control of bleeding was complete.

The best position for nursing the patient seems to be with the tube draining over the thigh and the scrotum supported by means of an elastoplast bridge.

The chief disadvantages of this method are as follows:

First, a scrotal haematoma may form. This does not appear to be a matter for great concern

WALTER ERNEST DIXON MEMORIAL LECTURE

[Number 5]

Pharmacology and Biochemical Lesions

By R. A. PETERS, M.C., M.D., M.A., F.R.S.

It is a pleasant but nevertheless exacting task to be invited to the honour of delivering a W. E. Dixon Memorial lecture. It is many years ago since I sat at the feet of Dixon to learn pharmacology from him. Still a clear visual impression remains of the high collar, the cigarette and the pungent wit which helped so signally the discourse and practical class. One of my earliest remembrances of the Physiological Society is of a demonstration in the small Lecture Theatre at Cambridge in 1911, of Dixon and Halliburton. Later, I came to understand more the vivid research interest, which was the spring of his lively teaching, and, shortly after World War I, I had the opportunity of closer contact with him in research for the Government connected with Chemical Defence upon which we were both engaged, under the ægis of Sir Joseph Barcroft. He worked very hard (with S. E. Gooding) to discover clues to the action of mustard gas. This work like that of two continents of varied scientists during World War II brought no final answer—but it left facts of value. For instance, Dixon and Gooding observed that protein solutions and silk adsorb mustard gas, so that it does not lose activity by hydrolysis. This curious phenomenon is not yet properly understood. He stressed the fact that mustard gas forms no toxic breakdown products or toxic substances with cell constituents, an important fact in connexion with its action. He considered that the effect upon blood-vessels was a valuable clue and believed in the involvement of an axon reflex produced by the continuous irritation of sensory nerves by slow hydrolysis. The latter is not regarded as true to-day, but his freshness of mind and willing reception of ideas will always remain a vivid memory, as also his intensely experimental outlook. Discussion with him (as with Barcroft) led so often to a resort to the immediate experiment.

In Dixon's book on Pharmacology (1912) there occurs a remarkably modern account of cell biochemistry; he has written: "If we remove from a living cell all dead materials, water salts and ferments, is it necessary to assume that there is anything left? We think not and believe that there is no inherent difficulty in regarding protoplasm as a system of ferments co-ordinated together," and a little further on "Drugs . . . may have an affinity for any of the dead particles undergoing analytical or synthetic reactions, and thereby either stop or accelerate the cycle of changes, or they may produce their effect on ferments". This is a really modern outlook and yet further scrutiny of the book does not suggest that these enzyme conceptions were used. As I believe, this was because knowledge of the enzymes which mattered in the intermediary metabolism of the life of the cell and of their organization was not then available. What have the tremendous advances of the last twenty-five years in the enzyme biochemistry of the cell meant for pharmacology? It seems that pharmacologists have been reluctant to apply the new knowledge; even as late as 1942 there is little mention of the possible importance of biochemistry in pharmacology textbooks. In that most scholarly statement of A. J. Clark (1937) it is true that emphasis is laid upon the

believe, be found to yield far better results in the long run. Post-operatively it confers an increased margin of safety on complete closure after operations on the bladder or prostate. Furthermore drainage can be maintained indefinitely and so ensure sound healing of the abdominal wound in the most unfavourable conditions.

The following cases and specimens were shown:

Hydronephrotic Twin Kidney.—Mr. CLIFFORD MORSON.

Pyelograms Showing Early Result of Rovsing's Operation.—Mr. JOHN EVERIDGE.

Two Cases of Double Kidney.—Mr. R. H. O. B. ROBINSON.

Kidney with Unusual Congenital Cysts.—Mr. B. H. PAGE and Dr. J. F. HEGGIE.

Pyonephrosis in Lower Half of a Double Right Kidney.—Mr. GEOFFREY PARKER.

Carcinoma of Ureter.—Mr. ALEX ROCHE.

(1) Large Diverticulum of the Bladder Removed by Operation. (2) Prostate and Seminal Vesicles Removed by Total Perineal Prostatectomy.—Mr. J. C. ANDERSON.

(1) Large Vesical Diverticulum Successfully Removed from an Octogenarian. (2) Orchido-vaso-vesiculectomy for Tuberculosis.—Mr. WILFRID ADAMS.

Foreign Body in the Bladder.—(1) Encysted Paraffin Wax; (2) Paraffin Wax (Mr. W. S. Mack's Case).—Mr. W. W. GALBRAITH.

Carcinoma of the Bladder.—Mr. F. R. KILPATRICK.

Carcinoma of the Bladder.—Mr. ASHTON MILLER.

Ectopia Vesicæ.—Mr. A. W. BADENOCH.

(1) Staphylococcal Inflammation of Urachus. (2) Congenital Pyonephrosis.—Mr. HENRY K. VERNON.

Heterotopic Bone Formation in Suprapubic Scar.—Mr. T. W. MIMPRISS.

Two Cases of Ureteric Transplantation for Systolic Bladder.—Mr. R. O. LEE.

Urethral, Prostatic and Vesical Calculi.—Mr. F. R. ST. G. STEAD (for Mr. G. NELIGAN).

Congenital Urethral Valve from Child of Two Years.—Mr. F. J. MILWARD.

initiated by attack upon enzymes. Indeed in retrospect it is curious to note how slowly the idea has been accepted that interference with enzymatic processes in intermediary metabolism in a tissue could produce abnormality, and that it was a fundamental method of approaching such a research.

VITAMIN B₁ AND CONVULSIONS

For many years now we have been interested in my laboratory in the detail of the biochemical action of substances causing pathological effects, and in particular in trying to understand the initial change. It is convenient to focus attention upon this initial biochemical step, by calling it a "biochemical lesion" (Gavrilescu and Peters [20]). I must first indicate how we came across the pyruvate oxidase system, an organized group of enzymes responsible for oxidizing pyruvate ($\text{CH}_3\text{CO COO}^-$)¹ which forms the main theme of my lecture. This was in the attempt to meet the challenge set by the opisthotonus signs induced in the rice fed pigeon by vitamin-B₁ deficiency because it seemed that something fundamental would be learnt when this was understood. After some search (with H. W. Kinnorsley [26]) a fault was found in the lactic acid metabolism of brain tissue. With the further discovery that this could be rectified *in vitro* by addition of the vitamin in parallel with the cure *in vivo* by dosing such birds with vitamin, and with the final delineation of the actively damaged stage as that involved in the oxidation of pyruvate, it became clear that the biochemical lesion was present in the intermediary metabolism of carbohydrate at the 3 carbon acid stage (Peters [35]). In 1939, some ten years after the initial discoveries, taking advantage of Lohmann and Schuster's proof that the co-enzyme for the decarboxylation of pyruvic acid in alcoholic fermentation was the pyrophosphate of vitamin B₁ (otherwise called cocarboxylase), Banga, Ochoa and myself [3] proved that the missing component in the brain system was this cocarboxylase. These experiments were done with finely divided brain tissue respiring in a suitable phosphate mixture with additions of pyruvate as substrate (fig. 3). At that time it was also shown that the enzyme system responsible for this oxidation of pyruvate was complex [4]; in fact that it consisted of a battery of enzymes, suggesting that the demolition of the pyruvate molecule required fire from several quarters. Fig. 4 shows that in the

FIG. 4.—Effect of phosphate (0.05 M), fumarate (0.005 M) and adenylic acid (0.00014 M) on the oxidation of pyruvate (0.0091 M) by dialysed dispersions from pigeon's brain. 1.5 ml. enzyme (dialysed 2 hr.) to 2 ml. with additions including 0.1 mg. Mg.⁺⁺ (as MgCl_2). The complete system contains enzyme + Mg.⁺⁺ + phosphate (P) + fumarate (fum.) + adenylic acid (Ad.) + pyruvate (pyr.). Sample with no phosphate buffered with NaHCO_3 to pH 7.3. Air, 38°C.

¹Throughout the term "pyruvate" is used rather than pyruvic acid; at the physiological pH the acid is mainly dissociated.

similarity observed in the poisoning of enzymes and drug effects in cells, but evidently he felt unable to carry the speculation further. As a matter of fact, pharmacologists have been right in their hesitation to lay much weight on the relation between drug actions and single enzymes; an exception is that of choline esterase and acetylcholine which formed the subject of the notable first lecture in this series by H. H. Dale [11].

I will try to relate pharmacology and toxicology with cell enzymes from the standpoint of biochemical lesions and modern biochemical research, in the hope of contributing to the further systematization of pharmacology. Though it is a commonplace that all pharmacological action requires as a first step contact and even some penetration into the tissue, it happens that recent advances in biochemistry have done more to clarify the enzymic constitution of the cell than to give us a clear picture of its varied mosaic surface. It seems more fruitful at this stage therefore to consider the enzymes. More especially the main emphasis will be upon collecting together threads of knowledge about the action of some toxic substances upon the enzymes known as the pyruvate oxidase system and of evaluating this in relation to some pharmacological problems. To do this, I shall speak in turn of some aspects of our vitamin B₁ work, of our work on arsenicals, and of some more recent investigations upon the poison fluoroacetate.

Let me first make the matter concrete by showing you the effects upon skin of the arsenical war gas lewisite, and of its antidote known as British anti-lewisite. Lewisite ($\text{CH}_3\text{CH}_2\text{CH}_2\text{AsCl}_2$) is a trivalent arsenical compound, discovered in U.S.A. by Lee Lewis in World War I. It is very quickly toxic upon injection into animals or when applied to skin and produces blisters when placed upon the human skin which take some twenty-four hours to develop. This type of arsenical penetrates skin because it is soluble in lipoids, and is hydrolysed when it reaches the aqueous phase to the oxide, which is still toxic.

As can be seen from these two photographs, for which I am indebted to the Staff of the Experimental Station, Porton, the blisters develop slowly. At the end of two hours, when the first photograph was taken (fig. 1), some erythema appears at the site of application of a drop of lewisite and some swelling may appear. Each of the forearms shown had application at A, B, C of a similar drop of lewisite two hours before the photograph was taken. The spots marked C were treated after two minutes with the current anti-gas ointment and BAL respectively. They show no erythema. Spots B and A show an erythema. Spots B were kept as a control; spots A were treated respectively with "anti-gas" and with British anti-lewisite. When seen at twenty-four hours (fig. 2), good blisters had developed in spot B,

Photographs at Experimental Station, Ministry of Supply. (Reproduced by permission of *British Medical Bulletin*.)

and in spot A treated with anti-gas. The spot treated with BAL, however, showed neither vesication, nor erythema. Hence there was actual reversal of pathological change.

I have begun my lecture by showing these photographs because they put the practical end of one problem which it is wished to discuss more theoretically here. New therapeutic discoveries have so often come rather accidentally, that it is worth while to point out that this antidote was discovered by a theoretical approach, if you will by academic research. I wish to show the background and indicate the trend of the work. At first sight it must seem to be almost impudent to advance the view that such a complicated pathological process as vesication may be initiated by damage to cell enzymes, but that is an object of this lecture. Though the door is wider open to-day, it is interesting to record that this method of investigating toxicity problems required vigorous defence nine years ago; there was wide scepticism then among our scientific colleagues that the train of events leading to vesication could be

attack upon the enzymes with vesication. At the same time I showed that glutathione would not reverse the effect. So it came about that when the war started, this idea of attack upon SH groups and the selective action upon the pyruvate oxidase system formed the spearhead of our attack¹ upon the problem of finding antidotes.

Quite early in the war, tests upon several enzymes then available confirmed the selective action of the arsenicals; for instance the pyruvate oxidase system in a brain brei was much more sensitive to trivalent arsenic than the succinate system; the same applied to the α -glycerophosphate and to the triosephosphate dehydrogenases. As an illustration in a brain brei, 0.017 millimol lewisite poisoned the pyruvate oxidation to the extent of 89%, whereas the succinate oxidation was only 5% inhibited [38]. Also upon poisoning animals with arsenite or with lewisite, there was an accumulation of pyruvate in blood, just as occurs in thiamine deficiency [51], suggesting interference with the disposal of pyruvate. Evidence

FIG. 5.—Course of oxidation of lactate by brain tissue and selective action of poisons. Cytochrome system not represented.

FIG. 6.—The diagram shows the original percentage of As in lewisite-kerateine, arsenite-kerateine, arsenate-kerateine, and in metakeratin compounds. The arrows indicate the change produced by a reprecipitation, which is slight for lewisite, though larger for arsenite. (From data of Stocken and Thompson, 1940.) In metakeratin sulphur is in oxidized (SS) form.

was also obtained (Thompson [50]) that lewisite interfered with the oxidation of pyruvate in skin, and that the enzyme system in brain contained an essential SH group [41]. This latter was dependent on indirect arguments used for other enzymes. From this it seemed clear that the pyruvate oxidase system could be used as an *in vitro* test, and in fact this proved to be completely justified.

At this stage it might be thought that the problem was virtually settled, and that the nature of the arsenical lesion was proved. If the arsenical attacked the SH group in the enzyme, there should be slight dissociation of the thioarsenite formed, and hence glutathione or some other such compound should protect, as was claimed to occur with arsenoxides and trypanosomes. Yet, in Oxford, it proved to be quite impossible to protect *in vivo* or *in vitro* from lewisite or arsenite with a variety of monothiol compounds (Sinclair). So we were faced with a dilemma and with no complete proof of the nature of the tissue arsenical compound. I will not go into the interesting story of how this matter came to be resolved, which depended at one stage upon an official discontinuance of the enzyme research owing to the prevailing scepticism. Suffice it to say that in connexion with a search for specific antibodies to possible lewisite-proteins, our colleagues Stocken and Thompson [45, 46] started to make and to analyse compounds of kerateine with these arsenicals; kerateine [22] is made by reducing the keratin in hair or wool. Upon adding these arsenicals to a solution of

¹The team who started work very early in the war consisted of two subgroups: upon the arsenical work H. M. Sinclair and R. H. S. Thompson; upon the mustard gas work E. R. Holiday, A. G. Ogston, J. St. L. Philpot, L. A. Stocken and R. W. Wakelin. After 9/10 months Sinclair and Philpot went to other work. Later, V. P. Whittaker and then G. Spray joined the arsenical work. Full discussions within the whole group took place at least once weekly. (For general review of BAL work see references Nos. 40, 55, 57).

absence of phosphate, of adenylic acid or of fumarate (in addition to the cocarboxylase), oxidation of the pyruvate molecule does not occur. I always find it exciting to realize that we might not any of us be thinking now unless this complex set of chemical changes were taking place in this simple 3 carbon molecule! A return will be made to a more detailed consideration of this enzyme system further in the lecture; it is very unstable *in vitro* in a ground brain preparation, being even damaged by freezing.

Turning to theory, it should be stressed that the opisthotonus signs clear up very quickly indeed upon giving vitamin, and that there is no detectable histological damage at this stage. It is in this sense an example of a pure biochemical lesion. This discourse has been started with a brief account of this ancient story because I regard the reversible change in vitamin-B₁ deficiency as the most definite instance in which it has been demonstrated that failure in an enzyme system, due to a lowered concentration of co-enzyme, can be related directly to the initiation of pathological change. As such it really illustrates the way in which biochemistry is at the basis of pathology, of pharmacology and even of medicine; for therapy will be most effective when the biochemical lesion is understood and reversed before it has gone too far.

THE ARSENICAL LESION AND BRITISH ANTI-LEWISITE

Up to the present point, nothing has been said which would connect the action of toxic substances with the vitamin enzyme system mentioned. The most striking available example of this is the action of lewisite and of its antidote, to which I have referred already. War gas compounds like lewisite are not as a rule general protoplasmic precipitants. The investigation of this problem, which I initiated at the start of World War II for the Ministry of Supply, was based on two ideas as to the nature of the biochemical lesions induced, (1) that the trivalent arsenical compounds attacked SH groups and (2) that these SH groups were part of the pyruvate oxidase system. The reason for using these ideas can be considered briefly, as it bears upon the main problem.

SH groups and arsenic.—The idea that arsenic attacked SH groups was not new. Ehrlich suggested in 1909 that the arsenceptor might be either hydroxyl or sulphhydryl in nature. No experimental evidence was available until the 1920 decade, and this was inspired by Hopkins' researches upon glutathione.

These SH compounds give an immediate vivid purple reaction with nitro-prusside and ammonia; there are several varieties of sulphhydryl groups in living cells, differing in chemical reactivity. Hopkins delineated two important classes, small molecular substances like glutathione, and proteins containing the so-called fixed SH group, to be found with boiled muscle, skin slices and the like.

In work which is not well known E. Walker, working under my direction for the Government in 1923–25 [42, 54], found that diphenylchloroarsine as well as the vesicants mustard gas sulphone and allyl isothiocyanate attacked the SH group in skin slices and boiled muscle tissue. This we were inclined to connect with the toxic action, though mustard gas was an exception. Much better known is the more extensive work of Voegtlin and colleagues [52, 53] carried out about the same time, where they connected the actions of the therapeutic arsenicals, especially arsenoxide, with an attack upon SH groups of glutathione, getting partial protection against toxic effects by use of a large excess of monothiol substances. As Eagle [16] later confirmed, large amounts of the monothiols are needed to give protective effects. This is due to the dissociability of the thioarsinites, as shown by Cohen, King and Strangeways in 1931; in alkaline solution they readily break up according to the following equation:

These observations explain the use of the idea that As attacked SH groups, though at the very start of the work an N group could not be absolutely excluded.

ARSENIC AND ENZYMES

The idea that arsenicals might be attacking an enzyme was also an old view which Walker and I had discarded in 1925. The facts which led me to take it seriously again take us back to the pyruvate oxidase system. During the course of our vitamin-B₁ work, we had found that the poison iodoacetic acid had a selective effect upon the oxidation of lactic acid in normal brain tissue [37] similar to that of deficiency of vitamin B₁ in the avitaminous brain; both led to an accumulation of pyruvate. In 1935/36 I found that the vesicant mustard gas sulphone in small concentrations [36] had the same selective action and that minute amounts of arsenite behaved similarly; Krebs [27] had found previously that arsenite in high concentration inhibited oxidation of a ketoacids. This meant that the whole cytochrome oxidase system as well as the lactate dehydrogenase was comparatively unaffected (see fig. 5). Since iodoacetic acid was known to be a weak vesicant, and since Dierckx [12] and others had shown its combination with SH groups, it was natural that I should connect the selective

Before continuing with our recent work upon the nature of the enzymes, I wish to discuss further this important matter of reversibility and of dissociation, because it must ultimately shed light upon the exact nature of the groupings in the enzyme. The amounts of BAL required to reverse a combination of an arsenical may differ with change in the structure of the arsenical. With lewisite, very little excess of BAL suffices to remove the arsenic from the protein. But, if we take mapharside (arsenoxide), *in vitro* it takes more arsenic to poison the enzyme system suggesting that the compound formed is more dissociable; similarly more BAL must be used to reverse the combination [48]. This is confirmed by the behaviour of the compounds lewisite-BAL and mapharside-BAL which Stocken prepared. Lewisite-BAL gives no nitroprusside reaction on treatment with alkali, whereas mapharside-BAL gives a slight pink colour. If we turn to the toxicity a rather curious point appears. Lewisite-BAL has only about one-fifth of the toxicity of lewisite; this is also true for mapharside-BAL if excess of BAL is present; but in absence of added BAL, the mapharside-BAL kills animals (rats) quicker than the parent mapharside [39]. The explanation seems to be that the BAL compound being lipid soluble penetrates quickly to the active centres, where its dissociation enables the As to poison the cell. In fact with ciliates, we could not reduce the toxicity of mapharside-BAL by addition of BAL and I think therefore that there is some difference in the protein attacked. A rather similar phenomenon has been found at Porton by Harrison and Randoll [24] with tissue cultures. I am mentioning these points to indicate that although the main story is clear, there is still work required on the theoretical side, before we shall fully understand all the details involved in the action of arsenicals, and the influence of organic structure upon dissociability. It is worth mentioning also, in parenthesis, that an important practical application of the dissociability of mapharside-BAL is being made by Friedheim and colleagues [19] in New York. They find that these compounds readily kill some of the protozoa of disease (*T. equiperdum*), the BAL in this case acting as a carrier for the arsenic and is an antidote in reverse.

Fortunately any paradox raised by these theoretical toxicities does not matter in practical medicine where we have enough BAL present to act as chaperone. A lucky dividend for medicine came out of the search for the lewisite antidote both in the treatment of arsenical complications and of mercury poisoning. In the development of this, much help was received from workers in the United States; we have been using for treatment in this country an oily mixture of BAL in benzylbenzoate and arachis oil worked out by H. Eagle. The results given in Table I show the number of cases of arsenical dermatitis judged to have received

TABLE I.—TREATMENT OF ARSENICAL DERMATITIS WITH BAL

(British report, 1948 [7].)

benefit in a clinical trial organized by an informal conference of the Medical Research Council [33]. Similar results have been found in the U.S. [17].

This practical application in clinical medicine of a theoretical research serves to emphasize the possible benefits which can come from an academic approach.

To summarize up to this point, it seems to be reasonably proved that, speaking broadly, trivalent arsenicals combine with SH groups in the pyruvate oxidase system to form a ring compound; in any case it must be some enzyme which can be only reactivated with a dithiol compound.¹ Hence we have unearthed an enzyme system which can be inhibited both negatively by lack of a co-enzyme or positively by an arsenical. The biochemical lesion so caused can be sufficiently severe to upset the functioning of the tissue cells and initiate a pathological state like vesication. The particular part of the body which is poisoned will depend of course upon the distribution of the toxic or deficiency agent. Accordingly the problem of chemotherapy by arsenic may be redefined as that of attacking the pyruvate oxidase system in the micro-organism without poisoning this in the host. The degradation of pyruvate is a stage in intermediary metabolism which is particularly sensitive to pharmacological disturbance; there are strong grounds for the belief that it is reversibly inhibited in

¹When a greater concentration of the arsenical is present, more enzymes may also be involved even those capable of being reactivated by monothiois.

kerateine at physiological pH, the powerful SH reaction given initially is practically abolished; the amount of arsenic taken up was limited and definite for a given sample and not increased even on adding a large excess (see fig. 6). The uptake of arsenic was enormously reduced if the SH group was converted to SS by oxidation. The lewisite-kerateine compound was surprisingly stable, both to dialysis and to reprecipitation. The next point made was the crucial observation. When the number of SH groups disappearing was compared with the amount of arsenic combining, the surprising fact emerged that more SH groups were disappearing than atoms of As combined. From this followed the inference that the As was combining in a ring form (to the extent of some 75%). At once this resolved the dilemma, and showed how the arsenic might be at the same time combining with the SH groups in the enzyme, and yet be forming a more stable compound than the ordinary thioarsinites formed with monothiol, because a ring formation is usually considered to be more stable by organic chemists. The theory emerging which we call Stocken and Thompson's dithiol theory may now be given precise form in this figure (fig. 7), in which has also been included the 2:3-dimercaptopropanol, known as BAL; the idea is that lewisite formed with the protein in the enzyme a ring compound, of unknown ring size¹; the compound so formed though slightly dissociable is much more stable than any thioarsinite formed with a monothiol;

FIG. 7.

FIG. 8.

FIG. 7.—Dithiol theory.

FIG. 8.—Brain brei preparation (pigeon) poisoned by sufficient lewisite oxide to produce approximately 50% decrease in respiration. BAL added at the points indicated after fifteen to forty-five minutes of respiration. Substrate—pyruvate. (Data of Stocken and Thompson.) Reproduced by permission of the *British Medical Bulletin*.

hence any monothiol compounds formed will gradually transfer their arsenic to the ring. If any compound is placed in contact with the lewisite which forms a still more stable ring, there should be a steady transfer of the lewisite from the protein to the most stable state. BAL is such a compound forming a 5 ring; it was the third compound to be tried and was a new compound made by Stocken for this purpose. Oddly enough, it is still the least toxic of its class of skin penetrant dithiols, even though a large number of other dithiol compounds have been made here, in the U.S. and in Canada.

When tried on the pyruvate oxidase system, it was found that a series of dithiols including BAL would protect the enzyme against lewisite, when added at the same time, whereas monothioethyleneglycol (SH.CH₂.CH₂.OH) was quite ineffective. Fig. 8 shows an even more important point, that BAL will produce reversal *in vitro* of a 50% poisoning of the enzyme system when this is already established. Poisoning is complete in less than ten minutes with lewisite. Restoration with BAL is rather slow, suggesting that the respective stabilities of the ring compounds of protein and of BAL are not far removed in stability. If the interval is too long there is irreversible change. I have already shown the effects upon human skin; it has been also proved that the arsenic is removed from skin by treatment with the antidote and excreted in the urine [47].

This practical proof of antidote action *in vivo*, together with the theoretical background, removed any doubts about the nature of the grouping attacked in the enzyme system.

¹It has been deduced (Whittaker, 1947) that the stability of the ring formed with the enzyme-protein lies between "those of eight- and fourteen-membered thioarsinite rings".

vulnerable. If, as we believe now, it really is the pyruvate-tricarboxylic cycle, a large number of enzymes have to function in an orderly manner to fulfil this final stage in metabolism; the poisoning of any one part must damage the whole; since individual enzymes involved will have differing sensitivities to different poisons, compounds of widely differing constitution will produce the same biochemical result. A possible explanation is reached for one fact that puzzled us during the arsenic work; the total oxidase system was much more sensitive to the arsenicals than the pyruvate dehydrogenase component, which is responsible for the initial step. As both the pyruvate dehydrogenase and the α ketoglutarate dehydrogenase are sensitive to arsenic (and it may be other enzymes too), it would follow that the total system would be more easily poisoned. Pyruvate is not the only substance which is oxidized through the tricarboxylic cycle; the oxidation of fat is now believed to go this way after conversion to a 2 carbon fragment (Lehninger (29)).

FIG. 10.—Dialysed brain dispersion (pigeon). The diagram shows in μ moles per respirometer bottle, the course of the oxygen uptake — ·····, pyruvate disappearance —, formation of citrate — (mainly α ketoglutarate), during a thirty-minute experiment with a dialysed brain dispersion (Banga *et al.*) at 38° C. In addition to pyruvate (0.013 M) fumarate (0.012 M), phosphate, Mg. ion, and adenine nucleotide were present. Appreciable amounts of citrate were formed in the preliminary period of incubation before readings of oxygen uptake were commenced. (Coxon, Liébecq and Peters—unpublished experiment.)

ACTION OF FLUOROACETATE

Following the theme which has run as a thread through this lecture, we should imagine that there will be other ways of producing a biochemical lesion in the tricarboxylic cycle, which would be equally damaging and equally able to initiate such processes as vesication. In this connexion, I will finish by mentioning the poison sodium fluoroacetate. The fluoroacetates came into prominence recently, and much work was done in England and in the U.S.A. Sodium fluoroacetate (as well as the acid) was first made in Ghent by the chemist Swarts (1896) and the sodium salt is now used as a rat poison. This table of toxicities (Table II) was compiled by Chenoweth and Gilman (1946) for methyl fluoroacetate. It is to

narcosis (Quastel [43]), and that it is much involved in oxygen poisoning (Mann and Quastel [32]; Dickens [13]).

Further definition of the pyruvate oxidase system.—Let us now examine some possible reasons for this sensitivity, which lead to a more useful generalization. I have mentioned already one relevant point; the system in brain was proved nine years ago to consist of a battery of enzymes, fumarate being an essential catalyst. For some time there have been two possible biochemical explanations for the necessity of fumarate: (1) that of Szent-Györgyi that it had a special catalytic action in the H transfer, or (2) that it is essential for the oxidation of pyruvate by some cyclical process. The most modern and interesting form of such a cyclical process is that proposed by Krebs [28], which combines features of earlier schemes by Toennisen and Brinkman, Szent-Györgyi and Knoop and Martius into a unity known as the tricarboxylic acid cycle (fig. 9).

The essential feature of this scheme is that a 2 carbon fragment formed by oxidative decarboxylation of pyruvic acid condenses with a 4 C dicarboxylic acid formed from fumarate. So there is formed a 6 carbon acid *cis*-aconitic acid (containing three carboxylic groups in the citric acid series). By a successive series of transformations this becomes 5 carbon and 4 carbon and so the process starts again; in one round of the cycle there is degradation of one molecule of pyruvate to CO_2 and H_2O . This scheme is very attractive because it explains successfully not only the method of degradation, but also the biological reason for the presence in most tissues of such a strange group of enzymes in such high activity. Krebs and his colleagues have worked out the scheme for muscle, kidney and liver, and there has been much modern experimental evidence in its favour. For reasons which I

FIG. 9.—The diagram represents the reactions of the tricarboxylic acid cycle, in which a 2 C fragment formed from pyruvate is condensed with oxaloacetate to form a 6 C tricarboxylic acid (3 COOH groups). This is then degraded to acids with 4 carbon atoms. CO_2 is split off at various points of the cycle, and also H_2 , which is taken up by the cytochrome system. During one round of the cycle, one molecule of pyruvate is degraded to CO_2 and H_2O with uptake of 5 atoms of oxygen. (After T. Mann.)

cannot enter into here, until very recently we were not able to satisfy ourselves that it applied to brain tissue. However, during the last few weeks, Liébecq, Coxon and myself have succeeded in removing some of the major objections, which existed before, and now I feel no reason to doubt that the tricarboxylic cycle in some form applies to the brain preparations which we have used. In extension of our previous work [4] Long [30] had been able to show that in presence and absence of fumarate, the same amount of pyruvate disappeared; but that when fumarate was present the pyruvate was more completely oxidized. We have now found that when fumarate is present with the pyruvate, there is an accumulation of citric acid as well as of some α ketoglutarate. Citric acid is not directly on the path of the cycle, but is in equilibrium with the other 6 C acids (fig. 10). These facts are best explained by the Krebs idea that there must be condensation with oxaloacetate, and that the compound produced goes round the cycle. The acceptance of this view will mean some reinterpretation of the published facts; meanwhile we see at once why the pyruvate oxidase system is so

induce a metabolic block. This hypothesis is consistent with both the oxidation evidence of Saunders and with the competition theory of Guzman Barron.

If fluoroacetate enters the cycle, why does it not interfere with the tissue respiration *in vitro* of the pyruvate oxidase system in brain? This can be explained speculatively as due to the fact that our brain preparations are unable to oxidize either acetate or citrate; they lack therefore the factor which will bring fluoroacetate into play with the cycle, and already have a partial block at the citrate stage. *In vivo*, presumably these factors must be present, but again this must be a subject for further research.

As it is our general view that fluoroacetate has a poisoning effect upon the reactions in the tricarboxylic cycle, it would be expected to have vesicant effects; it is therefore interesting that Bacq, with Goffart and Angenot [1], classes fluoroacetic acid among the "vesicants".

The pyruvate oxidase system has turned out to be even more complex than was imagined in my original statement that it was a battery of enzymes; at the same time it is also more of a biological unity, and it is this which is susceptible to pharmacological attack. In seeking the connexions between enzyme biochemistry and pharmacology, we shall be well advised to look among the organized enzyme systems rather than to highly purified single enzymes. In the course of this discussion it is surprising how near we have come to the statements of W. E. Dixon which I quoted at the start of this lecture.

Though the search for these enzyme "biochemical lesions" is not yet far advanced, I hope that enough has been said to indicate that it is a fruitful field for medicine as well as for pharmacology. Clearly there must be many other ways in which the balance of these reactions might be upset and so initiate a diseased state. It is well known to workers in this field that short periods of anaerobiosis may prove extremely dangerous to the subsequent activity of the enzymes; for instance the pyruvate oxidase system loses activity quickly in the absence of oxygen. Any disturbance of circulation *in vivo* may be potentially dangerous, as oxygen supplies are cut off. The real miracle is that these closely dovetailed reactions do not more often fail.

Before concluding, there are some general remarks which should be made by way of appendix. In dealing with the poisoning of cell enzymes, I hope that I shall not be thought to be unaware of the dominating importance of permeability and of physicochemical effects in many pharmacological actions. In the case of the arsenicals, it has been suggested from Hawking's experiments [25] that the puzzling acquired tolerance of some protozoa is due to an altered permeability to the particular compound. I have focused attention here on pharmacological actions upon the oxidation of pyruvate and upon the association of this with the tricarboxylic cycle because this leads to one simple generalization. It is natural to wonder why no attention has been given to the possibility of blocking the earlier metabolic reactions by which sugar and glycogen are transformed into the 3 carbon intermediate. Surely the sudden elimination of the source of energy at its origin must be dangerous, especially in a tissue primarily using sugar. Such actions have been already studied by biochemists; Dixon and Needham [14] and colleagues found that most vesicants attack hexokinase, and upon this based a theory of vesicant action. Hexokinase is the factor concerned in the first activation of glucose. Though inapplicable to lewisite because hexokinase poisoning can be reversed with a monothiol, the theory is nevertheless of much interest; and this effect may contribute to the total vesicant action in many cases.¹

As we have seen, our early feeling that effects upon -SH groups were implicated in the action of war gas substances has now been made concrete for the trivalent arsenicals as well as for mustard gas sulphone; G. Barron (with Singer) has even gone so far as to suggest that arsenicals are the prime agents for the detection of sulphhydryl groups in enzymes. How far is this attack general? In the last years M. Dixon and colleagues concluded that lacrimators (such as ethylchloroacetate) were specific inhibitors of these groups in SH enzymes, and, as a result of independent researches in Belgium during the war, Bacq [2] has advanced the generalization that the "war toxics" are "substances thioloпрives", eliminating essential SH groups either by combination or by oxidation. A good example of the terrific pathological damage produced in this way is that of sodium tetrathionate (oxidized sodium thiosulphate); this rapidly induces a severe kidney nephritis, almost certainly due to oxidation of SH [21, 23]. The "thioloпрives" classification is certainly useful, even though it does not apply to mustard gas or to fluoroacetate. I think it might be extended; substances producing biochemical lesions in the "cycle" might be also called "cyclotoxic" substances.

Any conclusions reached in the present state of knowledge must be, in some sense, provisional and can be only regarded as stepping stones to further work. It has taken

¹Recently, it has been found that adrenochrome also inhibits this stage [34].

be noticed that there is a rather wide variation in toxicity to different animals, and that there are two types of action, nervous and cardiac. In the rabbit for instance the signs are mainly cardiac, leading to fibrillation; in the dog, on the other hand, the nervous signs predominate and doses as small as 50 $\mu\text{g.}/\text{kilo}$ kill the animals with violent convulsions after an interval of two hours or so in which little is noticed. In the rat, nervous signs appear in one to two hours; if the animal survives, it usually dies with intense weakness in some twenty-four hours.

This toxicity is very remarkable because it is such a simple molecule, and differs little from that of sodium acetate; Swarts showed that the -C.F. bond is very stable. The action is therefore not due to liberation of inorganic fluoride and is quite different from that of iodoacetate; there is no reaction with an SH group. The Cambridge teams (McCombie and Saunders [31], with that of Adrian) have worked out that the toxicity resides in the $\text{F.CH}_2\text{CO-}$ grouping. Following the lines of Knoop's oxidation theory for fats, in a series of straight chain compounds containing an increasing number of C atoms, Saunders [44] and colleagues have found that those with an even number of C atoms were toxic and those containing an odd number are not so. It seems to be inconceivable that this simple fluoro-compound can produce permeability changes and likely that it intervenes in an enzyme system. Initial attempts in 1943 by several of us in this country were unsuccessful in finding any enzyme inhibited by fluoroacetate; indeed (with Wakelin) I could find no effect at all upon the oxidation of pyruvate in brain tissue. There is not yet any known case in which fluoroacetate inhibits a single isolated enzyme. Guzman Barron and colleagues [6], however, took up the acetate analogy and found that in several more organized tissue preparations (slices), there was a competition with acetate; addition of fluoroacetate to the preparations led to accumulations of acetate. They therefore proposed that the compound was a competitor for acetate, and that it prevented oxidation of this via the tricarboxylic cycle. On the whole the amounts used by the U.S. workers to produce *in vitro* action were considerably larger than the doses giving *in vivo* toxicity. Liébecq and myself decided to use fluoroacetate some eight months ago in the hope of shedding light upon the nature of the 2 carbon fragment involved in pyruvate oxidation. We have found some interesting new facts, which I thought that you would like to hear. Most of our work has been done with a finely ground preparation of guinea-pig kidney, using a very pure sample of sodium fluoroacetate, kindly presented to us by Dr. B. C. Saunders. We soon found that the poison is involved in enzyme reactions in the tricarboxylic cycle other than those of acetate. Unlike brain, our kidney preparations oxidize fumarate well and pyruvate badly. Fluoroacetate inhibits fumarate oxidation with accumulation of citrate (Table III); citric acid is normally well oxidized. Hence fluoro-

TABLE III
Kidney homogenate
(Guinea-pig) (0-120')

Substrate	$\text{O}_2\mu\text{l}$	Acetic acid	Citric acid
Nil	0	—	—
Fumarate	462	0.1	0.18
Fumarate + Fl.Ac. ..	275 (-40%)	0.1	0.365
Pyr. fum.	545	0.05	0.60
Pyr. fum. + Fl.Ac. ..	461 (-15%)	0.15	1.00

(Fl.acetate 0.0033M)

(Liébecq and Peters—unpublished.)

Table III shows per respirometer bottle the uptake of oxygen in μl and the formation of acetic acid and citric acids (mg.) by a guinea-pig kidney homogenate in two hours at 38°C., and suitable phosphate medium containing the substrates mentioned. The differences in the amounts of acetic acid are not significant owing to the experimental error. Addition of fluoroacetate causes increased accumulation of citrate.

acetate also intervenes in the actual reactions of the cycle. Furthermore under appropriate circumstances, we have found a toxic effect *in vitro* with amounts of the order of those acting *in vivo*.

This has led us to a somewhat different conception of the action of this interesting inhibitor. In agreement with the findings of Barron and his colleagues, it will compete with acetate as a 2 carbon fragment entering the tri-cycle; but it has the further effect that it will block the cyclical reactions by intervening at some stage between citric acid and oxaloacetate; this we believe to be the more important action. One possible way in which the block may be produced is by actual synthesis of fluoro *cis*-aconitate, which we are now investigating. If further work substantiates this hypothesis, it will be a first example (perhaps) of the building in of such a fragment by intermediary metabolic reactions to

Recent Progress in Nasal Physiology

By ARTHUR W. PROETZ, Saint Louis, U.S.A.

At first thought I had intended to pick up the thread where I had left it in a presentation before this Society in 1938 (*Proc. R. Soc. Med.*, 31, 1405) and to bring it up to date by reviewing the literature of the decade. It quickly appeared that such a report would be misleading since progress during this time has, in some phases, rested much more upon older investigations than upon current ones. A few titles of articles appearing since 1938 have been appended. From these it will be seen that research on nasal physiology is still restricted and, as usual, highly specialized.

Before our day, interest was sometimes concentrated upon special investigations such as Braune and Clasen's work on nasal air pressures (1876) and Zwaardemaker's practical treatise on the physiology of smell (1895), but all this seemed fairly remote from clinical rhinology and very little effort was made to bring it closer. Probably the germ from which sprang our present interest was an article written by an Englishman in 1924: "Methods of Estimating the Activity of the Ciliated Epithelium Within the Sinuses", by A. Lowndes Yates. It somehow fired the imagination of investigators in this country and in America and led to a recrudescence of interest in the whole subject of nasal physiology. Co-ordination followed and finally the more systematic application of physiological principles to a none too satisfactory therapy.

It has been reiterated in the textbooks, in a detached way, that the nose moistened and heated the air for the lungs and that it was coated with a ciliated columnar epithelium. In practice, however, physiological processes were treated as something academic, which could be disregarded when the problem was one of eradicating infection. Emphasis was laid upon the "vestigial" character of the nasal structures. Since their importance in maintaining nasal health was not understood it cannot be said that they were wilfully disregarded but the unsatisfactory results of radical extirpation finally forced us to examine them more closely.

To-day we have learned to conserve tissues and functions wherever possible.

Whenever this question of conservation is introduced someone invariably cites cases in which conservation would be folly. I also have such cases. However, these are the exception and we have found it practical to suit our procedures to the requirements and not invariably to go the limit on the mere basis of supposed thoroughness.

Among the trends of the past decade the appreciation of ciliary activity in the nose and especially in the accessory sinuses undoubtedly is first in importance. Cilia are primitive structures surviving anything which does not destroy epithelium. They are powerful in their effect and they behave in an orderly manner. They are our best allies in the prevention and removal of infection and they cannot be indiscriminately done away with if nasal health is to be maintained. The fact that in the average adult nose there are areas of altered mucosa without cilia—and this without producing untoward symptoms—may have led us to underestimate them. Patches of pseudo-squamous epithelium result where the air can strike directly and for this reason they are either dry or accessible to blowing. But in the meatuses about the ostia, and certainly in the sinuses where this is impossible, cilia persist and it is desirable to maintain the continuity of streaming from sinus to ostium, to meatus, to nasopharynx

many years to reach our present limited conceptions of the pyruvate oxidase system. For those who feel impatient at the slow rate of progress in research, I can quote the text which hangs in the Hall of our Laboratory, and which we owe to the suggestion of the late Archibald E. Garrod, who was himself so much interested in the genetically induced abnormalities of enzymes leading to inborn errors of metabolism:

"For at the first 'wisdom' will walk with him by crooked ways, and bring fear and dread upon him, and torment him with her discipline, until she may trust his soul, and try him by her laws. Then will she return the straight way unto him, and comfort him, and show him her secrets."

Entering a sinus surgically by enlarging its ostium is comparable to these experiments. It results in a denuded strip of injured bone and the tissue which forms in Nature's attempt to close the opening resembles the experimental fibrous septum and not the normal ostium.

Drainage artificially maintained by displacement over a period of time is preferable to instrumentation of any kind, since it maintains the continuity of ciliary activity.

In 1943 Hilding made a significant contribution to the controversial subject of negative pressure in the sinuses and more especially of its origin [5]. He introduced a needle into each of the frontal sinuses of a dog through the skull and connected them through tubes with separate manometers. A quantity of mucus was injected through another needle into one sinus, the other being used as a control. As the mucus was forced out through the ostium by the cilia the pressure began to fall in the manometer of that side, the other remaining stationary. The experiment was then repeated after killing the dog, to rule out possible air absorption. The results were the same except that the negative pressure was slightly less than in the living animal. The published graphs show a drop of 44 mm. of water in fifteen minutes in the dead animal. This is a negative pressure comparable to that produced by a violent sniff (50 mm. Braune and Clasen).

Ciliary streaming within a sinus does not approach the ostium in a haphazard pattern but assumes a roughly vortical character, the direction of whorl being opposite on the two sides [6]. This is of interest in view of a similar observation regarding the trachea and bronchi by Barclay, Franklin and Macbeth (1937, *J. Physiol.*, 90, 347).

It has been observed that stimulation of the intact vagus in dogs causes a vigorous constriction in the nose with a drop in nasal air pressures without affecting the general circulation as evidenced by the femoral blood-pressure [8]. Injection of histamine into the circulation causes a dilatation of the nasal vessels, but the effect in this case is general although there seems to be a certain specificity for the nasal vessels. Sympathetic activity is said to predominate following exposure to cold.

The absorptive capacity of the nasal mucosa is variable [10]. Any increase in blood and lymph circulation whether produced by physical or pathological agents increases absorption. The ease with which absorbable drugs are taken up by the sinus mucosa after displacement depends upon the viscosity. The absorption is apparently somewhat selective.

Protracted exposure to toxins of infection stops the activity first of mucous and then of serous glands [1].

The subject of lysozyme in the nasal secretions still appears sporadically in the literature. It is reported [13] that the lysis of test bacteria by nasal mucus is inhibited by acid concentrations which may be present "in the usual pH swings". In acid media adsorption takes place but no lysis. Change to a neutral reaction completes the cycle, but the bacteria may already have been killed by the adsorption, without being dissolved. The same author states that lysozyme disappears on the first or second day of a cold, and that there is none to be found in a "running nose". Secretions from hay-fever sufferers showed a high lysozyme content.

Some controversy still exists regarding the normal pH of the nasal mucosa. It seems likely that the figure closely approximates 7 under varying conditions and that the disparity in findings of various investigators is due to technical errors and the shifting reactions of the secretions on the surface [16, 17].

It has been shown clinically that deficiency of the thyroid hormone may result in changes in the nasal mucosa which can be recognized [25]. These changes may be either exfoliative in nature or resemble the pale, boggy manifestations of allergy. Patients deficient in the thyroid hormone commonly have an increased tendency to nasal infection which can be corrected by the administration of thyroid extract alone. Similarly, allergic individuals are less apt to exhibit nasal symptoms under an adequate thyroid supply.

as well as may be. Wherever disease or surgery results in a strip of non-ciliated epithelium in the path of the streaming there is a stasis of the mucus and conditions favourable to bacterial growth are set up. This is not always apparent on inspection for the normal mucus blanket is of microscopic thinness. The mucus is of such nature and of such minute quantity that unless it is augmented by exudates and the degenerative products of inflammation it cannot be seen. With a microscope and by other special means it can be demonstrated and in proportion to the size of the bacterial elements picked up it is completely adequate.

We were taught a generation ago, and with seeming logic, that removing a middle turbinate did not reduce the moistening surface of the nose so very much and that it could be sacrificed in the interests of drainage with relative impunity. To a great extent this is true owing to a circumstance not considered at the time, namely, that the middle turbinates are streamlined to the passing air currents. Thus, although the moistening surface is reduced, there is little interference with the distribution of inspired air. Minor changes of another type may be followed by distressing consequences. This occurs when the air stream is so obstructed or deviated as to project it in a concentrated jet against some restricted area or to deflect it away from some part of the nose, leaving an area unventilated.

As long ago as 1830 Bell described the constriction which exists approximately one centimetre proximal to the naris. Only recently was it pointed out that this constriction projected the initial air stream vertically, setting the pattern for its even distribution through the nose and being largely responsible for the prevention of local dry spots. Thus our predecessors, regarding the removal of nasal tissue wholly from the standpoint of its moistening function alone, did not hesitate to remove it extensively. We think of it now as upsetting the even distribution of air with its attendant mucus stasis and nasal infection.

We know also that the total moisture reaching the lung is not too dependent upon the retention of the nasal structures. It has been shown that breathing through the mouth supplies practically the same humidity at the glottis as breathing through the nose, with the important difference that the mouth soon dries while the nasal mucosa continues to supply moisture. There is one mechanical circumstance, however, which is commonly overlooked, namely, that the air channels are not a tube at all and certainly not a chamber but a series of extremely narrow slits by which arrangement all the inspired air is brought into intimate contact with the nasal surfaces. If we alter this condition the mechanics of nasal respiration are greatly upset.

That the nose is a filter has been known as long as anyone has paid attention to such things. "The nares", writes Cicero, "which are always open on account of necessary functions have narrower entrances lest anything which might be injurious should enter them, and they always are supplied with a moisture not useless for arresting dust and many other things." We know that this takes place through sifting, through impingement and through adsorption. It is axiomatic that a filter must be rid of the residue which accumulates upon it if it is to continue to function. This the nose does very well by means of the cilia and their mucus blanket. So long as these remain intact, infection cannot occur, largely for the reason that at the normal rate of progress bacteria which fall on the surface are carried past any given cell in something less than 1/10th second, a time too short for incubation and penetration [12]. What the effect of viruses may be in disrupting this system is as yet not clear.

Nevertheless we are confronted with the fact that all infectious ailments of the nose stem somehow from a single source, namely, the failure of the filter to cleanse itself. That this cleansing mechanism should have first consideration in every plan of treatment and surgery is only an extension of the old principle of maintaining drainage.

It has been shown experimentally that removing strips of mucosa within the sinus is not always followed by complete regeneration and results sometimes in fibrous septa, their extent depending in a general way on the width of the strip removed.

Gösta Dohlman (Lund, Sweden) asked whether the experiments with soluble dye were made on the living animal or on the preparation. He had put fluorescent particles in the nose and had not been able to observe that these soluble particles dyed the mucous membrane. This could be seen under ultra-violet light. He used fluorescent solution, which was carried away with the mucous blanket. He had tried to observe the same thing with pollen in hay fever, but he had not been able to trace what happened to the pollen. He wondered whether Dr. Proetz, working on these lines, had thought of the mechanism of action of the pollen as comparable with a soluble dye or a virus. Or was there some activity in the pollen particles themselves? Was there something in the action of the pollen, working itself down to the cell, which was likely to cause the allergic reaction or could the activity be compared with that of a virus or infectious agent in a watery solution?

R. G. Macbeth referred to the spiral movement of particles in the trachea. What did Dr. Proetz think was the explanation of this movement? If the particles did not go up in a spiral a certain number of them would reach the carinae at every bifurcation in the bronchial tree and tend to stick or to fall back again; but, in a spiral movement, there was greater likelihood that they would dodge the carinae and so reach the pharynx.

F. A. Pickworth asked what was the proportion of surface to blood-stream and lymphatic infections of the nasal sinus membrane. Professor Proetz had confined his remarks to surface infection, and the literature was vague on this question, except that it was established that in the specific infectious fevers the sinus membrane is always involved.

A point of interest concerning the cilia was their collective force. Sir Leonard Hill had shown that small brass weights were propelled along an excised strip of mucosa by ciliary activity. In numerous cases of histological sections of pus or mucopus in situ in a nasal sinus taken at autopsies on mental hospital patients, the mass had formed a ball which evidently had been turned round many times, so that there were layers—as indicated by the polymorphonuclear leucocytes—sometimes amounting to twelve or more.

A. W. Proetz, in reply to several questions, said that regeneration of the mucosa did take place in the right milieu. It was necessary to keep the surface as free as possible from the infectious material which accumulated in the viscous secretions. He used the displacement method in order to get the required vasoconstriction in the cells. This, since the solutions were retained for twelve or fifteen hours, got rid of the irritating substances on the surface. The next thing was to get the surroundings as moist as possible, especially during the hours of sleep. It was arranged that the nose should be in as nearly a physiological condition as possible by maintaining normal moisture and heat and keeping it perfectly free. If sticky mucus were left on the surface its presence was always an irritation.

The other thing which he used was a simple solution which he had found very useful—4% alcohol and 4% glycerin in normal saline. It was found a few years ago that the membrane could tolerate about 18% alcohol, so one was within very comfortable limits in using 4%. What he wanted to do was to have something which would stimulate the flow of mucus and then promptly get itself out of the way so that it would not be a constant source of irritation. Therefore they started with 4% alcohol. It stung mildly and then evaporated and disappeared, and the glycerin left behind held the moisture. If the patient were laid down and his head placed back it was slightly painful; he should be allowed to sit up and the solution be put over his turbinates. The action of this solution is the opposite to that of ephedrine. It was used every four hours for two or three days, and the nose was then given a chance to take care of itself. The blood came from small vessels into the mucosa, and he did not see why that should not be the path of the bacteria as well. He illustrated how the converging streams of mucus came along and the appearance of the section layer on layer.

On the question of spirals, he thought the theory of the Archimedean screw would be all right if the column of air were always upright, but in fact it was horizontal during sleep for eight hours of the night, and, moreover, it varied in different positions, being sometimes more uphill than at others. The drainage of the sphenoid was not entirely uphill; some of it was and some of it was downhill. He had the feeling that this was a developmental matter. In the trachea, considering the adjustment of the whole thing, he imagined that it would be better if the fibres were spiral than if they were longitudinal. He did not know about the accumulation of mucus at the carinae.

Apparently a small amount of injury of the nasal mucosa did not appear to make much difference. Numbers of people had considerable areas in the nose which were devoid of cilia altogether, and they got along just as well as other people. If the mucosa was anything like normal the cilia around the edge of an inactive area could pull the stream along for quite a distance, so that the inactive area did not really signify. There were no cilia in the pre-turbinate area, and yet the cilia at the margin were strong enough to carry the whole mucus right across the surface. If therefore the ciliated area were destroyed here and there it did not seem to make much difference, though if the destruction was at an important spot, of course, there was trouble.

In reply to a question on air circulation in the nose and the nasopharynx, this was checked by taking a section of a specimen head, not too emaciated, and pinching it between two plates of glass, then passing a current of smoke-laden air through the nose and taking motion pictures. It was found that a

The use of the extract and the dosage are best determined by the patient's response, the basal metabolic rate is of secondary importance and at times misleading.

This finding is in line with what is known of the general tissue reactions to deficiencies in the thyroid hormone. The symptoms arising in the nose which respond to thyroid administration, namely, extravasation, changes in the nature of the surface fluids, permeability, malnutrition, swelling and œdema, could logically result from these reactions. Any of them would render the mucosa more susceptible to infection and possibly to antigens as well.

This by no means touches upon all the individual observations in nasal physiology during the last ten years but it epitomizes those which are apt to have an influence on our clinical management of nasal disease.

mucosa and be identified in the lymph of the cervical pathway, which shares with lymph elsewhere the fundamental property of collecting extravascular protein and returning it to the blood. The significance of absorption from the nasal mucosa of particles up to the size of egg albumin, and even serum albumin (mol. wt. = c.70,000) need hardly be stressed. Though the actual amount of matter absorbed is not large, substances to which the organism has become hypersensitive can evoke a vigorous response in quite small quantities. Many of the allergic conditions of the nasal mucosa could no doubt be accounted for in some such manner. Bacterial antibodies are usually globulins with a molecular weight of about 180,000, and are too large to pass through the nasal mucosa. Toxins are a good deal smaller, and since a slight amount of toxin can stimulate considerable antibody formation, the introduction of toxin (e.g. diphtheria) into the nose has been used as a means of securing immunity.

Particulate matter such as India ink does not traverse the mucous membrane after nasal instillation, nor do viruses, in a susceptible animal, pass through the nasal mucosa immediately. However, after a period in which they proliferate locally and become established in the mucous membrane, they then enter the cervical pathway and reach the blood in a steady and continuous stream. Working with rabbits, Yoffey and Sullivan (1940, *J. exp. Med.*, 69, 133) showed that vaccinia virus was not merely not prevented from reaching the blood-stream by the filtering action of the cervical lymph node, but that on the contrary lymph nodes form a perfect mechanism for the dissemination of virus. The cytotropic virus particles enter the lymphocytes which are constantly leaving the node, and the lymphocytes thus act as virus carriers which protect the virus while in the blood-stream, and enable it to reach any part of the body.

What is the exact origin of the lymph in the cervical pathway? In part it arises in the usual manner, from the capillary filtrate of the submucous blood-vessels. But it also seems certain that some of the cervical lymph is derived from the cerebrospinal fluid, leaving the skull through the cribriform plate in association with the emerging bundles of the olfactory nerve. It has been generally accepted that if care is taken not to exceed the normal pressure of the cerebrospinal fluid, simple crystalloids injected into the cranial subarachnoid space readily pass through the cribriform plate and reach the nose, while particulate matter on the other hand does not. Statements about particulate matter are difficult to assess unless one knows the size of the particles, an item of information which has been conspicuous in the literature by its absence. Recently Field, Brierley and Yoffey (1948, unpublished), studying sections through the cribriform plate, after injecting into the cranial subarachnoid space at physiological pressures a suspension of India ink whose particles ranged in size from $0.5\ \mu$ to $1.5\ \mu$, found that the ink particles passed freely along the course of the olfactory nerve bundles, both around the bundles, and in their substance, to their termination in the olfactory mucous membrane. Here the sub-epineural spaces containing the ink ended in the immediate vicinity of the submucous lymph vessels. There must therefore normally be a steady flow of cerebrospinal fluid through the cribriform plate into the nasal lymphatics, and possibly also through the nasal mucous membrane to the nasal cavity.

This centripetal flow must be sufficiently vigorous to transport ink particles, but as yet we have no way of measuring it quantitatively. It is interesting to note that in the monkey there is usually a steady spontaneous flow of cervical lymph, whereas in the cat and dog such a flow is exceptional. The occurrence of this spontaneous flow in a microsmatic animal such as the monkey—and presumably man—is possibly due to the increased volume of the brain and cerebrospinal fluid.

If bacteria and viruses behaved as inert ink particles, no infection of the nose would be likely to reach the brain, against the current of cerebrospinal fluid. On the other hand bacteria or viruses which obtained access to the cerebrospinal fluid—e.g. in meningitis—would certainly reach the nasal mucous membrane and the cervical

vertical rush of air was an invariable result; the air then spread out in various forms of eddies. A point which worried him was that he was not sure that the eddies were not to be considered in relation to the distribution of air in the back of the nose. There was a certain fallacy attaching to a model viewed through a glass plate. The septum was not the equivalent of a straight glass plate. His anatomist and he were trying to work out some nasal reconstruction by means of plastic in such a way that they could get a true representation of the nose, but they had to admit that noses, like other parts of the anatomy, varied, and this was a long job, and he did not yet know the answer. Comparative anatomy could be studied to any extent. The functions of the sinuses, for example, differed very greatly. In some lower animals, such as the seal, there were no sinuses. He had an idea that the sinuses might be insulatory in their nature. The giraffe, for instance, had a brain about as big as one's fist, and all the rest was sinuses—an air jacket.

He had no particular experience of the phase of the subject which Dr. Dohlman had developed. He had wanted to make it clear that he was not so much concerned with the infection of the cells and whether they could be stained as he was to try to work out some means by which an invading mechanism could stay in contact with one cell surface long enough to infect. If the substance was soluble it could spread over enough of the surface as it moved along to affect the viscosity of the mucous blanket and so make it ineffective. A slight variation in the mucus content had a great effect on the viscosity. If a soluble substance could bring that viscosity down to a point where the mucous blanket could no longer be pulled over the surface, like a tablecloth over a table, an opening was afforded for infection. This was admittedly theoretical.

As to the nature of the ciliary movement, nobody knew why it took that particular pattern nor what caused it. He had tried ways of getting enough magnification of the cilia to see whether they had any structure that would give an indication as to what made them move. The cilia were difficult to study and to photograph; they were packed closely and were highly refractile. It was like taking a photograph of a plastic hair-brush while the bristles were moving at 10 or 15 cycles a second. Sodium light had been used, also polarization; the stroboscope and the high-speed flash had been employed, but no structure could be seen in the cilium. It was the deduction of Seo (1931, *Jap. J. med. Sc. Tr. III*, Biophys., 2, 47) that the movement was nervous. Various experiments had been made, but the result was hard to evaluate. It might be a chemical stimulation due to potassium secreted at the end of a nerve. The subject was an open one.

The Nasal Mucous Membrane in Relation to the Lymph Stream and Cerebrospinal Fluid

By J. M. YOFFEY

THE nose in mammals possesses a rich submucous lymphatic plexus, which drains finally into the deep cervical duct or jugular lymph trunk. The deep cervical duct descends alongside the internal jugular vein to enter the thoracic duct on the left side, and the right lymph duct on the right. The deep cervical duct passes in most mammals through one large lymph node, but in monkeys and man the single large node is replaced by several smaller ones, strung along the course of the duct to give a characteristic appearance. Submucous lymphatic plexus, collecting vessels, cervical lymph node or nodes, and deep cervical duct together constitute a single functional pathway for the flow of lymph, mainly from the nose, but to a lesser extent from the mouth, pharynx and deep structures of the neck. We have called this the deep cervical pathway.

The deep cervical pathway can be clearly demonstrated as a functioning unit by the nasal instillation of a vital dye, as shown by Yoffey and Drinker (1938, *J. Exp. Med.*, 68, 629). The dye passes through the intact mucous membrane, enters the submucous lymphatics, and passes through the lymph node or nodes and the cervical duct to reach the blood. On subsequent dissection the pathway stands out very sharply—almost diagrammatically—and is deeply coloured by the dye. The more functional aspect of the pathway can best be shown if the cervical duct is first cannulated, and clear lymph obtained, and then dye introduced into the nose. It is only a matter of minutes before dye begins to appear in the cannula in gradually increasing concentration.

Not only dyes, but also proteins of low molecular weight, such as egg albumin with a weight of about 34,000, can readily pass through the living and intact nasal

Menière's Disease

By A. J. WRIGHT, F.R.C.S.

SUMMARY

FROM the results of a clinical and statistical study of 350 cases of Menière's disease the following conclusions may be drawn. Acute disease or surgical operation, particularly dental extractions, seem sometimes to be related to the onset of the complaint. Allergy and true migraine do not frequently coexist. Allergy in general is not an important factor. Long duration of the complaint does not seem to be an adverse factor in prognosis but advanced age does. The surgical treatment of infection in nose, mouth or throat does as a whole improve the prognosis as compared with cases not so treated.

Of such surgical treatment dental extractions are found to produce the most favourable results with tonsillectomy a good second; operations on the nasal sinuses, however, do not seem to improve the prognosis but this may be accounted for by their failure adequately to influence the relevant infection.

DURING the period of fifteen years or so in which I have been interested in Menière's disease I have accumulated clinical records and carried out a follow-up of some 350 private cases.

pathway; and while viruses would find no difficulty in traversing this pathway, for the reasons already noted, bacteria would be held up in the uppermost node or two of the chain. But since bacteria and viruses are not merely inert particles, but can spread by active growth, new possibilities of extension are thereby created as in the possible neurotropic spread of a virus such as that of poliomyelitis.

A. W. Proetz said that it had been noticed clinically in certain patients that they had an irritative process beginning in the nasopharynx and going downwards, so that within thirty-six hours the patient was left without a voice. Was there any evidence from any of these specimens that materials could pass down immediately below the surface in the lymphatics? Clinically there was evidence that it did. It was such a continuous process that one could almost predict when it would reach the larynx and then the trachea.

F. A. Pickworth had done experiments with human material on cerebrospinal fluid pathways using the ferrocyanide technique, and had published a figure (*Z. ges. Neurol. Psychiat.*, 1932, 141, 425) where the dye had passed along the maxillary nerve and had formed a collection in the antrum which contained pus, had a thickened membrane, and local hæmorrhages. The antrum of the other side was normal and the nerve showed no passage of the dye. Professor Yoffey had illustrated the passage of sizable particles along the cerebrospinal pathways to the nasal mucosa in a rabbit suffering from "snuffles"; had he any other evidence of increased cerebrospinal flow into the tissues in diseased conditions affecting the nerve sheaths?

J. M. Yoffey, in reply to several speakers, said that he found difficulty in answering some of the clinical questions. Unless results were checked and rechecked on the experimental animal they could not make a dogmatic statement about pathways of lymphatic spread. In experiments on the main cervical pathway, outlined after nasal instillation of dye, communications with parapharyngeal and paratracheal lymphatics were not infrequently seen, but they were not so well-filled with dye as the main cervical pathway, along which lymph from the nose normally flowed most readily. However, if the main cervical pathway were to be obstructed, these collateral sources of lymph flow, which undoubtedly existed, extended right down to the lower end of the trachea, and could presumably account for some of the clinical observations on the paratracheal spread of infection. The classical method of interstitial injection of lymphatics in the dead animal merely showed injection material spreading in all directions from the site of injection, and gave no idea of the direction taken by lymph in the living functioning pathway.

With regard to the lymphatic vessels of the tonsils, he had nothing further to add to what he had already said, namely that in the experiments described peritonsillar lymph vessels were always evident, but not vessels arising directly from the tonsillar tissue. According to Aschoff's original classification of the lymphatic organs, the tonsils possessed efferent but not afferent lymphatics. If these efferent lymphatics existed in appreciable numbers, the larger peritonsillar lymphatics would represent the collecting vessels into which they drained.

With regard to Dr. Pickworth's question the ferrocyanide technique, unless employed with scrupulous care, was open to the objection that the solution may diffuse quite rapidly through the tissues, even through the substance of bones, and therefore may not be too reliable an indicator of normal fluid pathways. Nevertheless it was highly probable that the sheaths of the other cranial nerves possessed the same properties as those of the olfactory nerves though to a lesser extent. Schwalbe among the earlier workers reported the escape of India ink from the cranium along the nerves of the jugular foramen, and there seemed no reason why, under abnormal conditions, other cranial nerves besides would not also permit the perineural spread of crystalloid or particulate matter. The speaker had no direct evidence of increased cerebrospinal fluid flow into the tissues in diseased conditions affecting the nerve sheaths. However, it seemed highly probable that inflammatory conditions with a fair amount of fluid exudate would be very likely to facilitate this passage.

Menière's Disease

By A. J. WRIGHT, F.R.C.S.

SUMMARY

FROM the results of a clinical and statistical study of 350 cases of Menière's disease the following conclusions may be drawn. Acute disease or surgical operation, particularly dental extractions, seem sometimes to be related to the onset of the complaint. Allergy and true migraine do not frequently coexist. Allergy in general is not an important factor. Long duration of the complaint does not seem to be an adverse factor in prognosis but advanced age does. The surgical treatment of infection in nose, mouth or throat does as a whole improve the prognosis as compared with cases not so treated.

Of such surgical treatment dental extractions are found to produce the most favourable results with tonsillectomy a good second; operations on the nasal sinuses, however, do not seem to improve the prognosis but this may be accounted for by their failure adequately to influence the relevant infection.

DURING the period of fifteen years or so in which I have been interested in Menière's disease I have accumulated clinical records and carried out a follow-up of some 350 private cases.

Nov.—OTOL. AND LARYNG. 1.

This paper gives the results of an analysis of this material in certain particular directions which would seem likely to help in the solution of the problem of the causation of the disease.

The cases studied had been followed up for periods varying from one to ten years with an average of about three years. The investigation has been particularly designed towards arriving at an answer to certain defined questions which might be expected to provide some evidence as to ætiology.

(1) *The reason given by the patient for the onset of the complaint.*—In the very great majority of cases the patient is as mystified as the doctor as to why this distressing disease should have come upon him. Of the 350 cases dealt with in only 30 was any cause suggested. Of these 30, however, I was surprised to discover that in 15, i.e. no less than half, a recent extraction of teeth was blamed for the onset of the complaint.

Causes	Number of cases	Causes	Number of cases
Extraction of teeth	15	Influenza	3
Trauma: Blast of motor horn ..	1	Hysterectomy	1
Head injury	2	Removal of tonsils	1
Syringing ear	1	Severe epistaxis	1
Acute tonsillitis	1	Childbirth	1
Pneumonia	1	Childbirth with eclampsia ..	2

I feel that this curiously high occurrence of dental extraction as an alleged cause can hardly be regarded as coincidental.

(2) *The coexistence of allergic manifestations.*—In the present analysis only 20 cases (6%) gave history suggestive of allergy: Asthma, 3; nasal allergy, 10; skin lesions, 5; angioneurotic œdema, 2.

While I have no control figures as to the occurrence of allergy in the general population the figure of 6% would not seem to be high enough to suggest an ætiological factor of importance.

(3) *Migraine.*—Care is needed in dealing with case-histories since the vertiginous attacks of Menière's disease are quite frequently diagnosed as migraine both by the medical attendant and the patient. From the present series of 350 cases in only 8 (2%) was there a history of attacks of a classical migrainous type. In a number of others migraine was mentioned but on investigation it became obvious that the attacks so named had been, in fact, vertiginous and associated with a labyrinthine lesion.

The figure of 2% for the co-existence of migraine and Menière's disease in the same individual would not seem to me to suggest any close relationship between the two complaints.

(4) *The duration of the disease or age of the patient as factors in prognosis.*—Length of duration of the disease does not appear to be an adverse factor in prognosis. Thus, while the average duration of the complaint when first seen in the cases later shown as cured or improved was five to six years, in the group of those in which no improvement took place the relative figure was five years. It would seem, therefore, that the duration of the disease is not an important factor in prognosis.

Age of the patient.—Some support would seem to be given from an analysis of this material to the view that the age of the patient is an adverse factor. Thus of the cases aged 50 years or less 65% were shown as cured or improved while the comparative figure for those over 50 years of age was 45%.

(5) *The importance, or otherwise, of a focus of infection in the aetiology.*—In 1940¹ I presented to this Section a contribution on this question based on a series of cases in which surgical treatment had been carried out for the removal of such a focus from nose, mouth or throat. The results then given seemed to indicate that such treatment favourably influenced the course of the complaint. On the other hand, the period which had elapsed from the time of operation was relatively short and no control figures were then available.

In my present contribution cases have been followed up, in some cases for as long a period as ten years and in these have been included both those treated on the infective basis and those untreated, so that some comparative figures are available. Cases are grouped in accordance with the surgical treatment adopted and the results are recorded in regard to the symptom of vertigo. In the table "cured" means complete freedom from vertigo, and "improved" means an absence of attacks but with some remaining general unsteadiness.

RESULTS OF SURGICAL TREATMENT OF INFECTION

Form of treatment	Number	Average period of follow up	Cured	Improved	Unaltered	Worse	Cured or improved %
Tonsillectomy	32	3.50 yr.	20	1	8	3	66
Dental extraction	22	3.00 yr.	16	2	3	1	82
Nasal sinus operation	12	2.25 yr.	2	—	7	3	17
Combined operations (more than one of above)	16	3.00 yr.	9	4	2	1	81
Total	82	3.00 yr.	47	7	20	8	66
Untreated cases	30	3.00 yr.	2	4	17	7	20

It will be seen that of the 22 cases of dental extractions 16 were cured as far as vertigo is concerned. Of the 32 cases of tonsillectomy, 20 lost their vertigo, but of the 12 cases in which surgical treatment for nasal sinusitis was employed only 2 lost their vertigo. Thus removal of teeth produced the most favourable results, tonsillectomy came next, with nasal sinusitis little better than an also-ran. Figures for those cases in which more than one operative procedure was employed gave results which compared favourably with those of the nasal sinusitis group, but were not as good as the cases of dental extraction and tonsillectomy.

From consideration of the table it would appear that the disease in untreated cases with few exceptions tends to progress, thus of the 30 such cases in only 2 did the vertigo entirely clear up.

A comparison of all cases treated surgically to eradicate infection in mouth, nose or throat with untreated cases as a control shows a figure of 66% cured or improved in the treated group as compared with 20% in the untreated.

Mr. Terence Cawthorne said that while focal sepsis might possibly play a part in the causation of certain forms of vertigo he did not think that such cases were frequent. One of the aspects of Mr. Wright's paper that he would like to emphasize was the pathology of this condition. It was well known, thanks to the work of Cairns and Hallpike, that the disorder which they now called Menière's disease, and which used to be grouped under the umbrella-like term of "Menière's syndrome" or aural vertigo, had a definitely pathological basis. For this Lindsay and others had suggested the title "hydrops of the labyrinth", as being pathologically descriptive. But there were other forms of aural vertigo which were not infrequently confused with Meni re's disease. Since the original observations of Cairns and Hallpike there had been some twenty or more cases in which the temporal bones had been examined post mortem and the symptoms in all these cases were practically identical,

¹Wright, A. J. (1940) *Proc. R. Soc. Med.*, 33, 459.

This paper gives the results of an analysis of this material in certain particular directions which would seem likely to help in the solution of the problem of the causation of the disease.

The cases studied had been followed up for periods varying from one to ten years with an average of about three years. The investigation has been particularly designed towards arriving at an answer to certain defined questions which might be expected to provide some evidence as to ætiology.

(1) *The reason given by the patient for the onset of the complaint.*—In the very great majority of cases the patient is as mystified as the doctor as to why this distressing disease should have come upon him. Of the 350 cases dealt with in only 30 was any cause suggested. Of these 30, however, I was surprised to discover that in 15, i.e. no less than half, a recent extraction of teeth was blamed for the onset of the complaint.

Causes	Number of cases	Causes	Number of cases
Extraction of teeth	15	Influenza	3
Trauma: Blast of motor horn ..	1	Hysterectomy	1
Head injury	2	Removal of tonsils	1
Syringing ear	1	Severe epistaxis	1
Acute tonsillitis	1	Childbirth	1
Pneumonia	1	Childbirth with eclampsia ..	2

I feel that this curiously high occurrence of dental extraction as an alleged cause can hardly be regarded as coincidental.

(2) *The coexistence of allergic manifestations.*—In the present analysis only 20 cases (6%) gave history suggestive of allergy: Asthma, 3; nasal allergy, 10; skin lesions, 5; angioneurotic œdema, 2.

While I have no control figures as to the occurrence of allergy in the general population the figure of 6% would not seem to be high enough to suggest an ætiological factor of importance.

(3) *Migraine.*—Care is needed in dealing with case-histories since the vertiginous attacks of Menière's disease are quite frequently diagnosed as migraine both by the medical attendant and the patient. From the present series of 350 cases in only 8 (2%) was there a history of attacks of a classical migrainous type. In a number of others migraine was mentioned but on investigation it became obvious that the attacks so named had been, in fact, vertiginous and associated with a labyrinthine lesion.

The figure of 2% for the co-existence of migraine and Menière's disease in the same individual would not seem to me to suggest any close relationship between the two complaints.

(4) *The duration of the disease or age of the patient as factors in prognosis.*—Length of duration of the disease does not appear to be an adverse factor in prognosis. Thus, while the average duration of the complaint when first seen in the cases later shown as cured or improved was five to six years, in the group of those in which no improvement took place the relative figure was five years. It would seem, therefore, that the duration of the disease is not an important factor in prognosis.

Age of the patient.—Some support would seem to be given from an analysis of this material to the view that the age of the patient is an adverse factor. Thus of the cases aged 50 years or less 65% were shown as cured or improved while the comparative figure for those over 50 years of age was 45%.

cerebrospinal fluid could be reduced 50% by severe dehydration, and it seemed rational to think that one could do the same with the endolymph. He had been interested in the matter since 1935, when he heard of Temple Fay's work on the treatment of epilepsy by dehydration, and since then he had used this method in all his Menière cases. It also seemed possible that tea was an ætiological factor, as so many patients admitted that they were heavy tea drinkers, and attacks decreased after giving it up. He thought that tea might be a stimulant to endolymph secretion.

The following also took part in the discussion: Mr. E. J. Gilroy Glass, Mr. W. H. Bradbeer, Mr. R. D. Owen, Mr. J. C. Hogg, Mr. H. V. Forster and Mr. E. D. D. Davis.

Mr. A. J. Wright, in reply, said that Mr. Cawthorne had rather supported the use of the term "hydrops of the labyrinth". He was hoping they would get the name "Menière's" attached to this group. The material in his paper was selected on the basis of cases which, Mr. Cawthorne would agree with him, they were in the habit of calling Menière's disease.

A form of injury which he had encountered on one occasion was in the case of a lady who went for a long drive in the winter with the car window open and within a few hours she presented a typical picture of Menière's disease.

Mr. Davis had questioned whether one could have Menière's disease in which there was deafness and afterwards a return to normal. Occasionally one did find such cases. Out of the whole bulk of hospital and private cases he could recall two or three in which there was a considerable defect in hearing and afterwards a complete return to normal, but this was very exceptional.

There was no reason why any lesion of the labyrinth should not produce a somewhat similar type of clinical picture. Mr. Bradbeer had suggested that these cases arose because the function of the labyrinth had worn out in elderly people. But the point which seemed to him to be against that was the fact that this complaint was quite common in young people.

Mr. Owen had asked about middle-ear disease. That was a question they had discussed before. His own view was that it would obviously seem quite likely that inflammatory diseases in the neighbourhood would make the labyrinth itself more likely to become diseased, but from such studies as he had been able to carry out it did not seem likely that middle-ear disease was a causative factor in these cases. He was interested in the suggestion that sometimes the extraction of the teeth would apparently start the disease. He regarded that as evidence in support of the infective hypothesis.

Dr. Dohlman had mentioned milk as causing allergy; he himself had come across one case in which if the man took pork he got vertiginous attacks.

He suggested as a possible hypothesis for the mechanical explanation of obstructive attacks, alterations in the consistency of the endolymph. One had only to think for a moment of the series of small chambers communicating by extremely narrow passages through which the circulation had to take place, to realize how this might arise.

Mr. Angell James had stressed the suggestion that fundamental interference with resorption was a big factor. Possibly the reason for the attacks was a sudden obstruction in a portion of the labyrinthine circulatory system.

Purulent Pachymeningitis

By Sir HUGH CAIRNS, K.B.E., F.R.C.S., and F. SCHILLER, M.D.

IN this paper we report four years' experience of penicillin in the treatment of purulent pachymeningitis. Formerly the condition was almost always fatal, even after the introduction of sulphonamides: since the advent of penicillin 7 of our 15 cases have recovered, and these results should be greatly bettered now that penicillin is freely available and we are beginning to understand the problems of treatment. We have seen 33 cases of this disease in the last twenty years.

It will be best to begin defining purulent pachymeningitis by describing a typical case from the days before penicillin.

namely deafness, tinnitus, and spasmodic bouts of vertigo lasting a relatively short time. These bouts might occur at isolated intervals or in groups. The deafness had always been of the internal ear variety, and together with toxic deafness following quinine it was the only internal ear deafness which appeared to be reversible—a very important point he thought. Another thing about this deafness was the distortion of hearing which had accompanied it. The characteristic of the deafness in Menière's disease was a dislike of musical sounds or high-pitched sounds. The sufferers disliked music on the wireless, they disliked children's voices, and he had even heard them say that they disliked going to restaurants because of the clatter of knives and forks on plates producing high-pitched sounds. All the cases which he classified as Menière's disease, including two in which Hallpike and he had had the opportunity of examining the temporal bones, had exhibited these characteristics.

It was known that there were a large number of cases of so-called atypical Menière's disease—patients with postural dizziness or who had bouts of vertigo but no deafness, and others who had vertigo which lasted for a day or two and which was accentuated when they turned over in bed. There was this fairly large mixed group which in the past had been collected together under the term "Menière's syndrome", and although it was reasonably certain that the vestibular apparatus was at fault, it was not yet possible to say exactly where the fault lay. He did not think it fair to call them Menière's disease, because the pathological evidence was lacking.

The main difficulty in obtaining such evidence was that these attacks were never fatal and therefore the otologist never got the pathological material. He hoped that any otologist who had a fatal case of aural vertigo would ensure that the temporal bones and brain stem were made available for investigation. He was sure that the key to the better understanding of aural vertigo was more and still more pathological evidence of the underlying causes.

As to the ætiology of Menière's disease he agreed with Mr. Wright that patients with Menière's disease did not suffer more from allergy than did the ordinary run of patients. They had thought in the past that head injury played little or no part in the causation of Menière's disease—here he was talking of Menière's disease or hydrops of the labyrinth, and not of other forms of aural vertigo. But he could recall three cases of what he would describe as typical Menière's disease so far as the symptoms and physical signs were concerned which seemed to be precipitated by a head injury. This was a small number, much too small to permit any conclusion to be drawn and he was just mentioning them because he thought it was worth while making further enquiries into head injury as an ætiological factor.

He had had one interesting case of a patient who presented a typical picture of Menière's disease following an attack of mumps. The only atypical feature about this was that the patient had an almost complete deafness, but since the attack of mumps she had very typical attacks of giddiness lasting half an hour and going away, coming on again some days or weeks later. The similarity between that condition and hydrops of the labyrinth was so striking that he thought it worth mentioning.

On the question of assessing results, while naturally the vertigo was the important thing, he had found that the hearing was a delicate indicator of the state of affairs within the labyrinth. It was surprising how the hearing did fluctuate with the vertigo, and the hearing was something which could be measured much more easily than the vertigo. Admittedly one could do caloric tests, and the test results of vestibular function did vary, though not so quickly and delicately, he found, as the hearing, and he did think that in measuring the success or otherwise of conservative treatment the audiogram was an extraordinarily useful indicator. It had been to him a source of constant interest and, at first, surprise how the hearing in a case which by all tests was one of internal ear deafness, could vary as much as 40 decibels within a day. They had always thought that internal ear deafness was irreversible, but he knew hardly any other form of deafness which was so subject to variation as the internal ear deafness in Menière's disease.

Dr. Gösta Dohlman (Lund, Sweden) considered allergy an important factor and cited the case of a young man with severe attacks of vertigo which were abolished by elimination of milk from the diet.

Mr. J. Angell James said that if a group of cases of aural vertigo were taken they could be placed in two divisions, one in which there was undoubtedly a hydrops of the labyrinth, and the other in which the pathology was uncertain.

The hydrops may be accounted for in two ways, either there may be an increased secretion, or there may be failure of resorption of the endolymph. To his mind the failure of resorption seemed the more probable explanation, and on that possibility Cairns and Hallpike made an interesting point, that in their sections there was a definite fibrosis around the endolymph sac. This seemed an important possibility in preventing the resorption of the endolymph.

With regard to the control of the endolymph pressure it was well known that pressure of the

alterations of head posture, and penicillin does not pass freely between the blood and C.S.F.

In purulent leptomeningitis there are many cells in the C.S.F., and there are neck rigidity and the other signs of meningism. In purulent pachymeningitis there are few cells in the C.S.F. and little or no neck rigidity, unless and until the condition becomes complicated by leptomeningitis; the symptoms are those of a rapidly progressive paralysis of one or both cerebral hemispheres—hemiplegia, homonymous hemianopia, sensory loss in the paralysed limbs and, if the dominant hemisphere is involved, aphasia. Fits may occur in the early stages of this cortical paralysis. The temperature is usually higher than in leptomeningitis, probably because of the absorptive properties of the subdural space.

CAUSE

Purulent pachymeningitis is usually secondary to spreading osteomyelitis of the skull which is an unhappy sequel in some cases of pansinusitis. In our 33 cases the primary infection was in the paranasal sinuses in 23 cases, in the petrous bone in 6 cases, while in 4 cases the infection was from a distant focus. According to Turner and Reynolds (1931) the condition arises most commonly in chronic pansinusitis after some operative interference, sometimes no more than simple puncture of the maxillary sinus. As Dan McKenzie (1913) said: "What seems to be an irreproachable operation is followed by progressive osteomyelitis." The condition is clearly an uncommon one, but it has always made a deep impression because of the rapid intracranial spread of the infection and the almost uniformly fatal issue. One of the older otologists, describing the rapid spread of infection after some relatively simple and well-executed operation, said it was like setting fire to shavings.

ASSOCIATED LESIONS

We have described the pathology of this condition elsewhere (Schiller, Russell and Cairns, 1948) and it is only necessary here to mention the lesions which are associated with purulent pachymeningitis.

Spreading osteomyelitis of the skull was present in 26 of our 33 cases—in at least 26 cases for, as Dan McKenzie observed, the osteomyelitis may be overlooked. We have had a case in which at necropsy the skull vault was passed as normal by the pathologist, though at operation we had found beads of pus in the parietal diploe. Now that we have an effective antibiotic for this condition it is even more likely that spreading osteomyelitis will be overlooked unless the skull is repeatedly examined radiologically.

The osteomyelitis usually produces œdema and great venous engorgement of the overlying scalp; at operation the pericranium strips very easily and the exposed bone exudes blood from many points.

Thrombosis of the large dural sinuses or cerebral veins was present in 8 of our 33 cases, but Kubik and Adams (1943) found a higher incidence.

Multiple small cerebral infarcts have been found in some cases at necropsy. Loculated subdural abscess and cerebral abscess have become relatively common since we have been using penicillin and more will be said of these conditions later.

Leptomeningitis was a common sequel before the days of penicillin; also ventriculitis, when needling of the brain for abscess assisted the passage of infection into the ventricles. But these conditions have now become uncommon.

Lung abscess and purulent bronchopneumonia were seen in our series, and in this

This patient was a man of 47 seen by one of us with Mr. F. C. Capps in 1936. He had suffered from chronic pansinusitis for years and had recently developed an infected mucocoele of the frontal sinus with a lump on the forehead. Pressure on the lump produced a discharge of pus from the right nostril. Three months later both antra were drained of foul pus by the nasal route (*Str. hemolyticus* and in small numbers *Staph. aureus*), and drainage of the frontal sinuses was established by removing the anterior ends of the middle turbinate bones and external resection of the inner part of the floor of the right frontal sinus. For nine days the patient did well. Then he developed a spreading osteomyelitis of the facial bones with fever, swelling and abscess formation about the eyes and upper jaw, for which further operations were required. His wounds discharged much pus and he became weak, wasted and anæmic.

He was given sensitized streptococcal vaccine, prontosil and blood transfusions, but the facial osteomyelitis continued and, twelve weeks after its onset, spread to the frontal bone. During the next five weeks the osteomyelitis gradually extended backwards and the patient had headaches, facial pain and slight fever, and he became much more irritable.

Purulent pachymeningitis first showed itself on February 4, 1937, about sixteen weeks after the onset of facial osteomyelitis. The patient noticed a weakness and numbness of the right leg, and twelve hours later slight numbness and difficulty of control of the right hand; he vomited twice, had slight headache and fever (100.4°F.).

On examination there was slight hemiparesis and sensory loss in the right upper and lower limbs, more marked in the lower limb. Eighteen hours after the onset of these symptoms the patient began to show slight dysphasia, and right homonymous hemianopia. On the next day, February 5, he had gross aphasia, almost complete right hemiplegia, weakness and sensory disturbance of the left lower limb, incontinence of urine and fæces.

Operation on this day showed gross osteomyelitis of the skull, extending as far back as the parietal region, with subpericranial pus and extradural granulations. On opening the dura thick pus was found in the subdural space and small amounts could be collected for some time by depressing the brain away from the dura. Films of the pus showed streptococci and cultures yielded *Str. viridans*. The patient grew steadily worse and died on February 9.

In previous studies of intracranial spread of infection from the paranasal sinuses and mastoid little attention has been given to the subdural space. In their admirable work Logan Turner and Reynolds (1931) figure the dura as being in immediate contact with the arachnoid. In fact these membranes are separated from one another by a narrow space which usually contains a very small amount of fluid. This space may be occupied by a film of pus of variable thickness: the pus is not circumscribed in the first instance and may spread over part or whole of one or both cerebral hemispheres. This condition is called purulent pachymeningitis. If the condition is not cured at this stage, and the patient continues to survive, the pus becomes loculated by adhesions between dura and arachnoid to form one or more subdural abscesses. It is necessary at this stage to point out that not all subdural abscesses are secondary to purulent pachymeningitis; some, which are localized from the start, are secondary to necrosis of a patch of dura over the mastoid or frontal sinus, or are secondary to an abscess in the superficial part of the brain. We are not proposing to discuss these types of subdural abscess here.

In the early literature there was some confusion about the situation of subdural pus. Some cases of what was obviously purulent pachymeningitis were described as leptomeningitis. These two conditions, it must be emphasized, are quite distinct. The subdural space is quite distinct from the subarachnoid space; it is a single continuous space over the surface of the brain and spinal cord, except where it is crossed by blood-vessels and nerves, or where arachnoid granulations are embedded in the dura. Air passes readily from one end of the cranial subdural space to the other. Penicillin, as we have shown, passes readily to and fro between the blood-stream and any fluids which may accumulate in the subdural space.

The subarachnoid space, on the other hand, is a channel traversed by numerous fine septa and containing cerebrospinal fluid. Air in it cannot move freely with

alterations of head posture, and penicillin does not pass freely between the blood and C.S.F.

In purulent leptomeningitis there are many cells in the C.S.F., and there are neck rigidity and the other signs of meningism. In purulent pachymeningitis there are few cells in the C.S.F. and little or no neck rigidity, unless and until the condition becomes complicated by leptomeningitis; the symptoms are those of a rapidly progressive paralysis of one or both cerebral hemispheres—hemiplegia, homonymous hemianopia, sensory loss in the paralysed limbs and, if the dominant hemisphere is involved, aphasia. Fits may occur in the early stages of this cortical paralysis. The temperature is usually higher than in leptomeningitis, probably because of the absorptive properties of the subdural space.

CAUSE

Purulent pachymeningitis is usually secondary to spreading osteomyelitis of the skull which is an unhappy sequel in some cases of pansinusitis. In our 33 cases the primary infection was in the paranasal sinuses in 23 cases, in the petrous bone in 6 cases, while in 4 cases the infection was from a distant focus. According to Turner and Reynolds (1931) the condition arises most commonly in chronic pansinusitis after some operative interference, sometimes no more than simple puncture of the maxillary sinus. As Dan McKenzie (1913) said: "What seems to be an irreproachable operation is followed by progressive osteomyelitis." The condition is clearly an uncommon one, but it has always made a deep impression because of the rapid intracranial spread of the infection and the almost uniformly fatal issue. One of the older otologists, describing the rapid spread of infection after some relatively simple and well-executed operation, said it was like setting fire to shavings.

ASSOCIATED LESIONS

We have described the pathology of this condition elsewhere (Schiller, Russell and Cairns, 1948) and it is only necessary here to mention the lesions which are associated with purulent pachymeningitis.

Spreading osteomyelitis of the skull was present in 26 of our 33 cases—in at least 26 cases for, as Dan McKenzie observed, the osteomyelitis may be overlooked. We have had a case in which at necropsy the skull vault was passed as normal by the pathologist, though at operation we had found beads of pus in the parietal diploe. Now that we have an effective antibiotic for this condition it is even more likely that spreading osteomyelitis will be overlooked unless the skull is repeatedly examined radiologically.

The osteomyelitis usually produces cedema and great venous engorgement of the overlying scalp; at operation the pericranium strips very easily and the exposed bone exudes blood from many points.

Thrombosis of the large dural sinuses or cerebral veins was present in 8 of our 33 cases, but Kubik and Adams (1943) found a higher incidence.

Multiple small cerebral infarcts have been found in some cases at necropsy. Loculated subdural abscess and cerebral abscess have become relatively common since we have been using penicillin and more will be said of these conditions later.

Leptomeningitis was a common sequel before the days of penicillin; also ventriculitis, when needling of the brain for abscess assisted the passage of infection into the ventricles. But these conditions have now become uncommon.

Lung abscess and purulent bronchopneumonia were seen in our series, and in this

connexion it must be noted that Williams (1944) of the Mayo Clinic has described a group of cases of pansinusitis accompanied by bronchiectasis. Some of our cases may have had suppurative lung lesions before they ever got subdural infection.

DIAGNOSIS

The multiplicity of intracranial infective lesions which are possible in any one case indicate the difficulties of diagnosis. However, the clinical picture of purulent pachymeningitis is sharply defined and although it bears some resemblance to uncomplicated cerebral thrombophlebitis it should usually be fairly easy to recognize. Cerebral thrombophlebitis as the sole cause of intracranial symptoms in cases of pansinusitis and spreading osteomyelitis must be very rare, if our experience is any guide. In cases of doubt there should be no hesitation in opening the dura to inspect the subdural space; and this can if necessary be done through an infected field—through an extradural abscess, for example—now that the infection can be controlled by penicillin.

BACTERIOLOGY

The predominant causal organisms of our series were streptococci of anaerobic, or viridans, or non-hæmolytic forms (Schiller, Russell and Cairns, 1948). Staphylococcus and B-hæmolytic streptococcus were rare: although the pus from the sinuses usually contained these organisms, the pus from the skull vault and from the subdural space usually contained streptococci of the non-B-hæmolytic groups. These organisms may be difficult to culture, and their bacteriological classification is still very ill-defined. They are for the most part sensitive to penicillin: all the cases which we have treated *adequately* with penicillin have given a good clinical response, and in 3 of 4 cases where the *in vitro* sensitivity was tested the organism was completely inhibited by 0.04 unit/c.c. penicillin or less. However, in one other case the organism was completely insensitive *in vitro* at the usual dilutions; there was some inhibition by 20 U/c.c. but none by 5 U/c.c. The *in vivo* sensitivity of the organism to penicillin could not be tested, owing to shortage of penicillin.

The occurrence of such relatively insensitive organisms indicates that in all these cases the sensitivity of the organism to antibiotics should be tested, and that until the results of the tests are available exceptionally large doses of penicillin should be given.

EXPERIENCE SINCE THE INTRODUCTION OF PENICILLIN

Since penicillin became available we have had 15 cases of purulent pachymeningitis. Five were incompletely treated owing to shortage of supplies, and, though the infection was modified, all died. Ten have been adequately treated and all but three have recovered.

The methods of treatment.—Systemic penicillin is given in doses of 100,000 units three-hourly, at least until the *in vitro* sensitivity of the organism has been tested. If the organism is normally sensitive the dose may be halved. As bone infection is notoriously prone to relapse, and as there is considerable risk of localized subdural abscess, systemic penicillin should be continued for at least eight weeks.

It is usually impossible to drain the subdural space. When we tried to do it in the old days the brain plugged the holes in the dura (intracranial pressure is often very high in this disease). We no longer attempt subdural drainage and instead pass one or more rubber catheters into the subdural space through burr-holes. Through each catheter large quantities of dilute penicillin are instilled at frequent intervals—6 c.c. of a solution containing 500 U/c.c., or as much as the subdural space will comfortably hold. Most of this solution is evidently absorbed from the subdural

space, for very little of it drains away through the catheter. The solution destroys bacteria, dilutes the pus, tends to prevent loculation and probably has the effect of producing a very high level of penicillin in the blood-vessels of the overlying skull, for some of the venous return from the subdural space passes through the skull bones.

We have not always succeeded in preventing loculation of the pus with formation of a subdural abscess, especially on the medial surface of the hemisphere, and at present we are not sure whether a catheter should be invariably passed along the medial surface of the hemisphere, and whether penicillin should also be instilled into the subdural space of an apparently healthy cerebral hemisphere. Further experience is required on these points. Our present belief is that the more the subdural space can be irrigated the less the risk of loculation.

Subarachnoid and ventricular penicillin is injected as required whenever leptomeningitis is considerable, or there is risk of ventricular contamination, and in the usual doses (10,000 to 15,000 units once or twice daily).

With systemic penicillin in full doses it seems unlikely that there will be need to remove large areas of skull on account of osteomyelitis. It should rarely be necessary to undertake massive removal of the skull vault in the acute stage, as used to be done. These mutilating and bloody operations are ill-supported by a patient who already has purulent pachymeningitis, and in our experience they rarely remove all the infected bone. In the later stages, however, it is important to remove any focus of sequestration and suppuration which remains, for, quite apart from the discomfort of discharging sinuses, these foci are apt to produce a recrudescence of intracranial infection once penicillin is stopped. It is well to note that osteomyelitis of the skull treated by penicillin produces novel radiological appearances and not every area of osteomyelitic rarefaction requires surgical removal.

VARIETIES OF RESPONSE TO TREATMENT

The methods described have been evolved gradually, and there is reason to hope that future cases will be more successfully treated than the present series. Only 2 of our 10 fully treated cases have run an uncomplicated course under treatment. The remainder have developed a loculated subdural abscess and two of them have also had an intracerebral abscess. Sample cases will now be described.

An uncomplicated case.—A soldier of 28 who had suffered for years from bad dental sepsis developed pansinusitis and bronchopneumonia. After a fortnight his antra were washed out and next day he developed acute spreading osteomyelitis of the skull and purulent pachymeningitis (*Str. viridans*). When he came under our care on the following day he had right hemiplegia and had lost all speech. He was treated with penicillin intramuscularly (2.5 MU) and subdurally (0.15 MU for fourteen days through a catheter) and also had a few subarachnoid injections. The neurological signs disappeared almost completely; the osteomyelitis of the skull also recovered completely with discharge of pus and spicules of bone from the site of one of the burr holes. During convalescence he developed signs of consolidation in his right lung but this also recovered. This patient was treated in April 1943. He was probably the first patient with this disease to be treated with penicillin. In the ensuing five years he has had several focal fits affecting the right limbs, but has been otherwise well and has been in regular work.

Purulent pachymeningitis followed by loculated subdural abscess.—A boy of 11 developed right maxillary sinusitis after toothache in April 1944. In July for the first time he became generally ill and a painful swelling appeared on the right side of his forehead. His maxillary antrum was washed out, and next day he became unconscious and showed right hemiplegia. He was observed to have focal motor attacks on the right side. Burr holes were made and pus was found in the subdural space in the left frontal region; cultures yielded anaerobic streptococci. He was treated with penicillin, as in the previous case, also with sulphadiazine, for at one stage early in the illness he had severe leptomeningitis as well. After preliminary improvement he deteriorated in the fourth week of treatment and a further operation showed a loculated subdural abscess on the medial surface of the left cerebral hemisphere. This was drained. The boy was desperately ill for nearly two weeks, then he made a slow and complete recovery.

Eight months later, as his nose was still discharging, Mr. G. H. Livingstone performed a Caldwell-Luc antrostomy and removed nasal polyp and the anterior part of the middle turbinate bones. Three years later the boy was well and had no residual signs apart from an incomplete right lower homonymous hemianopia.

The onset of loculated subdural abscess may be suspected in these cases when the hemiplegia fails to recover, or when after a slight degree of recovery there is retrogression. The lumbar puncture pressure also rises. The common site for the abscess is between the medial and inferior surfaces of the hemisphere on one side and the falx and tentorium on the other. The pus is found by needling through the intact brain and it can only be distinguished with certainty from an intracerebral abscess or pyocephalus by thorotrast pyography. The characteristic appearance is that the medial and inferior walls of the abscess shadow correspond to the falx and tentorium.

In 2 cases a subdural loculation was not recognized because its development had been masked by continuing penicillin treatment, and the patient subsequently developed a cerebral abscess. We consider it important to establish by means of ventriculography that patients with purulent pachymeningitis have no form of intracranial abscess before their penicillin is stopped and they are allowed to leave hospital.

General management.—These patients may be extremely ill for three to four weeks. Stupor may interfere with swallowing, so that the risk of aspirating fluids into the trachea and bronchi is considerable. For this reason we usually nurse our patients with the head low, by means of low blocks to the foot of the bed; they are usually fed for several days by indwelling stomach tube. Blood transfusions are valuable in the acute stage of the infection. A careful day-to-day clinical assessment and frequent examination of the pressure and cellular content of the lumbar C.S.F. are required in order to detect the onset of subdural loculation and other complications.

The primary focus.—Whenever a primary focus persists after the acute symptoms have subsided we believe that it should be dealt with radically. If possible this operative treatment should be deferred for some months and penicillin should be given systemically for a few days before and after operation.

Prophylaxis.—It seems likely that the incidence of purulent pachymeningitis, uncommon though it may be, could be further reduced with adequate prophylaxis with systemic penicillin, since a considerable proportion of the cases follow operations on the paranasal sinuses and petrous bones. Should penicillin be given before all such operations, or is it possible to foretell the cases in which such complications may arise?

Mr. H. V. Forster desired to say a few words about prophylaxis. He would like members to tell if they had had experience of that rare complication osteomyelitis of the upper maxilla. It might follow quite conservative intranasal operations done to relieve chronic pansinusitis and which would include an intranasal antrostomy beneath the inferior turbinate.

He had seen very few examples of this complication, but the issue was fatal with eventual spread to the meninges, and in spite of post-operative treatment with the sulpha group of drugs in days before the discovery of penicillin. He could not account for the spread of this disease of the bone, except that one had sensed the poor general condition of the patient. One observed its slow advance upwards along the ascending nasal process and across the hard palate.

The surgeon would naturally dread the performance of extensive operations upon the bones of the face, though perhaps hope of recovery had rested with such drastic measures.

Ought we to use systemic penicillin treatment more often before and after operating intranasally on chronic cases of suppurative accessory sinus disease?

He had mentioned this complication in an earlier discussion at one of our meetings (December 5, 1947, see *J. Laryng.*, in press), and had had helpful replies from the opener and from members taking part.

Mr. A. M. Ross asked whether in operations when there was sinus infection the authors could specify whether it was the frontal or the maxillary or ethmoid sinus which was concerned. Was it one particular sinus or all the sinuses?

Mr. F. C. W. Capps said that he was unaware when he came to listen to this paper that the rather tragic case mentioned, and with which he had been intimately concerned, was going to form the basis of the discussion. That case was very fresh in his memory. It was a disastrous affair, and it was made the more disastrous in that the chronic sinusitis and the infected mucocele were found only in the course of a general examination of the upper respiratory tract. The man actually came for trouble in the external auditory meatus, and was persuaded that treatment was needed for the sinus disease.

He had had at least two other cases, one of which fairly recently had had a very happy sequel, thanks to the co-operation of a neurosurgical colleague, Mr. J. E. A. O'Connell. It was a relief to have now this penicillin regime, which could at least avert any trouble in a high proportion of cases. The question was whether in every simple intranasal operation on the antrum or ethmoid or other sinus they were to give prophylactic penicillin. It would seem at first sight an obvious thing to do, but penicillin had its disadvantages as well as its blessings. All those who had had experience of it would be prepared to say that it was a very unpleasant thing to have an allergic reaction in the case of a perhaps essential second course of penicillin after a very thorough first course had been given. Would Dr. Schiller consider it adequate if they waited for the first sign of something going wrong before attacking the case with prophylactic measures? In a high proportion of cases they would still have their penicillin in reserve and it might happen at a later date that it could be given without the unpleasant sequelae which sometimes attended a second course of penicillin.

Dr. Schiller had mentioned cases of thrombophlebitis as somewhat rare. He had certainly had two cases, both of which survived. The earlier was one in which he held his hand very considerably, as was now advised. It was the case of a girl who came in with an obvious orbital swelling, having had a sinus infection, and all that was done was to drain the peri-orbital tissues. She had a severe series of fits and the condition did rather suggest that it was not an ordinary case of meningitis. She recovered satisfactorily. This was before the days of sulphonamide or penicillin. At a later date he removed a deep sequestrum of the inner frontal crest from this patient. She had had a thrombophlebitis of the sinus with a spread of the phlebitis over the cortical area.

Another case was a child who was extremely ill with septicaemia and a hemiplegia. She had had a transient swelling over one eye. In that case he called in his neurological colleague, Dr. D. E. Denny-Brown, who thought it might be a thrombophlebitis and advised exploring widely the frontal area. This was done and a small, narrow, frontal sinus was found with a little bead of pus lying over the sinus. That child made an uninterrupted recovery. Thus of these two cases the one recovered as a result of masterly inactivity and the other as the result of extensive operation. It was to be hoped that these extensive removals in osteomyelitis cases were now at an end.

Mr. R. L. Flett said that he had seen osteomyelitis follow operation on the maxilla, but all the cases he had seen had been associated with polypi in the ethmoids or antra, with thick pus coming from the sinuses; and he thought that any case like that with cellulitis over the frontal bone should have injections of penicillin before surgery was undertaken. In this type of case penicillin was absolutely essential.

Mr. Norman Patterson said that he could recall only one case of osteomyelitis following operation on the frontal sinus, but he could remember three following operations on the antrum. One of these was a case on whom an operation on the other antrum had been done ten years previously without any complication. He was called in to see her because there was a slight swelling over the side of the nose. Large areas of bone were removed. In another case haemorrhage developed after intranasal antrostomy. The patient's nose was packed for about forty-eight hours; he soon afterwards developed osteomyelitis. The third case was one the late Mr. Herbert Tilley asked him to see. All three patients died. The other case following frontal sinus operation recovered after the removal of nearly the whole of the frontal bone.

Mr. E. D. D. Davis was of opinion that in cases where the possibility of osteomyelitis was expected a course of systemic penicillin should be given. If an extensive bone operation was to be done a course of penicillin should be undertaken before as well as after the operation. The earliest possible diagnosis of meningitis is of the greatest importance. Meningitis arising from the ear may be expected in certain cases. Children and young adults are more susceptible to meningitis particularly in cases of otitis media following scarlet fever and measles. The acute streptococcal mastoid of sudden and rapid onset in children was recognized by a profuse discharge of serous fluid from the ear, and when the mastoid was opened, the air cells were full of turbid serum: an osteomyelitis without localization.

Suppuration of the retrofacial mastoid air cells calls for a careful watch for threatened meningitis. A persistent headache with a slight rise of temperature and later vomiting is an indication of meningitis. An early diagnosis of meningitis cannot be made without an examination of the cerebrospinal fluid. Rigidity of the neck is a late sign and on two occasions he had seen a stiff neck resulting from acute adenitis of the glands of the neck. Both cases had been diagnosed as a meningo-encephalitis but they recovered in a few days. He examined the notes of 27 cases of meningitis with rigidity of the neck and only 4 recovered and these 4 were treated by large doses of penicillin and sulphadiazine. He believed the earlier the diagnosis and the more prompt treatment with penicillin and sulphadiazine the better the result.

The Chairman (Mr. Donald Watson), after saying how much the Section appreciated the paper, said that he had seen several cases of osteomyelitis in the frontal sinus cured practically without operation since the advent of penicillin. All the intervention that took place was the simple removal of pus. His own practice—he was thinking particularly of cases of polypi which had an underlying osteitis—was to use penicillin for twenty-four hours before operation and twenty-four hours afterwards. Thus one operated, so to speak, in a bath of penicillin and in that way infection was stayed. It was not necessary to give a long course of penicillin.

Dr. F. Schiller, in reply to the question as to whether it could be told which sinus was involved—the infection related to practically all the sinuses, and it was very difficult to single out one in particular. Certainly antral infection played a great part.

He wondered how important the problem of allergy and acquired resistance to penicillin really was, considering the life-saving properties of the drug.

[May 19, 1948]

DISCUSSION ON RADICAL EXCISION OF CARCINOMA OF THE RECTUM WITH CONSERVATION OF THE SPHINCTERS

Professor G. Grey Turner: In my remarks I only wish to refer to two types of operation which I have practised, though very infrequently, during the last thirty-five years. These operations have unfortunately been designated "conservative", which is often interpreted as meaning restricted in extent of removal, although it was only meant to designate that the sphincteric apparatus is "conserved" and continuity of the bowel restored. In the one plan, intended for growths situated in the lower rectum, the operation is conducted from an extended perineal incision and would be better designated as "posterior cuff resection with preservation of the sphincteric mechanism". The other plan is an upper or anterior trans-abdominal resection with restoration of continuity and similar preservation of the sphincters. This method can only be employed for growths at the pelvirectal junction or in the first part of the rectum. Of course, there are many other types of operation with the same object in view and I profoundly regret that the most untimely and tragically sudden death of my friend, Professor Joseph Sebrechts of Bruges, robs us of the opportunity of hearing from his own lips of the technique and results of the type of operation of which he was such a master. I refer to the plan in which the most complete and careful mobilization of the growth from the abdomen was followed by the separation of the lowest part of the rectum and anal canal from below inside the sphincters, the mobilized bowel with the growth being then drawn down through the dilated anus. The operation was completed by the most careful suture of the divided colon to a fringe of anal mucous membrane preserved for that purpose. I saw Professor Sebrechts carry out this operation in September of 1931 and can give testimony to the sufficient extent of the removal and to the accuracy and painstaking work which was employed. On that occasion I was invited to examine a case in which the operation had been carried out three weeks previously and vividly recall that the sphincter grasped the finger very satisfactorily.

I feel that the only justification for my taking part in this discussion is because I can tell you of the long after-history of a very small series of the lower type of resection which I have closely followed for a quarter of a century.

NATURE OF OPERATION

Before entering into details I do want to say that the operation practised was radical in the comparatively small growths for which it was used in so far that the perirectal tissues with any embedded nodes were completely removed so that the inner surface of the levator was quite bared, the muscular fibres being plainly seen. The length of bowel removed in the posterior cuff resection is an average of about 10 cm. so that there is a sufficiency of free bowel above and below any growth that it is justifiable to deal with by this method. That I dared to try out this plan was because I was accustomed to see patients alive and well without recurrence some years after the comparatively limited perineal removal of those days and as time went on I got more encouragement from my own results. In retrospect I feel that I was justified—now that one can contemplate the really long-term results—as in the case of the patient still alive and well thirty-five years after an extended perineal removal with a sacral anus. In that case the growth was extensive and was adherent to the posterior vaginal wall which had to be partially removed. Another case which made a great impression I referred to in some detail in my Presidential Address to the sub-Section, as it then was, in 1926 (*Proc. R. Soc. Med.*, 1926, 19, Sub-Sect. Proctology, pp. 27-44). Part of the prostate and seminal vesicles had to be removed but the man survived in good health until his death from advancing years twenty-seven years afterwards. These and other similar experiences taught me the extreme importance and the rewards of thorough local removal. Actually my first resection with restoration of sphincteric control was done for what was said to be a gummatous condition which had resisted persistent efforts at cure by traditional means. I am able to show you a lantern slide of the specimen from which you can see that the upper division of the bowel was made well above the level of the bottom of the pouch of Douglas but the result, as regards function, was so entirely satisfactory as to prove a great encouragement.

LONG-TERM AFTER-RESULTS

In 1932 I related my experience of 17 cases of posterior resection with preservation of the sphincters (*Acta Chir. Scand.*, 72, 519) and my excuse for referring to that old material

Mr. E. D. D. Davis was of opinion that in cases where the possibility of osteomyelitis was expected a course of systemic penicillin should be given. If an extensive bone operation was to be done a course of penicillin should be undertaken before as well as after the operation. The earliest possible diagnosis of meningitis is of the greatest importance. Meningitis arising from the ear may be expected in certain cases. Children and young adults are more susceptible to meningitis particularly in cases of otitis media following scarlet fever and measles. The acute streptococcal mastoid of sudden and rapid onset in children was recognized by a profuse discharge of serous fluid from the ear, and when the mastoid was opened, the air cells were full of turbid serum: an osteomyelitis without localization.

Suppuration of the retrofacial mastoid air cells calls for a careful watch for threatened meningitis. A persistent headache with a slight rise of temperature and later vomiting is an indication of meningitis. An early diagnosis of meningitis cannot be made without an examination of the cerebrospinal fluid. Rigidity of the neck is a late sign and on two occasions he had seen a stiff neck resulting from acute adenitis of the glands of the neck. Both cases had been diagnosed as a meningo-encephalitis but they recovered in a few days. He examined the notes of 27 cases of meningitis with rigidity of the neck and only 4 recovered and these 4 were treated by large doses of penicillin and sulphadiazine. He believed the earlier the diagnosis and the more prompt treatment with penicillin and sulphadiazine the better the result.

The Chairman (Mr. Donald Watson), after saying how much the Section appreciated the paper, said that he had seen several cases of osteomyelitis in the frontal sinus cured practically without operation since the advent of penicillin. All the intervention that took place was the simple removal of pus. His own practice—he was thinking particularly of cases of polypi which had an underlying osteitis—was to use penicillin for twenty-four hours before operation and twenty-four hours afterwards. Thus one operated, so to speak, in a bath of penicillin and in that way infection was stayed. It was not necessary to give a long course of penicillin.

Dr. F. Schiller, in reply to the question as to whether it could be told which sinus was involved—the infection related to practically all the sinuses, and it was very difficult to single out one in particular. Certainly antral infection played a great part.

He wondered how important the problem of allergy and acquired resistance to penicillin really was, considering the life-saving properties of the drug.

returned. Now *twenty-two years* after the resection he remains perfectly well and the functional result has always been most satisfactory (fig. 2).

Professor Grey Turner then showed some slides of specimens exhibiting the main features of the growths when freshly removed. All came within the "A" group of Dr. Cuthbert Dukes' classification. The specimens were all columnar-celled carcinoma. In none of the examples was there obtrusive evidence of naked-eye involvement of the lymph nodes.

The speaker then continued: It is my experience of the outcome of this original series of cases which has established for me some faith in the method of resection with preservation of the sphincteric mechanism.

Of the few subsequent cases of posterior resection I only want to refer to the difficult case of a young man of 19 who was brought to me in London because a most competent

FIG. 2.—Patient alive and well 22 years after resection.

surgeon in the North had advised that a very small early lesion should be treated by so radical a removal that the patient at the outset of his career would be faced with a permanent colostomy. This young man when first seen was in excellent condition, his only symptom being constipation followed by diarrhoea and some local discomfort of two months' duration. On first examination "a mass was felt suggesting carcinoma" and on further investigation this proved to be a polypoid growth with a hard base on the anterior wall of the middle of the ampulla. This growth was removed for biopsy purposes and reported as so suspicious as to justify the surgeon in advising the very radical operation proposed. When the patient came before my notice six months later, all that could be detected was a hard indurated area the size of a finger-tip in the situation from which the material for the earlier biopsy had been removed. In taking what was considered a sufficiency for a further biopsy almost the whole of the nodule was removed. Histological examination disclosed the typical and unmistakable histological appearances of a columnar-celled carcinoma. By this time the assurance born of the knowledge of the long-term results in my earlier cases convinced me that a complete cuff resection with restoration would be justified and that was carried out, a portion of rectum about 12 cm. in length being removed. Healing was without infection and bowel function and sphincteric control were satisfactory. Now, seven years after the operation, the patient reports that he is perfectly well and without handicap from his bowel condition.

So that, in my hands, this lower or posterior resection has been encouragingly successful as the long-term records which I have presented exemplify. Incidentally, may I say that the method is valuable for dealing with the occasional example of large non-malignant papillomatous conditions in which the circumference of the bowel is involved (fig. 3). The well-known association of this condition with the development of malignant disease furnishes an adequate reason for the most radical treatment, and by no other plan can the base be really effectually removed while normal function is preserved.

TECHNIQUE

If the method is worth while, what of the technique? Thorough local anæsthetic infiltration may be sufficient to enable one to carry out the resection satisfactorily, but I feel sure it interferes with healing and especially in the presence of even mild infection. I have always employed general or combined anæsthesia as this leaves the surgeon free to discuss without embarrassment any difficulties that may arise during the operation.

is that I can give the full history of all those patients. Of the series 3 were simple and 14 malignant, one being a sarcoma. There was no mortality, no serious sepsis or other immediate complication and no permanent fistula or serious stricture. Of the 14 malignant cases 6 died with recurrence or dissemination within three years, and 1 died suddenly without recurrence two years and ten months after operation; the other 7 either died without recurrence or were alive and well more than five years after operation, all with satisfactory rectal function and control.

I am not proposing to make any apology for those who died with recurrence other than to emphasize that the cases occurred early in my experience and that in retrospect I now know that some were totally unfit for any but the most radical removal. In one case the patient had expressed the greatest horror of any interference which committed her to colostomy and as there was extensive glandular involvement it was considered that the conservative operation would give her as long a period of relief as any other method of excision and with greater comfort in the interval. As a matter of fact the local result was very satisfactory and colostomy was never required; the patient died of abdominal dissemination two years after the operation.

Let me concentrate on the group of those without recurrence; there were 7 cases and in all the functional result was satisfactory. In one of the earliest cases death took place from cardiovascular disease twenty-five years and two months after operation when the patient was in his 81st year. In this man we feared a recurrence eleven and a half years after the resection of the rectum but it turned out that he had developed a constricting carcinoma of the hepatic flexure. This was removed in one stage, bowel continuity being restored and thereafter his condition remained very satisfactory until his final breakdown only a few months before death occurred. In the next case the survival was for fifteen years, when death followed an operation for strangulated hernia. A diabetic in very poor condition at the time of the resection survived in comparative comfort for nine years when gangrene of a lower limb carried him off. Another was 74 at the time of the operation and convalescence was rather slow but she eventually did very well and lived alone in comfort in a distant part of the country, until death took place in her sleep eight years and four months after operation. Bronchitis, to which he had long been subject, carried off the next patient eight years after operation. Of the two surviving patients one, a female, is alive and well *twenty-six years* after the resection (fig. 1). A most competent surgeon had declared that only

FIG. 1.—Patient alive and well 26 years after resection. (From *Acta Chir. Scand.*, 1932, 72, 530.)

a combined radical with a permanent colostomy held out any chance of success, but she knew much of the troubles of a relative who was the victim of colostomy and declared that she would rather die than submit.

The last of the group was a young man of 26 when he first came under my care. At such an early age I considered the prospects of cure after any type of operation, however radical, to be but poor and decided that he might as well have the benefit of continence till his disease

of the rectum must also be kept in mind. When the rectum has been dissected up as high as the conditions demand, it is divided and the upper end is then brought down and is laid in the sphincteric bed and is carefully stitched to the muscle and to the anal margin, the cut sphincter in turn being accurately repaired over the bowel. Though this operation is satisfactory it does not give such good functional results as in those cases in which the bowel can be transversely divided above the level of the sphincter and restored by suture. One difficulty is that the rectum, when brought down to the anus, occupies more space than the anal canal which it replaces, so that the suture of the sphincter is often rather under tension. Further it must be realized that the mucous membrane of the rectum is a poor substitute for the exquisitely sensitive lining of the anal canal.

There have been no serious complications and most of the patients have made quick recoveries, the average stay in hospital being just over six weeks, the shortest being three and the longest seventeen.

In nearly every case whether preliminary colostomy has been used or not there has been some infection of the wound, but it has always been slight and has remained localized and has never given rise to anxiety, and there has been no case of pelvic cellulitis. In most cases the temperature has never been raised during convalescence. In the past a more or less troublesome faecal fistula has been looked upon as the bugbear of this operation but in my series this complication has presented very little difficulty. In the one case in which there was considerable trouble in getting such a fistula to heal in a very fat lethargic man, a temporary colostomy had to be made to aid the process. This raises the question of whether or not colostomy should be carried out as a preliminary. I do not think it is essential, and question if the rectal wound has healed any better when it has been employed. Now I only make a colostomy where there happens to be some obstruction or the patient is in poor condition, and it is necessary to show what colostomy will do to improve it. In some cases I have first explored the abdomen to make sure that there has been no extension of the disease, but generally speaking I have not felt this step to be necessary in the type of case in which a conservative resection may properly be considered.

A complication which is often feared is stricture, but I have not found it to be a serious menace. In my first series of 17 cases there were only 4 examples and all were slight and easily controllable. In one case the condition was allowed to continue for five years because of the reluctance of the patient to have it attended to but at the end of this time it was easily cured by posterior linear proctotomy and the use of bougies.

The results from the point of view of functional capacity are what most concerns and interests both the patient and the surgeon. The most important point is the question of sphincteric control and this has usually been normal, and in all but one case at least entirely adequate. In the one case where the sphincter was incompetent the operation was done for a prolapsing sarcoma and the man had a patulous dilated anus at the time of the operation. As the disease rapidly recurred the sphincters never had a chance to recover their tone.

In operating for cancer the guiding principle must always be to remove the whole of the affected part with a wide area of healthy tissue, and the path of probable malignant invasion. Though this seems to be a too ambitious programme to be carried out by a comparatively limited excision there is probably a stage in all epithelial growths of the lower bowel in which this ought to be possible without the mutilating operations which are so usually required. The problem is to get the cases at an early stage and I have to admit that in my own experience it is only in about 2% of patients submitted to operation that I have considered the so-called conservative method justifiable. I must confess that at one time I was more hopeful about the prospects of this operation because I thought that a keener appreciation of the frequency of malignant disease of the rectum, an earlier resort to ordinary rectal examination by the practitioners who first see the patients and the more frequent use of the sigmoidoscope would probably result in many more cases being discovered at a stage at which this type of operation might properly be considered. To justify consideration of this method the growths should be small, not larger than about 3 cm. across, i.e. about the diameter of a two-shilling piece, and should be freely movable from side to side and should move up and down when the patient strains, and there must be no evidence of dissemination. Such growths will usually be discovered because hæmorrhage has been an early symptom or they will be found on routine examination and sometimes when unsuspected. They will usually belong to that type which is recognized as spreading on the mucous membrane and of the papillomatous variety (Dukes' Grade "A") rather than the infiltrating type in which the pararectal tissues and lymph nodes are early invaded.

For a time I expected that radium would be so successful in this type of case that operation would become obsolete but it is now recognized in Great Britain that in growths higher than the anal canal radium cannot be relied upon to bring about cure.

The case is so prepared that the rectum is as empty and as clean as possible. I prefer to operate with the patient in the left lateral position. An incision is made commencing at the side of the base of the coccyx and is continued forwards to the posterior margin of the anus. From just beyond the tip of the coccyx it follows the median sulcus. The posterior raphe of the levatores muscles is then divided in the middle line until the rectum is exposed inside its muscular bed. The rectum, with the whole of its surrounding pararectal tissues is then completely separated by blunt dissection until the inner surface of the levatores is left quite bare. This separation is carried out downwards as far as the upper border of the internal sphincter and upwards as far as the disease demands. In most cases this has meant opening the rectovesical or Douglas's pouch and dividing the bowel 5 or even 8 cm. above this point. After this section of rectum has been removed the ends are approximated and are carefully sutured end-to-end. The front of the anastomosis—i.e. the deep aspect in relation to the

FIG. 3.—Cuff resection of rectum for encircling papilloma. The bowel is turned inside out. (From *Acta Chir. Scand.*, 1932, 72, 533.)

surgeon—is first approximated by a row of mattress sutures; by this means the cut edges are turned towards the lumen. A continuous, or once or twice interrupted, suture completes the union. In every case it has been possible to get the ends into apposition without tension, but this results in straightening the rectum so that it passes directly downwards from the pouch of Douglas or rectovesical pouch towards the anus instead of following the curve of the sacrum and coccyx. This straightening is very well illustrated in roentgen photographs made some years after the operation had been carried out. The suture of the anterior and lateral walls is usually easy and satisfactory and by the method described a certain amount of tissue is turned into the lumen so that when it heals it forms a ring-like shelf on the anterior and lateral walls. The posterior wall, on the other hand, cannot be tucked in to the same extent. After the anastomosis is completed the median raphe of the levatores is carefully drawn together by interrupted sutures. A small drain of soft rubber is placed inside the muscles, the other end being brought directly out of the wound. The skin and subcutaneous fat are securely sutured over the muscles. In order to avoid tension in the rectum from the accumulation of blood and mucus or flatus a rubber tube is passed through the anus and is left there for four or five days. In some cases the lesion may be so low in the rectum that the bowel cannot be divided above the sphincter without either encroaching on the growth or at least leaving an insufficient margin below it. In these circumstances I have carried the division of the raphe right through both the internal and external sphincters and have enucleated the mucous membrane of the anal canal under the guidance of the eye. This can be carried out very thoroughly, the only difficulty being caused by the forward pouching of the rectum which occurs anteriorly just above the internal sphincter and this must be carefully followed otherwise the bowel will be torn. The varying size of the ampullary part

mortality of this method has been higher than in the combined operations but the later results have been most encouraging both to surgeon and patient. So far I am not able to put before you the long-term after-results such as I have given for the perineal restorative operations but I am hopeful as to the future.

CONCLUSION

Coming from Newcastle-on-Tyne I feel that I may be expected to mention the Rutherford Morison plan of anastomosis, spoken of as "the intussusception method" with a long rubber tube. This operation has been rediscovered more than once and is sometimes spoken of as the Lockhart-Mummery method or after the name of Balfour. As a matter of fact, so far as I have been able to observe, this plan has not been very successful and it is significant that it has not been generally adopted. As an aid to anastomosis deep in the pelvis there may be a place for some mechanical device and I never forget that I am one of the diminishing band of witnesses to the great place which was occupied by the Murphy button in the development of intestinal surgery. In the days of my youth I invented an apparatus to facilitate this particular anastomosis. Though I have never actually used the apparatus (lantern slide) I think it might sometimes have an application and possibly some of the younger Fellows present may be disposed to ponder the matter and perhaps even to give it a trial, possibly with modification out of recognition.

I do not think that we must conclude that on matters of technique finality has been reached and on rather broader principles I have often thought that some combination of radio-therapy with radical surgery may turn out to be more successful than surgery alone. I say this remembering the remarkably suggestive results that were brought before this Section by Sir Charles Gordon-Watson now a good many years ago (*Proc. R. Soc. Med.*, 1935, 28, 1251).

It is, I consider, a worthy objective to aim at the preservation of the sphincteric apparatus but of course it must not be done unless it can be combined with a sufficiently radical removal. There are those who appear to be so satisfied with colostomy that they blind themselves to some of the unpleasant disabilities which sometimes attend its application and those occasional accidents which may be so shocking as to

"... milk the heart out of a man and shame him before his kind" (Rudyard Kipling).

Speaking for myself, I cannot agree with those who give the impression that they themselves would be content to supplant the normal mechanism by this short cut—a faith which I have heard preached from this platform.

Let me once again reiterate my position with regard to this whole matter as I should be greatly distressed if, with a certain amount of experience behind me, I was quoted as lending the authority of years to general approval of a more limited operation for some types of malignant disease of the lower bowel. As I said on a previous occasion (*Acta Chir. Scand.*, 1932, 72, 519) I make no extravagant claims for these operations nor do I speak of them in any sense of general advocacy. For years I have been almost afraid to mention them lest any word of mine should help to put back the clock of surgical progress. The most I wish to convey is my honest feeling that in view of the great advantage to the patient these operations deserve the attention of earnest workers in proctology.

Professor Charles A Pannett: There can be no difference of opinion as to the revolting nature of a colostomy. No patient likes it, many become resigned to it and adapt themselves to an unfortunate situation; to some it is a calamity. In many cases of carcinoma of the rectum it can be avoided. The question is, however, whether the retention of a controllable sphincter is compatible with effective removal of the growth. I am not able to base an affirmative answer to this question on a statistical survey as the number of cases I have operated upon is not great enough to be significant for this kind of analysis. Yet all my experience points to conservative resection as frequently not only desirable but sufficient.

For many years surgery of malignant disease of the rectum has been dominated by the personality of that brilliant surgeon Ernest Miles. We accepted without demur his conclusions based upon his careful, painstaking and accurate observation. But in these deductions he was in error. It is perfectly true that in advanced cases of carcinoma of the rectum and in post-mortem examinations in this disease, the spread of the growth may be demonstrated downwards and laterally into the ischio-rectal space. But when it is possible to remove the growth surgically this is rarely the case. The credit for pointing out this must be given to Westhues. It was in 1930 that he first published his observations. His important monograph appeared in 1934. The most painstaking dissections of 74 operation specimens was undertaken. In brief, he demonstrated beyond doubt that spread is mainly upwards into the glands around the superior hemorrhoidal vessels. Only once in all these examples did he find extension beyond 1 cm. below the naked-eye margin of the growth. In the upward direction the spread in the wall of the bowel was a little more extensive, but in the tissue

THE ANTERIOR OPERATION

The other method which I have pursued is an upper conservative operation (i.e. conservation of the sphincter apparatus) which might perhaps be better named "anterior resection with restoration of continuity and preservation of the sphincters". I was first led to consider this idea by an early experience concerning a neglected large bowel obstruction in a man of 55. He was short, fat and alcoholic and it was only when survival had been despaired of that a life-saving cæcostomy changed the whole picture. Later on exploratory laparotomy disclosed a constricting carcinoma in the first part of the rectum almost flush with the bottom of the rectovesical pouch. It was difficult to expose but I managed to divide the bowel across just below the growth and to remove it with about a foot of bowel above. The operation was completed by closing the rectal end, making a terminal colostomy and repairing the cæcostomy. This man made an excellent recovery and to my astonishment after so inadequate an operation for cancer, he lived in good health for seven years when he died probably from secondary deposits in the liver, although there was some discussion as to whether it was not from alcoholic cirrhosis of the liver which he had most certainly earned.

Another thought-provoking case was that of a very stout woman with a growth on the lowest part of the pelvic colon and first part of the rectum. I was just able to divide the peritoneum around the growth and to cut the rectum across close below it and to tuck in the lower end. The affected part, with a sufficient length of bowel and corresponding mesentery, was then removed and the operation completed by a terminal colostomy. The lantern slide shows the enormous amount of fat with which one had to contend and I freely admit it would have been extremely difficult to make an anastomosis. To my astonishment this patient continued to keep well and nineteen years later was in excellent health without any suspicion of recurrence. Experiences such as these certainly encouraged the preservation of the lower rectum with restoration of continuity of the bowel.

The general technique of this anterior method is very straightforward, though difficult, especially when it is employed for examples of rectal growth rather than those which are situated about the termination of the pelvic colon.

I would always advise a preliminary exploration through a median incision to determine beyond all question that the case is suitable for the anterior resection with restoration. This is combined with a temporary colostomy of the dysfunctioning type which may be iliac or transverse. The lower segment of the bowel should be thoroughly emptied and cleansed by irrigation but the latter should be neither too frequent nor too vigorous as it may traumatize the growth or encourage dissemination. The mobilization and separation of the bowel above and in the vicinity of the growth, together with the removal of the lymphatic area, are made as in any of the combined operations but the exposure of a sufficiency of the rectum below the growth has to be carried out after incising the peritoneum circumferentially about 2.5 cm. from the bowel and then carrying on the separation amongst the cellular tissue into the depths of the pelvis between the levatores ani. When a suitable length of bowel below the growth has been exposed (I usually aim at 5 cm.), the bowel is divided, usually with right-angled scissors but without the use of clamps as I find it impossible to apply them in this situation without their getting very much in the way and they are really quite unnecessary. One has to take great care that the division of the bowel is not too oblique and of course any vessels must be picked up and tied as they are divided. The actual anastomosis is then made by direct suture using first a series of mattress guide sutures and then a continuous circular suture which may be applied just for convenience in two or more sections. In the presence of a satisfactory dysfunctioning colostomy I have not thought it essential to attempt a watertight union but, of course, so far as possible, the mucous membrane should be inverted. In all such cases the union is well below the level of the peritoneum and lies among the vulnerable cellular tissue. That being so, it is a relief to be able to use one of the penicillin powders as an additional safeguard. I have not systematically used a tube passed from the anus to a point above the level of the anastomosis though this may have advantages. It is most important that the end of any such tube should not actually rest against any part of the bowel, where it might cause pressure necrosis. Personally, when I omit such a tube a blunt-ended tube is left *in situ* just above the sphincter or a rectal tube is passed through the sphincter at least twice daily for about four days. This manœuvre is much less uncomfortable for the patient than the continuous wearing of a tube through the anus. I have never ventured to close the abdomen without some type of drain brought from the cellular tissue and out of the lower end of the abdominal incision but it may be feasible and advisable in these days of chemical prophylaxis. If union is going to be a success it should be secure by the end of a fortnight but I have not cared to risk closure of the colostomy sooner than the end of three weeks and must admit that this stage has sometimes been followed by a temporary faecal fistula in the lower end of the incision. Closure must not be deferred for too long as there is a risk of an obliteration at the site of the anastomosis which occurred in one of my cases. The

Operating from above, the surgeon is cramped by the narrow space in which he has to work. It is not possible to use clamps and some contamination must occur. Sulphathalidine for forty-eight hours before the operation and 250,000 units of penicillin immediately following it are some help. But if the immunity of the patient be high—a fact we cannot tell—good results are obtained without their aid. Equally, if his resistance happens to be low, serious, perhaps fatal, sepsis may follow. It is of some help to fix the two ends of the bowel behind by three cotton sutures which are all inserted and left loose before any are tied (fig. 3). The posterior line of the suture can then be completed. The anterior aspect is more easy to deal with. Provided the mucous membrane is accurately turned in everywhere, union takes place well, but the junction is not an easy one to make; there is a lot of tissue behind the stump difficult to deal with and the two ends may not be of equal calibre. The technical resources of the surgeon are called upon. Whilst I have operated upon a number of patients by the abdominal route without drainage, I think it better to have a drainage tube in the hollow of the sacrum passing upwards beneath the sigmoid to emerge in the left iliac fossa from a hole of its own (fig. 4). From this tube a most foul discharge will come away for

FIG. 3.—The insertion of the first fixation sutures.

FIG. 4.—Completion of the anastomosis and the placing of the drainage tube.

forty-eight hours and then often suddenly dry up. I remove the tube after four days. I also prefer to leave a tube in the rectum reaching up above the site of the anastomosis. Often this has been omitted without ill-result but in one patient intestinal obstruction came on and was only relieved by the passage of the tube. With the wholly abdominal operation there is little disturbance of the patient. Leaving the pelvic floor intact seems to lessen the shock considerably. For these reasons even if it is impossible to bring the colon down to the rectal stump I leave the pelvic diaphragm and the sphincters.

When the growth is too low to do the whole operation from above, the separated bowel is pushed down into the hollow of the sacrum, the cut peritoneum sutured to its sides and the abdomen closed. The junction is then made after excising the coccyx. I described the technique of this operation in 1935 (*Lancet* (ii), 43). Whilst the whole of the coccygeus is divided, as little as possible of the levator ani is cut and the incision made as close to the rectum as possible in order to preserve the nerve supply of the rectal stump and the bladder. In separating the rectum from the prostate in front one must be sure to cut through the visceral pelvic fascia or one may find oneself too far forward in the prostatic plexus of the veins. I always seem to get some leakage when making the anastomosis from below but I have never had a persistent fistula.

Liquid paraffin is given daily for fourteen days after the operation, but should not be persisted in too long. Patients must not get into the habit of taking liquid paraffin. In two cases troublesome strictures occurred at the site of the anastomosis because of this. When the paraffin was stopped and they began to pass solid faeces the strictures soon opened up.

behind the rectum it extended up to 10 cm. or exceptionally 12 cm. above the growth. Laterally spread did not occur. Locally there was apt to be a break-through behind, and in front the rectovesical pouch was sometimes invaded. Both of these happenings are of serious import, but not, as I can vouch, incompatible with lasting cure. Dukes, Gabriel and Bussey (*Brit. J. Surg.*, 1935, 23, 395) support these views. In only two of those dissections depicted were infected paracolic glands shown below the growth and these are very close to its margin. These observations show that the wide removal of tissue laterally and below a growth of the rectum, as advocated by Miles, is unnecessary and unwarranted by the facts.

In a malignant growth of the rectum, the growth itself should be removed with two centimetres of normal rectum below its margin, and also 22 cm. of the rectum above its upper margin, because here there may be undischarged polypi, the forerunners of carcinoma, and all the tissue behind the bowel surrounding the superior hæmorrhoidal vessels upwards for 12 cm. This allows of the inferior mesenteric artery being tied at such a place that the blood supply of the sigmoid loop is preserved, and, if the loop is of ordinary length, sufficient is left to reach the stump of the bowel below.

The technical problem of joining the two ends of the severed gut is not a simple one. It can be accomplished either wholly from above, or if the stump of the rectum is very short, from behind after removing the coccyx. In both cases, by simple methods of suturing, perfectly controlled evacuation can be preserved. Unless this can be done the added risks of infection associated with conservative resection are not worth taking. The patient would be better off with an iliac colostomy. Pull-through methods or those necessitating division of the sphincter posteriorly, or any method requiring removal of the anal mucosa, all lead to imperfect control and should be discarded. Fig. 1, picture of a dissected fœtus, shows how intricate is the nerve supply of the rectum, anal region and bladder. The plexus of nerves is more complex than shown there, many fibrils being too fine to preserve. Physiological investigation shows that control depends upon the parasympathetic supply. Damage to the extrinsic sympathetic nerves does not lead to loss of control. This is fortunate from a surgical point of view. The nerves of the sacral plexus are preserved from damage in freeing the bowel from the hollow of the sacrum by the parietal layer of the pelvic fascia. In separating the

FIG. 1.—Dissection of infant's pelvis from side.

FIG. 2.—Dissection of perineal aspect of rectum in infant.

connective tissue here the fascia must be very closely adhered to, otherwise dangerous tissue may be left behind. Nerve branches which perforate this fascia to go to the rectum, as the sympathetic branches do, are necessarily ruptured. The important parasympathetic branches from S3 and S4 are deep to the rectovesical fascia and are in no danger when the whole pelvic diaphragm is preserved in the upper method of restoration. When, however, the junction is made from below there is some risk of harm being done. To avoid it the coccygeus should be divided close to the bone and as little as possible of the levator ani cut, the incision here being close to the rectum. The position of the nerves as seen from behind is shown in fig. 2.

operations. It is difficult for the pathologist examining operation specimens to evaluate the importance of excising these structures since they are normally in some degree of tension and after division they collapse and become misplaced.

Another point with regard to the radical removal of annular or anteriorly placed growths of the lower half of the rectum in females is the necessity to remove the posterior vaginal wall as a routine in order to reduce the possibility of vaginal recurrence; this of course is incompatible with any restorative procedure. The pathological findings of Dukes, David, Gilchrist and others indicate that it is necessary to divide the bowel and its mesentery at least 4 to 5 cm. below the lesion.

In the transabdominal restorative operation the division and removal of an adequate amount of mesorectum for growths in the lower half of the rectum offers difficulties. The mesorectum can be regarded as a cone and it will be seen from the accompanying diagrams (fig. 1) that the upper mesorectum is relatively narrow and a wide excision can be accomplished.

FIG. 1

FIG. 2.

FIG. 1A.—Diagram of growth in the upper half of the rectum showing complete removal of all the mesorectum 4-5 cm. below the growth.

FIG. 1B.—Diagram of growth in the lower half of the rectum showing inadequate removal of mesorectum.

FIG. 2.—Diagram of anastomosis in abdomino-anal excisions showing drainage of presacral space through the posterior part of the anastomosis.

In the lower half of the rectum the mesentery is much broader and to divide it adequately below the growth on a broad base in the depths of the pelvis is a difficult procedure. The surgeon is often forced to indulge in a whittling process, particularly in a narrow pelvis, in order to define the bowel before division.

For these reasons growths of the lower half of the rectum, that is, growths which can be easily felt with the finger, growths which are below the peritoneal reflexion, cannot be as radically dealt with by restorative methods and should be excluded unless the growth is particularly suitably placed and extremely early. Tumours in the upper half of the rectum at or above the peritoneal reflexion which, as a rule, can barely be felt with the tip of the finger, may in general be regarded as suitable but other factors such as a short pelvic loop or diverticulitis may diminish the number of cases in which a restorative operation can be performed.

Operation methods.—With regard to the methods I shall briefly describe those which we have used. In the first place the anal canal musculature and its sensitive lining must be retained intact if proper control and continence are to be maintained. All the methods which involve the removal of anal mucosa and its replacement by colon mucosa, or in which the anorectal ring is divided, merely result in giving the patient a perineal colostomy. Secondly, for the very reasons that the combined excision has superseded the perineal excision, no perineal approach alone can be adequately radical. In our series of restorative cases at St. Mark's we have performed three types of operation: (1) abdominosacral excision in which the whole dissection is from above and the anastomosis performed through a parasacral or perineal incision; (2) abdomino-anal excision: here again the whole dissection is from above, the anastomosis being performed outside the anus by invaginating the remaining cuff of

Convalescence after the coccygeal anastomosis takes weeks longer than if everything is done above, but the ultimate result is just as satisfactory.

One other question arises. Is it necessary to make a preliminary colostomy? In the presence of a pronounced obstruction it is advisable; but colostomy should be avoided if possible, as almost certainly there will develop a fibrous stricture at the site of the anastomosis which will remain, in spite of fortnightly digital dilatation, until it is subjected to the daily passing of solid faeces.

I have lived to see demonstrated the hollowness of cherished surgical beliefs—to see the indestructible atom shattered into fragments—so that I have come to feel that scientific advance can be made only if we regard our contemporary beliefs as always wrong, or at most only half-truths. But when I remember, in connexion with the conservative resection operation, patients living twelve and thirteen years in normal health, unaware that they have a rectum, except for a satisfactory reminder once a day, I am tempted to place the foundations on which the conservative operation is based amongst the dependable half-truths.

Mr. O. V. Lloyd-Davies: It has always been one of the goals of the surgeon to be able to remove rectal growths without the necessity for a permanent colostomy and many attempts have been made over the course of years. In the past, sepsis, both local and general, was such a predominating factor that it gave rise to a mortality rate which forbade the general use of these methods and hence it was never possible to study the end-results. In 1887, Shede performed a preliminary colostomy before resecting a tumour posteriorly and restoring continuity but this very advisable step was never popularized. In later years, surgeons tended to rely upon a caecostomy to act as a vent and reduce gas tension, and upon tubes passing through the anastomosis, since it was realized that increased gas tension or activity of the anastomosed gut might be the all-important determining factors in success or failure.

Few considered the advisability of a preliminary transverse colostomy and although this procedure has since been criticized for various reasons, it was a distinct advance towards safety in restorative operations. There have been no deaths from sepsis at St. Mark's since a preliminary transverse colostomy has been used; I refer of course to cases performed before the discovery of the bowel sulphonamides. Milligan in 1926 was the first at St. Mark's to use a preliminary colostomy before resection and in 1935 Devine made a good case for a preliminary transverse colostomy.

Since the advent of the sulphonamides, more particularly sulphasuxidine and sulphathalidine, there has been a renewed and increasing trend towards attempting restorative resections for cancer of the rectum and rectosigmoid. The wave of enthusiasm has been so forceful, that in reading the surgical literature of some countries one might almost be persuaded that these restorative operations were the operations of choice and that all the older-established combined operations had had their day.

The development of sound methods for accomplishing these restorative operations is very desirable but a long view must be taken and at this stage it is worth while analysing the objectives which one hopes to attain. In assessing our work on rectal cancer we have a yardstick with which to check the results of new developments. This is the combined excision operation first developed by that great surgeon, Ernest Miles, who planned the abdomino-perineal operation in 1908. To-day there are various other forms of combined excision, the perineo-abdominal operation of Grey Turner and Gabriel and the synchronous combined excision, and we know from the figures of many clinics that a 50% five-year cure rate is the best that can be obtained by surgery and that only earlier diagnosis will improve this figure in any substantial way.

The first objective in restorative operations must therefore be long-term results which are as good as those of combined excision operations. We are not entitled to take risks with the growth or the patient merely to avoid a colostomy and restore continuity. The restorative operation must be as radical as a combined excision.

Upper limits.—The upper limit of division of the inferior mesenteric vascular and lymphatic trunks in a synchronous combined excision is immediately below the left colic artery in two-thirds of the cases and below the first sigmoid artery in the remaining third. This should be the criterion for restorative operations but since a greater length of colon has to be retained this may not always be possible and an additional strain is placed on the acumen of the surgeon who has to judge whether his operation is still as radical as it should be. In some cases this difficulty can be overcome when the middle colic vessels are sufficiently long to allow the transverse colon to be anastomosed to the rectum.

Lower limits.—There is no lower limit in a combined excision operation. It is a wide removal of all the tissues surrounding the lower half of the rectum including the greater part of the levators and the rectal fascia of Waldeyer. The fascia of Waldeyer and the broad pubo-coccygeus portions of the levator are in intimate contact with the lower half of the rectum and must have a definite lymphatic significance; they are not removed in restorative

operations. It is difficult for the pathologist examining operation specimens to evaluate the importance of excising these structures since they are normally in some degree of tension and after division they collapse and become misplaced.

Another point with regard to the radical removal of annular or anteriorly placed growths of the lower half of the rectum in females is the necessity to remove the posterior vaginal wall as a routine in order to reduce the possibility of vaginal recurrence; this of course is incompatible with any restorative procedure. The pathological findings of Dukes, David, Gilchrist and others indicate that it is necessary to divide the bowel and its mesentery at least 4 to 5 cm. below the lesion.

In the transabdominal restorative operation the division and removal of an adequate amount of mesorectum for growths in the lower half of the rectum offers difficulties. The mesorectum can be regarded as a cone and it will be seen from the accompanying diagrams (fig. 1) that the upper mesorectum is relatively narrow and a wide excision can be accomplished.

FIG. 1.

FIG. 2.

FIG. 1A.—Diagram of growth in the upper half of the rectum showing complete removal of all the mesorectum 4-5 cm. below the growth.

FIG. 1B.—Diagram of growth in the lower half of the rectum showing inadequate removal of mesorectum.

FIG. 2.—Diagram of anastomosis in abdomino-anal excisions showing drainage of presacral space through the posterior part of the anastomosis.

In the lower half of the rectum the mesentery is much broader and to divide it adequately below the growth on a broad base in the depths of the pelvis is a difficult procedure. The surgeon is often forced to indulge in a whittling process, particularly in a narrow pelvis, in order to define the bowel before division.

For these reasons growths of the lower half of the rectum, that is, growths which can be easily felt with the finger, growths which are below the peritoneal reflexion, cannot be as radically dealt with by restorative methods and should be excluded unless the growth is particularly suitably placed and extremely early. Tumours in the upper half of the rectum at or above the peritoneal reflexion which, as a rule, can barely be felt with the tip of the finger, may in general be regarded as suitable but other factors such as a short pelvic loop or diverticulitis may diminish the number of cases in which a restorative operation can be performed.

Operation methods.—With regard to the methods I shall briefly describe those which we have used. In the first place the anal canal musculature and its sensitive lining must be retained intact if proper control and continence are to be maintained. All the methods which involve the removal of anal mucosa and its replacement by colon mucosa, or in which the anorectal ring is divided, merely result in giving the patient a perineal colostomy. Secondly, for the very reasons that the combined excision has superseded the perineal excision, no perineal approach alone can be adequately radical. In our series of restorative cases at St. Mark's we have performed three types of operation: (1) abdominosacral excision in which the whole dissection is from above and the anastomosis performed through a parasacral or perineal incision; (2) abdomino-anal excision: here again the whole dissection is from above, the anastomosis being performed outside the anus by invaginating the remaining cuff of

rectum and joining colon to rectal cuff as in the rectosigmoidectomy operation; (3) entirely transabdominal resections.

Lower pelvic colon growths naturally come into this series and we decided to include only those in which the growth was too low for a Paul-Mikulicz operation to have been performed.

These operations have been done in one, two and three stages, the three-stage operation being a preliminary laparotomy and transverse colostomy followed by a resection operation and later extraperitoneal closure of the colostomy. In the two-stage operation a temporary transverse colostomy is performed at the end of the operation and closed at a later stage.

Complications.—The earliest cases in the series were abdominosacral operations and this operation was abandoned owing to the development of a fistula between the anastomosis and the perineal or sacral wound. These were all three-stage operations and because of delay in closure of the fistula the transverse colostomy had often to be retained for a considerable time. In no case was the fistula permanent.

Our method of abdomino-anal excision was devised to overcome this difficulty, the presacral space being drained *per anum* through the posterior part of the anastomosis (fig. 2); this permitted an earlier closure of the colostomy.

In both these operations some narrowing at the site of anastomosis has been frequent. This has been due to anastomosing the narrow colon to the wide lower cuff of rectum. In those cases in which there has been enough length of colon to divide it sufficiently obliquely, no strictures have developed. These operations require a greater length of bowel than the entirely transabdominal resections.

Sepsis.—To ascertain how the battle of sepsis is progressing let us examine the entirely transabdominal or intraperitoneal resection series, all of which had a preoperative five-day course of either sulphasuxidine or sulphathalidine. There have been seven cases, approximately 25%, with temporary complications in association with the anastomosis.

TABLE I

Complications (7 cases)

- (1) Posterior separation, pelvic cellulitis
- (2) Colo-vaginal fistula
- (3) Posterior separation with abscess
- (4) Posterior separation and colo-vaginal fistula
- (5) Faecal leak along pelvic drain
- (6) Faecal leak along pelvic drain
- (7) Para-rectal abscess

All of these cases have probably been due to some partial deficiency in the blood supply to the junction and there is no doubt that more serious complications as the result of this defect have been prevented by pre- and post-operative chemotherapy. These complications have been more common in the one-stage operations but in no case has permanent trouble resulted.

The two-stage operation in which a transverse colostomy is performed at the completion of the resection appears to offer a greater measure of safety to the patient than the one-stage operation should any complication occur.

With regard to the three-stage operation, this may now only be necessary when it has been impossible to empty the colon adequately before operating.

Blood supply.—Regarding the blood supply a decision has to be made as to whether or not the descending branch of the left colic artery will adequately supply a sufficient length of bowel. If this vessel appears to be large and suitable a further test can be made by compressing the main inferior mesenteric trunk and noting at what point arterial pulsation ceases on the bowel wall. If this length of bowel is not sufficient the first sigmoid artery will have to be retained. Further length of vascular bowel can be obtained by dividing the remaining sigmoid arteries proximal to their arcades (figs. 3 and 4). Viable bowel is determined by its colour, pulsating arterioles and finally by free bleeding from the divided end.

The majority of these transabdominal pelvic anastomoses have been of the open end-to-end type and in this connexion it must be remembered that whilst accurate anastomosis is all-important, excessive suturing will devitalize the end blood supply.

It is important to make division of the two opposing ends of bowel as oblique as possible. To obtain full advantage of the length of the pelvic loop the mesenteric border of the colon can be applied to the antimesenteric surface of the rectal stump and vice versa. This rotates the colon slightly but does not twist the mesentery and has the additional advantage of uniting the most vascular borders to the least vascular borders and makes for greater safety. There have been no complications in using this method. The site of the anastomosis should always be drained.

End-results.—In the three methods which we have used we have tried as faithfully as possible to be as radical as in a combined excision. The majority of the tumours have been at or above the peritoneal reflexion. The average height of the lower border of the growth in the abdomino-anal and sacral series is 11.5 cm. and in the intraperitoneal resection series

FIG. 3.—Diagram to show the usual arrangement of sigmoid vessels.

FIG. 4.—Diagram to show division of sigmoid vessels proximal to their arcades to obtain maximum length of viable bowel. The dotted line indicates the amount of tissue removed.

13 cm. The average distance of free bowel and mesentery below the lesion has been 1.8 and 1.5 in. (4.5 and 3.8 cm.). In half the intraperitoneal cases the anastomosed proximal colon has been supplied by the descending branch of the left colic and in the remaining half the first or second sigmoid arteries have been left as a supply.

rectum and joining colon to rectal cuff as in the rectosigmoidectomy operation; (3) entirely transabdominal resections.

Lower pelvic colon growths naturally come into this series and we decided to include only those in which the growth was too low for a Paul-Mikulicz operation to have been performed.

These operations have been done in one, two and three stages, the three-stage operation being a preliminary laparotomy and transverse colostomy followed by a resection operation and later extraperitoneal closure of the colostomy. In the two-stage operation a temporary transverse colostomy is performed at the end of the operation and closed at a later stage.

Complications.—The earliest cases in the series were abdominosacral operations and this operation was abandoned owing to the development of a fistula between the anastomosis and the perineal or sacral wound. These were all three-stage operations and because of delay in closure of the fistula the transverse colostomy had often to be retained for a considerable time. In no case was the fistula permanent.

Our method of abdomino-anal excision was devised to overcome this difficulty, the presacral space being drained *per anum* through the posterior part of the anastomosis (fig. 2); this permitted an earlier closure of the colostomy.

In both these operations some narrowing at the site of anastomosis has been frequent. This has been due to anastomosing the narrow colon to the wide lower cuff of rectum. In those cases in which there has been enough length of colon to divide it sufficiently obliquely, no strictures have developed. These operations require a greater length of bowel than the entirely transabdominal resections.

Sepsis.—To ascertain how the battle of sepsis is progressing let us examine the entirely transabdominal or intraperitoneal resection series, all of which had a preoperative five-day course of either sulphasuxidine or sulphathalidine. There have been seven cases, approximately 25%, with temporary complications in association with the anastomosis.

TABLE I

Complications (7 cases)

- (1) Posterior separation, pelvic cellulitis
- (2) Colo-vaginal fistula
- (3) Posterior separation with abscess
- (4) Posterior separation and colo-vaginal fistula
- (5) Faecal leak along pelvic drain
- (6) Faecal leak along pelvic drain
- (7) Para-rectal abscess

All of these cases have probably been due to some partial deficiency in the blood supply to the junction and there is no doubt that more serious complications as the result of this defect have been prevented by pre- and post-operative chemotherapy. These complications have been more common in the one-stage operations but in no case has permanent trouble resulted.

The two-stage operation in which a transverse colostomy is performed at the completion of the resection appears to offer a greater measure of safety to the patient than the one-stage operation should any complication occur.

With regard to the three-stage operation, this may now only be necessary when it has been impossible to empty the colon adequately before operating.

Blood supply.—Regarding the blood supply a decision has to be made as to whether or not the descending branch of the left colic artery will adequately supply a sufficient length of bowel. If this vessel appears to be large and suitable a further test can be made by compressing the main inferior mesenteric trunk and noting at what point arterial pulsation ceases on the bowel wall. If this length of bowel is not sufficient the first sigmoid artery will have to be retained. Further length of vascular bowel can be obtained by dividing the remaining sigmoid arteries proximal to their arcades (figs. 3 and 4). Viable bowel is determined by its colour, pulsating arterioles and finally by free bleeding from the divided end.

The majority of these transabdominal pelvic anastomoses have been of the open end-to-end type and in this connexion it must be remembered that whilst accurate anastomosis is all-important, excessive suturing will devitalize the end blood supply.

It is important to make division of the two opposing ends of bowel as oblique as possible. To obtain full advantage of the length of the pelvic loop the mesenteric border of the colon can be applied to the antimesenteric surface of the rectal stump and vice versa. This rotates the colon slightly but does not twist the mesentery and has the additional advantage of uniting the most vascular borders to the least vascular borders and makes for greater safety. There have been no complications in using this method. The site of the anastomosis should always be drained.

In considering the above possibilities it is particularly disturbing to observe that four A cases have developed local recurrences. To compare with this the A cases in a series of combined excisions of over five years' duration were examined and of 54 cases none had developed local pelvic recurrences.

Lastly, distinct second primary tumours developing away from the anastomosis.

A local recurrence rate of 24.6% is too big a price to pay for avoidance of a permanent colostomy. Death from local recurrences is always a miserable ending.

The final figure may be worse since a half of the cases have yet to run a complete five-year course and a second primary may arise at any later date.

We have performed secondary excision operations for a number of these recurrences but our experience is that these second operations are always troublesome since the normal tissue planes no longer exist, the growth does not spread along the normal channels and it is often difficult to distinguish fibrous tissue from growth.

If in view of the present greater safety in performing these restorative operations they are to have a permanent place in the treatment of rectal cancer then the end-results will have to be considerably improved.

Growths of the lower half of the rectum below the peritoneal reflexion must be excluded. There should be an adequate removal of tissue and division of the bowel and its mesentery at least two inches below the tumour.

Especial care must be taken to avoid implanting cancer cells. We at St. Mark's have been aware of this danger for some time and have adopted the following plan when performing restorative resections.

A clamp is applied to the bowel at least 2 in. below the growth and the distal portion is irrigated through the anus with 1 : 1,000 perchloride of mercury. The bowel is then divided, the distal portion being held with tissue forceps or stay sutures. To complete the toilet perchloride swabs followed by dry swabs are pushed down to the anus where they are removed by an assistant.

Since the patients are always placed in the lithotomy-Trendelenburg position this manœuvre is a simple matter.

It is too early to give any statistics which will prove whether this method is effective in reducing local recurrence due to implantation.

My impressions are that results will be improved now that we are aware of this danger and are taking steps to combat it.

A very close follow-up must be kept upon these patients and this means rectal examination by palpation and sigmoidoscopy three-monthly and later six-monthly and then yearly for the rest of their lives. It will be necessary in a few years' time to make a complete review of these cases; meanwhile restorative operations must be as radical as possible always bearing in mind the grave risk of local recurrence and taking every precaution to prevent it.

[July 14, 1948]

MEETING AT THE GORDON HOSPITAL, VAUXHALL BRIDGE ROAD, LONDON, S.W.1

Two Cases by ERIC A. CROOK, M.Ch.

I.—Sarcoma Discovered in Hæmorrhoid after Ligature Operation.

E. J. H., aged 40.

Ligature operation for hæmorrhoids, one of which was excised on account of its size and microscopic examination showed sarcoma.

The problem was whether radical treatment should be adopted.

The opinions expressed were that in view of the hæmorrhoid having been completely removed, the patient should be kept under observation and further operative measures carried out if there were any evidence of local recurrence.

II.—Urethral Fistula Following Abdominoperineal Excision of Rectum.

W. E. U., aged 59.

Abdominoperineal excision of the rectum on 15.10.47. Growth $3 \times 2\frac{1}{2}$ cm. Microscopically Grade II malignancy (Broders') and Class B case (Dukes').

Wound was slow in healing and a urethral fistula persisted. The latter has healed and broken down periodically, otherwise his condition has been entirely satisfactory.

The problem was whether surgical measures should be adopted to make the fistula heal.

The views expressed were that the fistula would probably consolidate on its own, without operative treatment.

An analysis of this small series of 54 restorative cases done at St. Mark's gives the following results (Table IV); they are seriously disappointing. The bright side to the picture is the operative mortality of 5.5% with no deaths from sepsis or peritonitis. This compares with our mortality of 4.1% for Paul-Mikulicz operations. One-third of the cases were done before the days of the bowel sterilizing sulphonamides but these were all three-stage operations.

TABLE IV.—OPERATIVE MORTALITY FOR RESTORATIVE CASES

Abdomino-anal and abdomino-sacral ..	24	1 death
Intraperitoneal resections (transabdominal)	30	2 deaths
Total	54	3 deaths

Mortality rate 5.5%.

Of the 54 cases half of them are too recent for follow-up purposes and so to obtain a broader picture the results of 19 radical Hartmann operations were investigated, the palliative operations, that is those with known liver secondaries, being excluded. In these Hartmann operations the bowel is divided in much the same way as in restorative operations and there remains an invaginated rectal stump which provides a somewhat similar state of affairs to study.

If these figures be all grouped together and all palliative operations are excluded a total of 65 cases is obtained made up of: 23 abdomino-anal and sacral; 23 intraperitoneal or transabdominal resections, and 19 Hartmanns and to date 16 have developed a local pelvic recurrence (Tables V, VI and VII).

TABLE V

	Local recurrences
Abdomino-sacral and anal cases	
24—1 death = 23	9
Intraperitoneal resections	
30—2 deaths—5 palliatives = 23	1
Hartmann operations	6
Total 65	16

Percentage recurrence 24.6

TABLE VI.—ABDOMINO-ANAL AND ABDOMINO-SACRAL CASES

Local Pelvic Recurrences Occurring Between Six Months and Six Years after Operation

9 cases	Position of Recurrence	
A cases 2	Rectovaginal septum	3 cases
B cases 2	Suture line and drain track	3 cases
C cases 5	Insufficient data to determine initial site of recurrence ..	3 cases

TABLE VII.—HARTMANN OPERATIONS

Excluding palliative operations	19 cases
Local recurrences 6	
Recurrences at invagination	3 { 2 A cases 1 B case
Noted twelve, fifteen and eighteen months after operation	
Implantation	1 C case
Noted six months after operation	
Second primary growths	2 { 1 A case 1 C case
Noted two years and seven years after operation	

There have been recurrences at the suture line, drainage track implants and second primary carcinomata. This gives a local recurrence rate of 24.6%, which is a serious matter. There are several possible explanations:

First, inadequate removal of the primary tumour, in other words failure to carry out the criteria which have been just described for performing a radical operation.

Secondly, implantation of cancer cells at the time of the operation. We know that this can occur as we have instances of adenocarcinomata developing at the external openings of fistulous tracks, there being no direct continuity with the primary tumour in the bowel.

Thirdly, a traumatic factor caused by the suturing may, as experimental work on cancer has shown, result in the stimulation of rectal epithelium which has a predisposition to producing malignant change. Quite a number of these recurrences have occurred in the rectal rather than colonic side of the anastomosis.

In considering the above possibilities it is particularly disturbing to observe that four A cases have developed local recurrences. To compare with this the A cases in a series of combined excisions of over five years' duration were examined and of 54 cases none had developed local pelvic recurrences.

Lastly, distinct second primary tumours developing away from the anastomosis.

A local recurrence rate of 24.6% is too big a price to pay for avoidance of a permanent colostomy. Death from local recurrences is always a miserable ending.

The final figure may be worse since a half of the cases have yet to run a complete five-year course and a second primary may arise at any later date.

We have performed secondary excision operations for a number of these recurrences but our experience is that these second operations are always troublesome since the normal tissue planes no longer exist, the growth does not spread along the normal channels and it is often difficult to distinguish fibrous tissue from growth.

If in view of the present greater safety in performing these restorative operations they are to have a permanent place in the treatment of rectal cancer then the end-results will have to be considerably improved.

Growths of the lower half of the rectum below the peritoneal reflexion must be excluded. There should be an adequate removal of tissue and division of the bowel and its mesentery at least two inches below the tumour.

Especially care must be taken to avoid implanting cancer cells. We at St. Mark's have been aware of this danger for some time and have adopted the following plan when performing restorative resections.

A clamp is applied to the bowel at least 2 in. below the growth and the distal portion is irrigated through the anus with 1 : 1,000 perchloride of mercury. The bowel is then divided, the distal portion being held with tissue forceps or stay sutures. To complete the toilet perchloride swabs followed by dry swabs are pushed down to the anus where they are removed by an assistant.

Since the patients are always placed in the lithotomy-Trendelenburg position this manoeuvre is a simple matter.

It is too early to give any statistics which will prove whether this method is effective in reducing local recurrence due to implantation.

My impressions are that results will be improved now that we are aware of this danger and are taking steps to combat it.

A very close follow-up must be kept upon these patients and this means rectal examination by palpation and sigmoidoscopy three-monthly and later six-monthly and then yearly for the rest of their lives. It will be necessary in a few years' time to make a complete review of these cases; meanwhile restorative operations must be as radical as possible always bearing in mind the grave risk of local recurrence and taking every precaution to prevent it.

[July 14, 1948]

MEETING AT THE GORDON HOSPITAL, VAUXHALL BRIDGE ROAD, LONDON, S.W.1

Two Cases by ERIC A. CROOK, M.Ch.

I.—Sarcoma Discovered in Hæmorrhoid after Ligature Operation.

E. J. H., aged 40.

Ligature operation for hæmorrhoids, one of which was excised on account of its size and microscopic examination showed sarcoma.

The problem was whether radical treatment should be adopted.

The opinions expressed were that in view of the hæmorrhoid having been completely removed, the patient should be kept under observation and further operative measures carried out if there were any evidence of local recurrence.

II.—Urethral Fistula Following Abdominoperineal Excision of Rectum.

W. E. U., aged 59.

Abdominoperineal excision of the rectum on 15.10.47. Growth $3 \times 2\frac{1}{2}$ cm. Microscopically Grade II malignancy (Broders') and Class B case (Dukes').

Wound was slow in healing and a urethral fistula persisted. The latter has healed and broken down periodically, otherwise his condition has been entirely satisfactory.

The problem was whether surgical measures should be adopted to make the fistula heal.

The views expressed were that the fistula would probably consolidate on its own, without operative treatment.

Eight Cases by RONALD W. RAVEN, O.B.E., F.R.C.S.

I.—Carcinoma of Rectosigmoid Colon with Hepatic Metastases. Partial Colectomy and Insulin Therapy.

Female, aged 43, married with three children, noticed abdominal colicky pain in 1944. In July 1947 an exploratory laparotomy was performed by another surgeon who found a carcinoma at the rectosigmoid junction with metastases in the right lobe of the liver. The condition was pronounced inoperable and a left inguinal colostomy was established. The patient became aware of her condition and her husband and she were most anxious that an attempt should be made to eradicate the disease. On examination the patient was very thin, the liver was just palpable and there was a left inguinal colostomy with a spur. On rectal examination the lower margin of a carcinoma was felt.

Investigations: R.B.C. 3,190,000; W.B.C. 5,800; Hb 74%; blood urea 22 mg.%; plasma proteins, chlorides and ascorbic acid within normal limits. X-ray chest—no metastases.

Operations (Mr. R. W. Raven).—(1) on 1.10.47: Exploratory laparotomy revealed three metastases, 5 cm. in diameter, in the anterior and posterior aspects of the right lobe and Spigelian lobe of the liver. The left lobe appeared normal. Aortic lymph nodes not enlarged. An operable carcinoma was present at the rectosigmoid junction; partial colectomy was performed with closure of the two open ends of the colon. (2) on 29.10.47: The abdomen was reopened with the object of performing a partial right hepatectomy; the right lobe of the liver was mobilized but it was not possible to proceed further on account of the poor general condition of the patient.

She recovered from the operation but her condition continued to deteriorate, with loss of weight and anorexia. The use of a growth inhibitor substance was considered but not adopted. Mr. S. O. Aylett suggested insulin therapy and it was decided to give the patient 15 units t.d.s. In a short time a very marked improvement occurred; she became ravenously hungry and it was difficult to appease her appetite. She lost her depression and lethargy, became alert and had an intense interest in living.

Follow-up examination (14.7.48).—The patient is very well, with a good colour, and is able to work hard looking after her home and three children unaided. She has gained 4 st. in weight. The appetite continues to be excellent, insulin therapy is maintained and there are no signs of spread of the disease; the lower margin of the liver is just palpable.

Comment.—The relationship between the pancreas and malignant disease has been the subject of a number of investigations and several facts have been elucidated. Hypertrophy of the islets of Langerhans has been found in human cancer and in tumour-bearing mice. Several workers have reported the presence of substances in tumours which are capable of lowering the blood sugar, but this has not received complete confirmation. The view was put forward that hypertrophy of islet tissue in the presence of malignant disease was a defence mechanism with the underlying supposition that insulin might exert an inhibitory action on the growth of a tumour. This view appears to be reinforced by the knowledge that carbohydrates administered orally or parenterally cause tumour growth and therefore a substance which produces hypoglycaemia would have the opposite action. There is experimental evidence that insulin does exert a growth-inhibitor action in certain forms of malignant disease; on the other hand, there are a number of reports of the failure of insulin to affect tumour-growth. When insulin therapy has been used in human cancer it has been pointed out that the dosage of insulin and amount of carbohydrate ingested must be regulated so that the critical level of hypoglycaemia is just avoided. A series of 16 cases with inoperable cancer was treated by Silberstein¹ and co-workers when it was noted that improvement occurred in the general condition and the growth of the tumour was arrested. It has been shown, however, that after insulin therapy ceased the growth of the tumour was rapid.

II.—Carcinoma of Rectum with Hepatic Metastases. Abdominoperineal Excision and Partial Hepatectomy.

Female, aged 52, had diarrhoea, bleeding from the rectum and loss of weight extending over a period of six months. On examination she was pale and thin. There was a large, nodular, hard swelling in the position of the left lobe of the liver. On rectal examination an ulcerating carcinoma of the rectum was found, the lower margin was 7.5 cm. from the anal verge, and it was somewhat fixed anteriorly.

Operations (Mr. R. W. Raven).—23.3.48: Abdominoperineal excision of the rectum. 20.4.48: Left hepatectomy—the whole of the left lobe of the liver was massively involved.

¹Silberstein, F., (1932) *Schweiz. med. wscrh.*, 62, 153.

—, French, J. and Révész, T. (1927) *Z. ges. exp. Med.*, 55, 78.

by metastases; the right lobe was clear. Microscopic examination showed adenocarcinoma of the rectum and liver.

Follow-up examination (14.7.48).—Patient is well; no sign of recurrence.

Comment.—The operation of left hepatectomy whereby the whole of the left lobe of the liver is excised is a feasible operation when metastases are localized to this lobe, the primary growth is operable and there are no other distant metastases.

III and IV.—Carcinoma of Rectum. Abdominoperineal Proctosigmoidectomy.

III.—Male, aged 34, had suffered from constipation, rectal bleeding and loss of weight extending over a period of five months. On examination he was thin and pale. There was an ulcerating carcinoma in the left lower quadrant of the ampulla of the rectum whose lower border was 7.5 cm. from the anal verge; freely mobile.

Operation (Mr. R. W. Raven).—18.11.47: Abdominoperineal proctosigmoidectomy. Eight days after the operation the bowels were opening normally. Faradic stimulation given to the anal sphincters.

Follow-up examination (14.7.48).—Patient is well. No sign of recurrence. He has good sphincteric control of faeces. There is some stenosis at the anosigmoid junction.

IV.—Male, aged 55, had suffered for seven years with soreness at the anus, recurrent attacks of rectal bleeding, and prolapsing internal hæmorrhoids requiring replacement. On examination his general condition was good. On rectal examination there were prolapsing internal hæmorrhoids. Sigmoidoscopy revealed a carcinoma situated 15 cm. from the anal verge, chiefly involving the anterior wall. Carcinoma confirmed by biopsy.

Operation (Mr. R. W. Raven).—26.1.48: Abdominoperineal proctosigmoidectomy. Several days after operation there was some sloughing of the sigmoid colon at the anus with infection and fever. It was decided to institute a transverse colostomy on 31.1.48.

Follow-up examination (14.7.48).—Patient is well. No sign of recurrence. Good healing of anal canal. Transverse colostomy working well. This was closed later and patient has good sphincteric control of faeces.

Comment.—The two patients were selected to show certain features of the results of the operation. In the first patient a stricture has developed but this does not appear to affect the bowel action and he has almost perfect control over the stools. Stricture formation often occurs after abdominoperineal proctosigmoidectomy. In the second patient the sigmoid colon which had been brought through the anus sloughed and in order to prevent further infection and pelvic cellulitis a transverse colostomy was instituted and the infective process subsided; the patient made a good recovery. If this condition occurs after the operation a transverse colostomy is very desirable.

The perineal part of the operation of abdominoperineal proctosigmoidectomy is carried out as follows, with the patient in the lithotomy position: After the usual toilet preparation an incision is made in the mid-line commencing at the tip of the coccyx and ending to the posterior border of the internal sphincter muscle of the anus. This incision is deepened until the fibres of the levatores ani muscles are seen and these are separated in the mid-line. The fascia propria is incised and the rectum and sigmoid are delivered into the wound. The levatores ani muscles are cut laterally from the rectum which is separated anteriorly from the urethra or vagina. The anorectal junction is identified and divided, the upper divided end of the anal canal is held in tissue forceps. The tape around the area of proved vascularity in the sigmoid is identified and the colon is divided 6 cm. distal to this; the growth is thus removed. The proximal end of the sigmoid is passed through the anal canal and the tape should be localized at, or distal to, the anal orifice. No sutures are used to anchor the bowel; appendices epiploicæ are not removed since they carry small nutrient arteries to the bowel. A saline compress is placed around the protruding bowel. The levatores ani muscles are sutured together in the mid-line with interrupted sutures of silk, care being taken not to compress the bowel and the rest of the wound is closed around a small rubber tube inserted into the presacral region. Several days after the operation the patient is instructed to exercise the anal sphincters; later faradic stimulation may increase their power of contractility. About the tenth post-operative day the protruding bowel is divided with the cautery at a point 2 cm. beyond the anal orifice providing the perineal wound has healed satisfactorily. The patient commences to have bowel actions about the fifth post-operative day and thereafter he is given a lubricant by mouth until these are regulated. Digital dilatation is carried out if the anus tends to constrict. After an interval of two months most patients have excellent sphincteric control of the anus with little or no soiling.

Eight Cases by RONALD W. RAVEN, O.B.E., F.R.C.S.

I.—Carcinoma of Rectosigmoid Colon with Hepatic Metastases. Partial Colectomy and Insulin Therapy.

Female, aged 43, married with three children, noticed abdominal colicky pain in 1944. In July 1947 an exploratory laparotomy was performed by another surgeon who found a carcinoma at the rectosigmoid junction with metastases in the right lobe of the liver. The condition was pronounced inoperable and a left inguinal colostomy was established. The patient became aware of her condition and her husband and she were most anxious that an attempt should be made to eradicate the disease. On examination the patient was very thin, the liver was just palpable and there was a left inguinal colostomy with a spur. On rectal examination the lower margin of a carcinoma was felt.

Investigations: R.B.C. 3,190,000; W.B.C. 5,800; Hb 74%; blood urea 22 mg.%; plasma proteins, chlorides and ascorbic acid within normal limits. X-ray chest—no metastases.

Operations (Mr. R. W. Raven).—(1) on 1.10.47: Exploratory laparotomy revealed three metastases, 5 cm. in diameter, in the anterior and posterior aspects of the right lobe and Spigelian lobe of the liver. The left lobe appeared normal. Aortic lymph nodes not enlarged. An operable carcinoma was present at the rectosigmoid junction; partial colectomy was performed with closure of the two open ends of the colon. (2) on 29.10.47: The abdomen was reopened with the object of performing a partial right hepatectomy; the right lobe of the liver was mobilized but it was not possible to proceed further on account of the poor general condition of the patient.

She recovered from the operation but her condition continued to deteriorate, with loss of weight and anorexia. The use of a growth inhibitor substance was considered but not adopted. Mr. S. O. Aylett suggested insulin therapy and it was decided to give the patient 15 units t.d.s. It has been shown, however, that after insulin therapy ceased the growth of the tumour was rapid.

II.—Carcinoma of Rectum with Hepatic Metastases. Abdominoperineal Excision and Partial Hepatectomy.

Female, aged 52, had diarrhoea, bleeding from the rectum and loss of weight extending over a period of six months. On examination she was pale and thin. There was a large, nodular, hard swelling in the position of the left lobe of the liver. On rectal examination an ulcerating carcinoma of the rectum was found, the lower margin was 7.5 cm. from the anal verge, and it was somewhat fixed anteriorly.

Operations (Mr. R. W. Raven).—23.3.48: Abdominoperineal excision of the rectum. 20.4.48: Left hepatectomy—the whole of the left lobe of the liver was massively involved

¹Silberstein, F. (1932) *Schweiz. med. wscrh.*, 62, 153.

—, French, J. and Révész, T. (1927) *Z. ges. exp. Med.*, 55, 78.

On examination.—Before operation a ring of prolapse 1½ in. in length protruded through a completely lax sphincter giving the impression of being mucosa only.

Admitted to hospital on 1.6.48. Examination under spinal anaesthesia: No more rectal wall could be pulled down and vaginal examination revealed much scarring and adhesions between the cervix and the posterior vaginal wall.

Operation (7.6.48).—Thiersch operation. Steel wire inserted subcutaneously around the lower end of the anal canal and tightened to the diameter of the proximal interphalangeal joint of the index finger.

Bowels opened on the sixth morning after operation with some difficulty owing to the very big faecal result, otherwise uninterrupted convalescence with no recurrence of the prolapse.

Patient is now taking normacol daily and complains of no prolapse.

Present state on examination: On straining a small portion of mucosa is visible through the sphincter which has not completely recovered its tone, but has improved with the post-operative exercises.

Hirschsprung's Disease

By F. DOUGLAS STEPHENS, D.S.O., M.S.Melb., F.R.A.C.S.

THE purpose of this paper is to emphasize three features concerning the group of cases characterized by megacolon without obvious organic obstruction such as atresia or stenosis: First, the subdivision of this group into clinical types, secondly, a brief outline of the general features of true Hirschsprung's disease, and the differentiation of this condition from the subgroups, and thirdly, clinical evidence that spasm in the rectosigmoid region is present in true Hirschsprung's disease and is the cause of the obstruction.

From the miscellaneous group of cases suffering from severe constipation with idiopathic megacolon, the following two clinical sub-groups are apparent.

(1) *True Hirschsprung's disease.*—This is a congenital condition characterized by constipation and abdominal distension, commencing at or soon after birth. In this series the majority are boys. It occasionally has a familial tendency, and in one family in this series of 30 cases there were two boys afflicted with this condition. There is abdominal distension caused chiefly by the gradual dilatation of the sigmoid colon. Gas formation occurs presumably as a result of prolonged stagnation of faecal contents and large quantities of foul flatus are passed *per rectum*. There are visible peristaltic waves. The stools in this condition are characteristically small round pellets or thin ribands like toothpaste. Faecal accumulations occur in the sigmoid colon but these are not as a rule palpable in the abdomen owing to the gaseous distension. Rectal examination reveals a normal sphincter and rectum which is usually empty, except perhaps for a small pellet of faeces. Faecal matter in the sigmoid colon can be palpated through the rectal wall. In babies it may be possible to pass one's finger proximally into the rectosigmoid region which sometimes simulates a stricture as a result of the spasm of the wall of the bowel at this site.

Pain is not a feature of Hirschsprung's disease unless it is that caused by acute gaseous distension due to inability to evacuate the flatus.

Vomiting may occur in the presence of severe abdominal distension.

(2) *Chronic constipation.*—Although in some cases constipation of a mild nature may have been noted since birth it is usual to find that in this condition it becomes severe at a later date.

In a number of cases exciting causes such as psychological trauma, enforced rest in bed due to an illness, or a domestic disturbance in the family involving parental neglect, are considered to be factors which precipitate an attack of persistent constipation. Mental backwardness has been noted in some cases.

There is more emphasis on the constipation than on the abdominal distension in this condition. Banking up of hard faeces in the rectum and sigmoid produces virtually an incomplete intestinal obstruction. There is overflow incontinence of the faeces from the anus and the stools are characteristically large in diameter and size. Abdominal colic and painful defaecation are common. It has been observed in some cases that defaecation in the standing position is less painful to the child than in the normal posture. The pain of defaecation causes voluntary retention of faeces and further constipation.

On examination the abdomen is moderately distended, and faecal accumulations are readily palpable. Peristalsis is less in evidence. The signs of chronic abdominal distension such as flaring of the ribs and eversion of the umbilicus are more commonly absent. Rectal examination reveals hard large faecal accumulations readily palpable in a distended rectum. The sphincter may even be held slightly open by the pressure of faeces above.

V, VI and VII.—Rectal Incontinence. Reconstruction of Anal Sphincters.

V.—Male, aged 40, complained of rectal incontinence. Two years ago he had an operation for an anorectal fistula at another hospital and since that time he has had complete loss of sphincteric control. Patient had an anxious expression. There was marked scarring of the perianal region with loss of sphincteric control.

Operation (Mr. R. W. Raven).—19.1.48: Reconstruction of the anal sphincters. An elliptical incision was made around the posterior aspect of the anus and deepened until the levatores ani muscles were identified. These muscles were reconstructed in the mid-line with interrupted sutures of silk. The divided ends of the internal sphincter muscle were identified and this muscle was reconstructed with interrupted sutures of silk. The wound was closed.

Follow-up examination (14.7.48).—Patient looks well and has lost his anxious expression. He is now continent with no fecal leakage or discharge. Digital examination shows good sphincteric action of anal muscles.

VI.—Female, aged 50, complained of rectal incontinence. In 1928 patient had an operation for gastric ulcer and peritonitis at another hospital. Intestinal occlusion followed later and she was operated on elsewhere. Subsequently she had eight operations on the rectum for anorectal fistula, the last being four years ago. As a result of these operations the patient was absolutely incontinent of feces and had an enema daily in an endeavour to empty the bowel and relieve the incontinence, but with poor results. She was unable to leave her house and life was a burden to her. She was advised to have a left inguinal colostomy at another hospital but refused. She looked distressed and anxious. There was marked scarring in the perineum; the rectovaginal septum was fibrotic and there was no evidence of any anal sphincteric action.

Operation (Mr. R. W. Raven).—30.10.46: Reconstruction of the anal sphincters. The rectovaginal space was exposed through a longitudinal incision through the posterior vaginal wall, the flaps being dissected up laterally. The divided ends of the levatores ani and internal sphincter muscles were identified and reconstructed using interrupted sutures of silk. The posterior vaginal wall was then repaired. Later faradic stimulation of the anal sphincters was carried out.

Follow-up examination (14.7.48).—Patient looks extremely well, is happy and her expression has completely changed. She has perfect control of feces, no leakage, bowels open normally and she now lives a normal life. Digital examination of the anus shows good sphincteric action.

VII.—Female, aged 47, complained of rectal incontinence following an operation on the rectum in U.S.A. twenty-two years ago. An operation for rectal incontinence was performed in Paris four years ago without improvement. She had severe fecal incontinence and the bowels were opened up to ten times a day. Patient looked anxious. There was very poor sphincteric action of the anal sphincters with marked scarring around the anus especially in the rectovaginal septum.

Operation (Mr. R. W. Raven).—9.1.48:—Reconstruction of anal sphincters through an elliptical incision anterior to the anus. The rectovaginal space was opened up and the levatores ani and internal sphincter muscles were identified and reconstructed with silk.

Follow-up examination (28.2.48).—Patient feels well. There is no incontinence of feces, if there are not too fluid; she can hold flatus.

Comment.—These three patients, suffering from a severe degree of rectal incontinence following anorectal operations, demonstrate the value of the operation for reconstruction of the anal sphincters. The improvement in the mental outlook of these patients following operation was most impressive.

VIII.—Carcinoma of Anus. Teleradium Therapy: Twelve-year survival without recurrence.

Male, aged 57, had noticed a growth around the anus for seven months with a gradual increase in size. There was a papilliferous carcinoma surrounding the anus with palpable lymph nodes in both groins. Biopsy of growth showed a squamous-cell carcinoma. He was treated by teleradium to anus and groins, total dose 124,114 mg. hrs.

Follow-up examination (14.7.48).—No sign of recurrence.

Comment.—This is an example of the successful treatment of squamous-cell carcinoma of the anus by teleradium without colostomy; twelve-year survival without recurrence.

Prolapse of the Rectum—Treated by Thiersch Operation.—K. L. JAMES, M.S.

Female, aged 61. Prolapse of the rectum with loss of sphincter control for two years, dating from an operation for prolapse of the uterus treated by anterior and posterior colporrhaphy with amputation of the cervix.

It has been noted that a sigmoid colostomy when performed on a child with true Hirschsprung's disease functions normally and the troublesome offensive flatus ceases. Closure of the colostomy is often difficult owing to fistula formation, but when successful is associated with recurrence of all the symptoms and signs. It would appear, therefore, that the dilated and hypertrophied colon functions normally, and that the segment between the sigmoid and the anus is abnormal and produces the obstructive phenomena.

Finally, if a spinal anæsthetic is administered and the barium enema performed during this anæsthetic, the rectosigmoid spasmodic segment is seen to increase in diameter and lose its haustrations. Therefore, it is highly suggestive that true Hirschsprung's disease is an obstruction caused by spasm in the region of variable length demonstrated by X-rays as a relatively narrow segment connecting the dilated colon with the anus.

The course of chronic constipation.—Most of the cases of chronic constipation, including those showing the long dilated sigmoid loop and the terminal reservoir, have responded satisfactorily to conservative treatment. It is necessary first to evacuate the colon and rectum completely by regular bowel washouts over a period of three to six weeks, and then to purge and train the child to normal bowel habits.

Pathology.—In performing the preliminary colostomy in 10 cases recently, I have studied carefully the transition site between the dilated hypertrophied sigmoid and the more normal-looking rectum and rectosigmoid. The former suddenly narrows down to join the rather thin-walled flabby rectosigmoid which to the naked eye appears quite normal. The length of the normal-looking rectosigmoid varies considerably.

The histology of the dilated portion of the bowel showed hypertrophy of the muscle coats with normal distribution of the ganglion cells in the Auerbach's plexus. In the rectum and distal colon in two post-mortem cases and one specimen removed at operation studied by Dr. Martin Bodian at the Hospital for Sick Children, Great Ormond Street, the ganglion cells in the plexus of Auerbach were completely lacking. It is assumed that this defect seriously interferes with peristaltic movements of the affected bowel segment, and that this leads to secondary hypertrophy and dilatation of the intestine proximal to it.

Treatment of true Hirschsprung's disease.—With attention now focused on the rectum and rectosigmoid the surgical approach lies in the elimination of this portion of the gut as opposed to procedures directed towards the dilated hypertrophied portion.

Operation.—At the present moment there are in progress at The Hospital for Sick Children, Great Ormond Street, two-stage procedures for the removal of the rectum and rectosigmoid segments with preservation of the sphincters in 10 cases. Orvar Swenson in Boston (personal communication) is doing at the present time a pull-through operation with satisfactory cures.

Sympathectomy may have a place in the surgery of this condition in those cases in whom previous surgical procedures have rendered the new approach impracticable or perhaps in those cases in whom the abnormal spasmodic segment is very short.

CASE HISTORIES OF HIRSCHSPRUNG'S DISEASE

CASE I.—P. S. (fig. 1), aged 4 years. Height 39½ in. Weight 34½ lb. This child has been constipated since birth.

Bowel history.—There was no anomaly of the anus at birth. The meconium was noted to come away later than usual. The motions have always been small in diameter. A foul offensive flatus has been constantly present. He strains in an effort to pass his motion but has no pain.

FIG. 1.—P. S., aged 4 years. Hirschsprung's disease showing abdominal distension and peristaltic wave in the sigmoid colon. Previous treatment includes three spinal anæsthetics.

Abdominal distensions.—This was noted to be severe at about 4 months of age. Sometimes the abdomen was very hard and tense, and at other times it was flat and deflated. His mother can deflate him either by abdominal massage or by the insertion of a high rectal tube.

Past history and family history.—Nothing relevant.

Present examination.—Sphincter normal tone, no faeces in rectum; rectum appears normal.

Investigation.—Barium screening shows normal-sized rectum; narrow spasmodic "trickle through" at rectosigmoid region, and a dilated colon above. Evacuation of barium was incomplete.

Treatment.—Liquid paraffin, abdominal massage, deflation with a rectal tube. Mechloly-bromide

X-ray examination.—In true Hirschsprung's disease rectosigmoid spasm or narrowing can always be demonstrated on the X-ray screen in the course of the barium enema and also in most cases on the film. The rectum is found to be of normal size, and the sigmoid above the rectosigmoid segment is dilated, and between the two a barium "trickle through" can be demonstrated on the screen and usually on the film. Evacuation of the barium is incomplete.

In the newborn baby the dilatation above the area of spasm may be absent or so slight in degree that the diagnosis remains in doubt, until the child is a few weeks old. In one baby an area of spasm was demonstrated in the rectosigmoid and sigmoid region, though no dilatation above has been visualized as yet.

In the cases of chronic constipation with faecal retention, after the bowel has been thoroughly evacuated of its contents, examination with the barium enema may show: (1) A long sigmoid loop of slightly increased but uniform diameter which extends distally to the rectum and anus with no evidence of persistent spasm. Evacuation of the barium is quite good; or (2) a terminal reservoir which fills with barium and extends from the anus through the distended rectum to involve the distal portion of the sigmoid. I have called this for descriptive purposes a terminal reservoir. There is no evidence of spasm and it evacuates the barium fairly efficiently.

In regard to the X-ray examination we have used with success a paraffin emulsion of barium which has the advantage of being more easily removed by bowel washouts from the sigmoid in true Hirschsprung's disease. The emulsion needs to be freshly prepared and used within a week:

Barium sulph.	5 oz.
Muc. trag.	2½ oz.
Glycerin	½ fl. oz.
Paraffin emulsion (50% liq. paraffin)	2 fl. oz.
Aq. ad one pint.					

In examining the rectosigmoid region with barium in Hirschsprung's disease it is necessary to allow only a very small quantity of barium to flow in under low pressure as the barium quickly passes through the small rectum into the dilated sigmoid and obscures the picture. Anteroposterior and lateral films are necessary at this stage in order to demonstrate this region properly.

Course of true Hirschsprung's disease.—In this series of cases the course of true Hirschsprung's disease has been one of recurrent obstruction relieved by flatus tubes, bowel washouts or a colostomy. Death has occurred in 10 out of 30 cases, and in the remainder various operations have been performed including spinal anaesthesia, sympathectomy of various types and partial and complete colectomy. None of these cases can be considered a cure, and the following five cases illustrating these procedures show evidence of persisting obstruction (*see* Cases I-V and Table I).

Type of treatment	Number of cases	TABLE I	
		Immediate	Late
Spinal anaesthetic (1-7 given)	22	In some peristalsis and evacuation of flatus were noted	Relapsed to previous state
Sympathectomy ..	3	1 improved for 3 years 1 no immediate effect 1 no effect	Relapsed to previous state Can now manage but still troubled with foul flatus, recurrent abdominal distension. Bowel dilated No effect
Colostomy-sigmoid ..	5	4 colostomy functions normally. General health greatly improved 1 dead	3 relapsed on closure 1 resisted closure and in good health with faecal fistula
Colostomy-transverse (preliminary to rectosigmoidectomy)	11	All function normally and are greatly improved in health	
Colopexy	2	? improvement	Relapsed
Sigmoid colectomy ..	1		Relapsed
Hemicolectomy ..	1		Relapsed
Total colectomy ..	2	1 improved 1 dead	Improved but gross distension of the ileum has occurred

CASE IV.—G. B. (figs. 5 and 6), aged $4\frac{1}{2}$ years. Weight $35\frac{1}{2}$ lb. Height 3 ft. 4 in. This child developed vomiting, constipation and abdominal distension four weeks after birth.

FIG. 5.—G. B., aged $4\frac{1}{2}$ years. Hirschsprung's disease. Showing dilated sigmoid and narrow rectosigmoid before partial colectomy.

FIG. 6.—G. B. Showing dilated transverse colon and narrow rectosigmoid after excision of left half of colon and anastomosis of the right half of the transverse colon to rectosigmoid.

Bowel history.—There was no anomaly of the anus at birth, and the meconium was passed at the usual time. When first seen at the age of 1 month the abdomen was distended with gas, and ladder patterns were visible. Constipation and gaseous distension of the abdomen have persisted.

Rectal examination.—At 4 weeks of age a suggestion of an inner sphincter was palpable at the tip of the finger.

There are no relevant details in the family or birth histories.

Treatment.—Bowel washouts have always been essential to relieve flatus and to evacuate the bowel. At the age of 2 years, an emergency transverse colostomy was performed. At the age of 3 years a partial colectomy was performed, the left half of the transverse colon, the descending colon and the sigmoid being excised. The right half of the transverse colon was anastomosed to the rectosigmoid segment using the spur technique, and the colostomy was finally closed at the age of $3\frac{1}{2}$ years.

Course.—Abdominal distension with peristaltic patterns, flatus and severe constipation have recurred.

Investigation.—X-rays show the narrowing of the rectosigmoid before the colectomy and afterwards, and the dilatation is now gross in the transverse colon proximal to the anastomosis.

CASE V.—M. G. (figs. 7 and 8), aged 15 years. Height 5 ft. 1 in. Weight $94\frac{1}{2}$ lb. This boy has had constipation since birth.

FIG. 7.—M. G., aged 15 years. Hirschsprung's disease. Recurrence of abdominal distension with peristaltic patterns after total colectomy.

FIG. 8.—M. G. Retouched X-ray to show relative diameters of terminal ileum and rectosigmoid segment.

FIG. 8.

and syntropan have been tried without success. At times regular enemas have been necessary. Three spinal anæsthetics have been administered without improvement.

Present situation.—Continual recurrence of abdominal distension associated with listlessness; constipation very persistent. Much foul flatus. General physique poor.

CASE II.—G. J. (figs. 2 and 3), aged 2 years 2 months. Weight 26 lb. Height 34 in. This child has been constipated since birth.

Bowel history.—There was no anomaly of the anus at birth. The meconium was noticed to be passed later than normal. Motions have always been small pellets. The child strains to pass his

FIG. 2.—G. J., aged 2 years and 2 months. Hirschsprung's disease showing abdominal distension.

FIG. 3.—G. J. Showing absence of distension after transverse colostomy which functions normally.

motion but there is no pain on defecation. The constipation has gradually increased and for the last six months has required enemas twice weekly in addition to liquid paraffin and medicines.

Abdominal distension.—This was first noted soon after birth. It is somewhat relieved by the passage of offensive flatus. Visible peristalsis has been observed.

Family history.—Nothing relevant.

Present examination.—Abdomen distended and tympanitic. The distension is central and in the flanks. Visible peristalsis and patterns noted. Ribs flared, umbilicus everted, no masses palpable.

Rectal examination.—Rectum empty, sphincter normal, upper end of the rectum appears to grip the tip of the finger.

Treatment.—Regular bowel washouts and medicines. Two spinal anæsthetics have been administered without alleviation of symptoms. A transverse colostomy was performed at the age of 2 years and 3 months. The subsequent course has been satisfactory with subsidence of distension, regular bowel actions from the colostomy and improvement in health.

FIG. 4.—R. G., aged 9 years 8 months. Hirschsprung's disease showing persistence of dilatation of sigmoid after sympathectomy.

CASE III.—R. G. (fig. 4), aged 9 years 8 months. Height 4 ft. Weight 54½ lb. This child has been constipated since birth.

Bowel history.—There was no abnormality of the anus noted at birth. The motions have always been thin ribands or small pellets and accompanied by much flatus. He strains to defæcate but has no pain other than the ache caused by the abdominal distension. A number of medicines such as senna, milk of magnesia, syrup of figs, paraffin, &c., have been used without permanent relief. For the first two years he required daily enemas.

Abdominal distension was noted soon after birth.

Family history.—This child is one of twins (his twin brother is alive and well and is a much stronger and taller boy).

X-ray.—A barium enema reveals a distended sigmoid colon, a normal-sized rectum, but the rectosigmoid segment is small in comparison with the huge size of the sigmoid.

Treatment.—Medicines, four spinal anæsthetics, and a lumbar sympathectomy caused no noticeable improvement. Spasm, in the rectosigmoid segment, however, cannot now be demonstrated on the X-ray screen.

Present situation.—This child is listless, has recurrent attacks of abdominal distension and his constipation requires only an occasional bowel washout, but his bowels require constant care and attention. Foul flatus is a continual embarrassment.

[June 24, 1948]

DISCUSSION ON THE SURGERY OF URETHRAL STRICTURE

Mr. H. L. Attwater: The extreme gradualness of onset and the frequently insidious nature of its development place urethral stricture in an almost unique class. The initial cause is sometimes a trivial bacterial, chemical, or traumatic event; perhaps long forgotten before the actual contraction makes itself evident. Stricture is less severe to-day than formerly, no doubt due to the greater respect now paid to the canal during manipulations; the control of infection by penicillin and the sulphonamides has doubtless also led to further improvement.

Its slow onset is revealed by the fact that only 5% of cases appear in five years after the initial lesion, whilst some 66% become apparent in fifteen years or more, the average period of generation being 21.5 years (Beard and Goodyear, 1948).

One treatment, though not ideal, has stood the test of time. For some 3,000 years man has dealt with his strictures by means of dilatation but the necessity for extreme gentleness and patience in its use has only been appreciated comparatively recently (Attwater, 1943). From time to time attempts have been made to shorten the tedium of the process and, as early as the first century B.C., it would appear, from the nature of certain instruments discovered in parts of the Roman Empire, some form of external urethrotomy was practised; but even to-day no form of treatment provides a certain cure. All operations involving the urethra are in themselves traumatic procedures, and may be the precursors of stricture, so that there is every need for constant watchfulness and regular dilatations after them: "Once a stricture always a stricture."

SURGERY

The indications for surgical interference are: certain acute complications, a failure to achieve a reasonable result by means of dilatation, or, in some cases, to pave the way for more efficient dilatation later. Cases may fail to dilate because response to the stretching does not follow the usual progressive course. A stricture may be so dense that little, if any, advance can be achieved by the routine use of bougies or sounds; or frequent acute outbreaks of sepsis may make the attainment of even moderate relief impossible. Surgical interference may also be necessary in the case of irritable strictures, which are followed after stretching by fevers, rigors, or attacks of epididymitis. Calculi in the upper urinary tract or behind the stricture, or the spread of sepsis generally, may also demand it. Again, patients sometimes fail to stand up to the routine of dilatation; the fear of pain, and exaggerated sensitiveness, making them intolerant of the passage of instruments through a difficult stricture. In my experience the so-called resilient stricture is by no means a common variety and is often a type of irritable stricture, the apparent rapid return of the stenosis after dilatation being due to muscular spasm rather than to a quick reformation of the actual fibrous constriction. Such can often be circumvented by means of extreme patience and gentleness, or by the use of continuous dilatation by means of an indwelling catheter.

Impassable and impermeable strictures must be dealt with by some form of operative technique in order to gain control of the canal and enable the stenosis to be dealt with by appropriate measures.

URGENT SURGERY

In uncomplicated cases the onset of urgent symptoms, such as retention of urine, may require immediate operation. If the case is already known to have a constriction the state of the renal function may be already known, but in many instances the attack of retention occurs as a primary event. If, after the trial of all conservative measures, it is found impossible to pass any instrument *per urethram*, it is best to do a preliminary cystotomy and to drain the bladder. Special care is necessary if the renal function is low, and prolonged manipulations should be avoided (Stern, 1919). A patient with a chronically distended bladder due to stricture is in much the same position as a man with an enlarged prostate but, possibly because he is often in a lower age-group, he may stand more manipulation than the comparable case of prostatic enlargement. However, if such a case of retention reveals any symptoms of uræmia a rapid survey of the renal function should be made, and great care exercised, if the kidneys are badly compromised.

Urgent sepsis, such as the presence of extensive peri-urethral abscesses, or extravasation, DEC.—UROL. I

Bowel history.—There was no anomaly of the anus at birth. It is not known by the mother how long after birth the meconium was passed. From the first two weeks of life bowel washouts were necessary. The motion if passed spontaneously was like a thin riband of tooth paste in shape. At 3 months it was necessary to perform a colostomy because of a "stricture" three inches above the anus.

Abdominal distension.—The abdominal distension was noted at birth, and this was relieved by the passage of offensive flatus.

Past history and family history.—Nothing relevant.

Treatment.—The colostomy functioned satisfactorily and the child thrived. The colostomy was finally closed at 7 years of age, but the abdominal distension and constipation recurred. Between the years of 7 and 12 he required routine bowel washouts and rectal dilatation at regular intervals. At the age of 12 years, increasing abdominal distension, abdominal pain and vomiting necessitated further treatment in hospital. A barium enema X-ray examination revealed a rectosigmoid narrowing with enormous distension of the colon above this site. A total colectomy was performed in two stages, first a side-to-side ileosigmoidostomy, and later removal of the colon. At the first operation the rectum and rectosigmoid appeared normal and the colon was greatly dilated. The small bowel was not distended. Two months later abdominal distension with visible peristalsis recurred and further laparotomy did not reveal the cause of the obstruction.

Present situation.—Now 15 years old. The patient still suffers from some abdominal distension and much foul flatus, but with a carefully controlled diet in which he avoids the foods which cause him discomfort he can evacuate his semisolid faeces spontaneously.

On examination.—Much scarred abdomen, abdominal distension with visible peristalsis, audible borborygmi.

Rectal examination.—Some solid faeces in the rectum, sphincter normal, no narrowing palpable.

A barium X-ray now reveals a grossly distended ileum and a moderately large rectum but the upper rectum and remaining rectosigmoid appear of normal calibre with very sharp transition to the dilated ileum.

I wish to express my thanks to the surgeons and physicians of The Hospital for Sick Children, Great Ormond Street, for permission to use their cases in this work, to Dr. Benjamin Ward for his co-operation in the interpretation of the X-rays of these patients, and to Mr. Derek Martin for the photographic illustrations. My thanks are due also to Mr. Harold Edwards, for his kindness in providing me with Case V in this series.

DEMONSTRATIONS OF PATHOLOGICAL SPECIMENS BY RONALD W. RAVEN, O.B.E., F.R.C.S.

(1) Right hemicolectomy.

(a) Sarcoïd of ascending colon.

(b) Carcinoma of ascending colon.

(c) Chronic pyogenic infection of the ileocaecal region.

(2) Partial hepatectomy.

(a) Right lobe.

(b) Left lobe.

(3) Sacrococcygeal chordoma with microscopic preparations.

DRAWINGS.—Mr. Raven showed a series of drawings of sacrococcygeal cysts and tumours with reference to the embryology of the anorectal region.

OPERATIONS PERFORMED BY A. LAWRENCE ABEL, F.R.C.S.

for (a) Abdominoperineal excision of rectum.

(b) Hæmorrhoidectomy.

(c) Anal fissure, in the operating theatres, concluded the Meeting.

A new type of traumatic stricture, which illustrates the need for careful handling of the canal, has presented itself in this region in recent years, occurring after endoscopic resection of the prostate, the slight bruising caused during this procedure being capable of initiating a contraction. This is supported by the observations of Stratte and Stratte (1947) who have made a count of the separate movements of the resectoscope and cold punch in the hands of expert resectionists in the U.S.A. during prostatic resection. He finds that these average some 800 odd during resection and 150 or so more during the cold punch operation.

Chronic prostatitis and prostatectomy can set up a fibrous contraction of the internal meatus with occasional involvement of the prostatic urethra. The latter condition can often be extremely difficult to deal with, continuous dilatation followed by intermittent stretching being the method most frequently adopted, though perhaps the recent retropubic approach to the region may inspire some hope that this part of the canal may be attacked more directly in the future. Narrowing, if confined to the internal meatus, may be dealt with successfully, either by suprapubic cystotomy and the resection of a wedge from the neck, or by endoscopic resection of the constricting band.

There is little to be said here about the surgery of stricture of the urethra in the female, though these lesions are more common than is generally supposed (Daniel, 1939). They can be easily missed and may be the only lesions responsible for the patient's symptoms. They should not be neglected because, as the female urethra corresponds to the posterior canal in the male, and as the effect of a stricture varies inversely with its distance from the bladder, any contraction in the female canal will have, other things being equal, a more profound effect than the usual anterior stricture in man. Their ætiology is the same as in the male, but parturition must be added to the list of traumatic causes of injuries to the urethra. Most of the strictures are situated in the outer third of the passage (Pugh, 1932). The existence of congenital stricture in the woman has been denied but this is disproved by the fact that cases are on record which have existed from birth without evidence or history of injury or inflammation (Boyd, 1929a). Whilst the inflammatory varieties can be dilated the congenital stricture, whether a simple constriction of the external meatus, or taking the form of a little flap-like formation of the lower lip, can be readily dealt with by simple section.

CONGENITAL STRICTURES

A detailed description of the various congenital contractions of the urethra would be too long to include in the present discussion. In addition to pin-hole meatus other conditions of a highly diverse character are occasionally met with and may be situated in almost any part of the canal, sometimes affecting the urethra alone, and at others being only a portion of a widespread collection of deformities of the urogenital and other systems. Each case may present individual characteristics which may demand special methods according to the particular problem involved. They may present great difficulties during the course of surgical intervention and are often more fitted to the craft of the plastic surgeon than to that of the urologist.

SURGICAL METHODS

If dilatation of a stricture is inapplicable some method of surgical approach must be selected. Caulk (1931) has stated that, out of 45 cases dealt with by simple section, 2 were done by internal urethrotomy, and 43 by the external method, and that of uncomplicated cases only 0.6% to 1% were so dealt with. It must always be remembered that it only needs slight trauma to initiate a stenosis, and that it may take many years before the constriction becomes apparent. Any external or internal wounding of the urethra, therefore, may be followed by a contraction; and this would seem to be more liable to occur when the wounded area is the seat of an inflammatory fibrosis. Sepsis undoubtedly plays a part, both in the original genesis, and in the reformation of a stricture; and, although this may be modified by modern methods of control, the danger exists. For this reason it has always appeared to me to be better to deal with a case presenting urgent and complicating symptoms, not otherwise remediable, by a preliminary suprapubic and by subsequent dilatation when possible, rather than by cutting the stricture and adding trauma to sepsis.

A suprapubic allows inspection of both extremities of the blocked canal and will often permit dilatation to proceed as soon as oedema and spasm have subsided. Subsequent stretching also can often be carried out more easily and smoothly owing to the passage being at rest (King and Smith, 1935). If stretching is impossible urinary diversion provides a period during which sepsis can be controlled and will pave the way for a more deliberate approach later. Also during this time fistulæ in the neighbourhood of the stenosis which may occasionally refuse to heal and which are maintaining active sepsis can be dealt with by dissecting them out, and any other complication can be attended to before proceeding to the attack on the stenosis.

must be dealt with by urinary diversion, and appropriate incisions for the local drainage, according to the particular nature of the case. Antibacterial therapy, penicillin and the sulphonamides, should also be freely employed.

Traumatic lesions of the urethra with a view to preventing stricture must receive careful attention. Such cases fall into three classes: those which are due to actual wounding by flying fragments, stabs, &c.; bruises ranging from slight contusions to actual laceration, such as may result from kicks, falling astride beams and the like, which are usually situated in the bulbar area; and lastly major accidents such as the result of crushing injuries with fractures of the pelvis.

In the latter type, in which the urethra may be merely bruised, lacerated, or even torn completely across, the profound shock must first be combated. If the urethra appears to be damaged, in order to relieve retention a simple, not too determined, attempt to pass a small, soft rubber catheter is permissible, provided that efforts are not pursued too long or too energetically. If the catheter slips into the bladder, well and good but, if not, a suprapubic cystotomy should be done at once and the urine diverted. At the same time an incision may be made over any swollen area to evacuate blood-clot, or to drain an extravasation, and even in a suitable case to repair the torn urethra. This last, however, will often have to be deferred because of the shocked state of the patient, a careful watch being kept meanwhile for signs of extravasation or of pus formation.

As soon as permissible a careful investigation of the exact urethral deformity must be undertaken by means of cysto-urethrography, urethroscopy, or by sounding. If discontinuities are found, and the case allows the passage of instruments, gentle intermittent dilatation should be commenced. If, however, this is difficult or impossible, a careful exploration of the injured region by way of the perineum will be required, as soon as all evidence of acute sepsis has completely subsided.

There is one serious type of injury where, occasionally, as the result of a crushed pelvis, there is a complete division of the prostatic urethra and perhaps a wide separation of the segments by a collection of blood. An immediate suprapubic cystotomy and an opening up of the blood-filled cavity must be provided and, as soon as the condition of the patient will permit, an attempt should be made to approximate the severed portions of the urethra. If this is not done, either a complete block, or a severe form of stricture in the pelvic urethra, is certain.

Many traumatic urethral injuries are difficult to assess, and whilst it is easy to undertake too much, it is equally possible to be too conservative. Vigorous instrumental attempts to relieve retention, or to reach an exact diagnosis immediately after the injury by means of catheters, sounds, urethrosopes, or by the injections of radiopaque substances *per urethram* must be sternly held in check, and nothing but a simple gentle trial with a soft rubber catheter permitted. All such active measures may cause further laceration and spread infection; and even evidence derived by the use of a catheter may prove fallacious, unless carefully checked, as it may tap a pool of extravasated blood-stained urine which is not in the bladder at all, a condition, which if not appreciated, may lead to disastrous consequences.

Intravenous pyelography, which is reasonably safe in such cases, will sometimes reveal the nature of the injuries when the distribution of the shadows produced after the contrast medium has collected in the bladder is carefully studied (Boyd, 1929b; Troell, 1945).

DELIBERATE SURGERY

When surgical intervention in stricture is to be undertaken for any reason some form of deliberate approach must be adopted according to the requirements of the particular case; and the best results are to be expected when all septic reactions are completely under control. Any operation should cause the least possible trauma to the urethra because, although it may result in an immediate opening up of the canal, it may cause injurious stimulation to the constricting process already present. Any injury, however trivial, may cause stenosis, and wounding of the urethra, even when carefully performed during an operation, may result in subsequent contraction. For this reason, the simple cutting of a stricture, whether by internal or by external urethrotomy, cannot be regarded as certainly curative but only as a means of circumventing an awkward corner. Many cases no doubt cease to contract after cutting but such a result is fortuitous and should not be too optimistically anticipated.

About 70% of stenoses are situated a centimetre or so beyond the distal end of the membranous urethra in the bulb and from time to time all varieties occur in this locality, inflammatory, traumatic, and congenital; the impassable and impermeable types of these being the conditions which most often call for surgical interference. Such strictures are usually single in number though double or even multiple constrictions occur.

method is especially suitable for cases in which the narrowing consists of a single constriction in the perineal urethra.

The technique which I employ can be best illustrated by a short résumé of a case, the details of which have been already published. After a motor accident, which had caused a rupture of the bulbar urethra, an external urethrotomy had been done. This was followed by a tight stricture with a permanent perineal fistula. When I first saw him, five weeks later, there was an impassable stricture and all the urine was being passed by way of the fistula though fortunately the external sphincter was undamaged and he had a good control. There was a large tender mass in the perineum consisting of septic infiltration round the fistula and the site of the damage to the canal. A suprapubic cystotomy was done and nothing further was attempted for three months. By this time the perineal mass had greatly diminished in size though there was still considerable induration. The perineum was opened; all the indurated tissue was cut away by sharp dissection; and the two ends of the urethra were mobilized as far as I felt justified in doing so, and mobilization can be carried out extensively without fear of necrosis because of the good vascularity. In spite of this a gap of about 2 cm. remained even after tension sutures had been inserted in the posterior part of the wound. Accordingly a catheter was passed through the length of the canal bridging the raw gap, and the wound was lightly closed. Subsequent progress was uninterrupted and both suprapubic and perineal wounds were soundly healed in five weeks with a perfect functional result. Intermittent dilatation followed. (Attwater and Preiskel, 1933.)

This type of single constriction in the bulb will nearly always respond to such a method with a high proportion of good results and with modern uses of chemotherapy would seem to have a much wider application than formerly even when the urethral gap is complete and extensive.

If the ends of the urethra can be approximated without tension they should be accurately sutured. MacGowan (1923) does this by dividing the end of each segment longitudinally for half an inch (1.25 cm.) or so, so as to provide three flaps, or tags, one posterior, and two lateral ones, one on each side. The corresponding ends of these flaps are sutured together transversely, and the resulting longitudinal slits are either lightly sutured or left open. If the stricture can be excised together with all indurated tissue without completely sacrificing the mucosa at the site of contraction, this should be done whenever possible; a strip along the roof is usually retained to act as a bridge to encourage the proliferation of the epithelium.

When fibrosis has encroached upon the membranous and prostatic urethra, the outlook is often unfavourable and opinions as to the best method of dealing with them are divided. Excision of as much as possible and dilatation of the rest has been adopted by some. Others on a few occasions have attempted an elaborate deep dissection of the stenosed area by the Young (1936) perineal route through an inverted Y- or U-shaped incision, but during all such proceedings great care must be taken to avoid injuring the external sphincter or its nerve supply which may result in an uncontrollable incontinence.

Actual plastic proceedings in cases of excision of the bulbar urethra are rarely called for, but if, owing to massive destruction of the canal, no sort of approximation can be made, a skin flap can be grafted across the whole deficiency between the two openings of the severed urethra, thus converting the gap between the widely separated segments into a temporary skin-lined gutter with the anterior extremity of the membranous and prostatic urethra opening on to it behind and the posterior end of the anterior segment leaving it at its distal extremity. As soon as this flap has safely healed further procedure involves the refashioning of an intervening channel which will fill the space between the two urethral openings. This is done by means of two lateral flaps turned inwards so as to reform the canal lined with skin connecting the segments of the urethra. The resulting raw area is in turn covered by a graft. Such procedures are akin to those used in some cases of hypospadias when using the Ombredanne technique.

As a rule, however, in the absence of inflammation and sepsis, reliance can be placed on the natural tendency of the urethral mucosa to proliferate quickly and to cover a raw gap, which may have been left after an excision, even when this is of an extensive nature.

In recent years some attempts have been made to make more certain of a rapid epithelial regeneration by passing a catheter when the excision is completed, a skin graft being wrapped round the catheter with the epithelial side inwards. The instrument is so adjusted that its graft-covered portion bridges the raw space in the canal, the essential being to bridge any part of the urethral channel which has been denuded of its mucosa with healthy epithelium as soon as possible.

I suggest, therefore, that in the treatment of stricture the method of intermittent dilatation, though not ideal, is still the method of choice; and that, if circumstances render surgery necessary, simple division of a contraction, either by internal or external urethrotomy, is not enough (it may be used on special occasions but is apt to be followed later by recontract-

EXTERNAL URETHROTOMY

That urethrotomy cures is a fallacy, it only provides an immediate relief, often temporary, to the most painful and dangerous symptoms, and in too many cases it is followed later by a recontraction perhaps in a worse form than before.

There are two ways of doing an external urethrotomy: (1) The Syme technique, in which a special narrow-ended grooved staff is passed and cut down upon. This demanding as it does the passing of an instrument through the stricture was never extensively practised because it did not deal with the impassable case and only complicated subsequent dilatations.

(2) When no instrument could be passed some form of Wheelhouse technique held the field for a long period and is still practised. Without going into operative details, which are well known, there is, however, a noteworthy point. In the past tracing the narrow stenosed part of the canal was often extremely difficult, even with the use of methylene-blue staining to facilitate the finding of the narrow path, or by a deep dissection of the perineum and opening the urethra behind the stricture, thus allowing the latter to be attacked both behind and in front.

This finding of the urethral lumen within the stricture has usually been regarded as obligatory but my colleague Loughnane (1941) cuts down on a sound in the anterior urethra and withdraws it with a 22F rubber tube threaded over its tip, thus implanting the tube in the anterior urethra from the perineal wound to the external meatus. He then passes a retrograde sound from the suprapubic opening and cuts down on its tip, where it bulges in the perineum. He now withdraws it with the perineal end of the rubber tube threaded upon it. This tube now passes continuously from the external meatus to the bladder and out through the suprapubic opening. It is fixed in position by a safety pin at either end. No notice is taken of the constricted part of the canal which is by-passed. If there is a fistula, or the perineal wound is septic, it is loosely packed with acriflavine gauze and allowed to granulate. The rubber tube is rocked to and fro daily, and changed weekly for a larger size, until 30F is reached. It is retained until the perineal wound is healed. A 28/32 Clutton sound is then passed intermittently at increasing intervals until a space of six months is attained which is kept up indefinitely.

INTERNAL URETHROTOMY

I have always regarded internal urethrotomy as having a limited application. It presents a dangerous appeal because it cuts short the distresses and difficulties of urethral stricture in an almost dramatic manner and is, therefore, pleasing to both patient and operator alike. Unfortunately far too often it fails to produce a lasting result, and the subsequent recontraction is frequently so hard as to be quite undilatable, demanding a second application of the urethrotome, or even more extensive interference. Moreover, the proceeding itself is not free from danger and may be followed by untoward symptoms from bleeding and sepsis.

There are, however, a few occasions when the method may be useful. When for some reason it is necessary to obtain a quick restoration of the urethra to an approximate normal (Lowsley, 1935); when after a previous internal urethrotomy a stricture has become so indurated and gristly as to be quite undilatable (Lazarus, 1941); or it may be used sometimes when dealing with a true resilient stricture though this type is not so common as is sometimes imagined; and lastly strictures have been so dealt with on occasions as a preliminary to an urgent cystoscopy or lithotripsy, or when the patient finds it impossible to attend regularly for treatment of a narrow stenosis.

As this operation seems to be an apparent short cut to normality it is popular with military surgeons because of its comparative simplicity and frequent good immediate results, permitting the man to be returned early to duty (Botsford, Harrison and Trichel, 1945). It is forgotten, however, that a traumatic stricture may have been superimposed upon an inflammatory one or that a later recurrence of the contraction may be much worse than the original.

EXCISION

If the stricture-bearing area can be wholly removed, the edges of the divided urethra accurately joined, and if healing takes place with a minimum of scar formation, excision holds out a far greater hope of permanent relief than any other method; but again, owing to the slow and insidious onset of recontraction, it would be a bold man who with present knowledge would give his patient *carte blanche* as being completely cured, even after excision. The only safe course is to maintain careful supervision and six-monthly dilatations.

The first urethral excision was done about the year 1812 but produced no results to encourage its being generally adopted and it was not until Legueu introduced preliminary suprapubic diversion of the urine that surgeons began to look upon excision with any favour. Drainage of the bladder permits the control of sepsis at the site of the stenosis and often renders the case suitable for the removal of the diseased portion of the canal. The

External urethrotomy is essential in some instances but it does lead to a greater amount of fibrosis afterwards. Marion's method of urethroplasty seems to me to be limited in its application to cases of traumatic stricture where only a short length has been affected by fibrosis; in strictures of inflammatory origin, the urethral narrowing usually spreads for a considerable distance beyond the grossly constricted portion of the urethra. I have carried out urethroplasty in half a dozen patients and I do not regard it as curative since they all required regular dilatation; one patient, after two easy dilatations, failed to report for two years when his stricture was found to have reformed and was so tight that an external urethrotomy had to be performed. Marion actually mentions in his book that he sometimes has to carry out an external urethrotomy after his operation to permit of the initial dilatation. I have been struck by the fact that sexual function is not impaired, and may be actually improved, following urethroplasty and three of my patients, at least, have had no trouble with intercourse.

One type of stricture will not respond to dilatation and that is the meatal. Where only the external meatus is involved a simple meatotomy will suffice but I have encountered a number of patients with extremely tight strictures of the meatus where the process has spread back until it involved the last 2-3 cm. or more of the urethra. Many of these people have shown, in addition, a peculiar induration of the glans and it was not possible to relieve them by the usual type of meatotomy. In such cases it is my practice to create an artificial hypospadias by making a short incision immediately behind the glans and then stitching the urethra, diamond fashion, to the skin. This gives a complete relief and does not interfere with sexual function. The urinary stream is apt to spray but this can be minimized if the incision used is short. I do not know what the ætiology of this peculiar condition is but, once started, it appears to be progressive and it may spread back for a considerable distance. After the creation of the artificial hypospadias the glans loses its induration and becomes soft and supple.

Mr. H. Hamilton Stewart: I wish to describe briefly a procedure which I have carried out for the treatment of cases of generally contracted and strictured penile urethræ. There are two essential prerequisites.

(1) The urethrogram should reveal that the urethra behind the region of the peno-scrotal angle is of normal calibre.

(2) A foreskin should be present.

Stage I.—Having discovered that the region of the bulb and posterior urethra are normal, the penile urethra and skin on the ventral surface of the organ are split down the middle line until the normal urethra is reached. The external urethral orifice is now situated in the region of the peno-scrotal angle or just behind it. The cut edge of the skin and mucous membrane of the urethra at the new external urethral orifice are sewn together with ten-day fine catgut. Elsewhere the skin and mucous membrane of the guttered urethra are sutured together with fine nylon sutures.

Stage II.—After a period of three months or longer a plastic operation of the Ombrédanne type is performed. A skin flap is obtained from the scrotum and the foreskin is also utilized.

Stage III.—This is carried out exactly as advised by Ombrédanne, and is a very important part of the operation. This stage should not be performed until at least two months have elapsed after the second stage.

This procedure makes it unnecessary for any further instrumentation to be carried out, and the organ erects in a perfectly normal manner.

I strongly recommend this procedure for the treatment of these difficult cases.

[Lantern slides of urethrograms before and after operation were shown.]

Mr. H. P. Winsbury-White: Mr. Attwater rightly called attention to the seriousness of stricture in the female. I have seen a number of these cases and I entirely agree with him. It has been my experience that when one of these cases comes to the Out-patient Department it is often impossible to get even a filiform bougie through the obstruction, and one generally has to admit the patient to hospital for treatment under an anæsthetic. Subsequently unremitting attention for dilatation is required.

These female patients are undoubtedly very prone to attacks of pyelonephritis.

With regard to treating an impermeable stricture by the retrograde method, I have done several cases in this way and have found the ultimate results highly satisfactory. When suprapubic cystostomy is carried out for the relief of retention of urine in stricture cases if the drainage is continued indefinitely the stricture will get very much worse, and at last may become impermeable. It is therefore necessary to see that the suprapubic drainage is not unduly prolonged. On the other hand relief of the retention due to stricture by suprapubic drainage benefits the stricture when the drainage is continued only for a short time.

External urethrotomy in the ordinary sense is, in my experience, a very bad operation.

tion of the stenosis in a more intractable form than the original); and that, whenever possible, after diversion of the urine in order to gain control of all septic reaction in the field of operation, a complete excision of the stenosis together with all inflammatory induration should be adopted. During all such proceedings every effort must be made to avoid unnecessary trauma and the new canal should be afforded every opportunity of relining itself with healthy mucosa as quickly as possible.

Mr. William S. Mack: There is a general impression that, with the advent of sulphonamides and penicillin, gonorrhœa and non-specific urethritis have ceased to give rise to urethral stricture. I am by no means convinced that this is so and I still encounter early strictures during routine urethroscopies on treated cases of gonorrhœa; these patients have all had previous attacks of urethritis, either gonococcal or otherwise, and the strictures are presumably caused by these previous infections. The ominous feature, however, is that some of these patients were treated in the past purely by sulphonamide and were dismissed "well" after a smooth and rapid recovery. Figures are fallacious but the following are of interest: During 1935 and 1936 just before sulphonamides were used in treatment, 3,142 male patients, suffering from acute gonorrhœa, were dealt with in the Corporation of Glasgow Venereal Diseases Clinics. During routine tests of cure, five patients of this series were found to have urethral stricture on urethroscopy. During 1946 and 1947, 18 examples of urethral stricture were detected on urethroscopy out of 6,082 patients with acute gonorrhœa. On questioning a number of these patients it was found that some of them had had their previous attack of gonorrhœa subsequent to 1936 and had been treated with one or other of the sulphonamides only; there was nothing in their story to suggest that progress had been slow.

These figures do not include cases of stricture found in patients with non-specific urethritis, since the record system in Glasgow does not deal with this, but there is no doubt that non-specific urethritis has increased greatly during recent years and that it is often difficult to clear up. Stricture can, and does, follow these non-specific infections of the urethra. While non-specific urethritis may represent a clinical entity, many patients suffering from it give a history of a previous gonorrhœa and there seems no doubt that some examples of the condition do represent the end-results of this antecedent infection. It is not uncommon, indeed, to find that a mild urethral discharge is due to a stricture and the discharge may be present for many years before there is any disturbance of micturition. Possibly the public is more "venereal disease conscious" as a result of so much propaganda and it may be that patients with very early strictures are going to venereal diseases clinics rather than waiting until they develop dysuria. I am convinced that gonorrhœa is still playing a major part in the ætiology of stricture in spite of modern methods of treatment. It is still too early to say what will happen with penicillin—after all, strictures do not cause dysuria for many years after they have begun to form—but it is well known that penicillin-treated gonorrhœa may leave a patient with a slight urethral discharge for months afterwards; it may be that this represents a mild inflammatory process which will later give rise to a stricture.

There are, as the opening speaker has pointed out, few advances in the actual treatment of stricture, and treatment depends largely on individual preferences. I prefer to rely on very slow and gentle dilatation and to avoid operation, unless this is absolutely necessary. Where operation is required I generally employ internal rather than external urethrotomy. The urethrotome merely divides the fibrous ring at one part and thus permits of dilatation.

[May 24, 1948]

MEETING HELD AT THE ROYAL COLLEGE OF SURGEONS, LONDON

Variations of the Teeth of the Green Monkey in St. Kitts

By Sir FRANK COLYER, K.B.E., F.R.C.S.

THE Green Monkey (*Cercopithecus aethiops sabaeus*), whose normal habitat is West Africa, was introduced into the West Indian island of St. Kitts by the French when it was in their possession. I am informed by Mr. Carleton Evelyn that the monkey "has been locally established for quite 250 years. Père Labat who visited the island in 1700 speaks of some of them being shot and of others kept as pets, which indicates that they were then well established, and Dr. Graenger writing some years later calls them 'the pest of Liaminga's hills.' They are still a pest destroying the sugar cane, ground provisions and anything that they can lay hands on. The wild berries would appear to be the chief diet of those living in the high wooded area of the island."

In the early part of 1939 I received from Mr. Carleton Evelyn a parcel of 14 skulls and amongst them were two showing numerical variations. As it was possible that this marked rate of variability was a fortuitous circumstance I decided to try and obtain more material. Unfortunately war broke out and it was not until last year that further consignments of skulls were received, bringing the number available for investigation up to 92, a number sufficient to allow a fairly reliable idea to be gained of the variability of this animal.

The permanent dentition is present in 76 skulls and amongst these are four with numerical variations of the teeth. The details are as follows:

(i) Male. An extra tooth—unerupted—posterior to the mandibular right third molar. The tooth, as shown in fig. 1, is embedded in the ramus, the crown is close to the third molar and the root is directed upwards (A. 72.615).

FIG. 1.—*Cercopithecus aethiops sabaeus* (The Green Monkey). Right half of the mandible, view of the inner surface. An extra tooth is embedded in the bone posterior to the third molar. The bone has been removed to uncover the root of the tooth (A. 72.615).

(ii) Female. An extra incisor in the left side of the mandible (A. 72.63).

(iii) Female. An extra incisor in the left side of the mandible. In this specimen the mandibular right third molar and the right maxillary third molar are misplaced as shown in figs. 7 and 9. On the external aspect of the roots of the mandibular third molar there is a web of cement which extends about two-thirds down the roots. In each maxillary third molar the external roots are fused with the internal root (A. 72.6712).

(iv) Female. The mandibular right third molar is absent. The mandibular first molars are rotated, which is a rare positional variation (A. 72.637).

The number of skulls showing absence of, or extra teeth is 5.3%, which is a marked variability in a species. In 104 skulls of animals from Africa, some of which had been in captivity, there were two extra teeth, a percentage variation of 1.9.

Amongst the twelve skulls with the deciduous dentition in position there is one in which the crown of the mandibular right second incisor shows partial dichotomy (A. 72.6361).

Variations in the number of the roots of the third molars are present in 20.8% of the 72 skulls in which the teeth are fully, or almost fully, formed. The variations of the maxillary teeth are fusion of the external roots, of the postero-external and internal roots, of all three roots. The variations of the mandibular teeth are fusion of the anterior and posterior roots on their internal aspects and complete fusion of the roots. The variations are not always symmetrical; in one case of fusion of the postero-external and internal roots of the left maxillary tooth the right tooth is normal in shape, and in another of complete fusion of the roots of the maxillary third molar the right tooth alone is affected.

* The numbers refer to the catalogue of the Odontological Section of the Royal College of Surgeons' Museum.

The worst strictures I have seen are those which have been subjected to this method. On the other hand internal urethrotomy is a most excellent procedure in many cases. There are some cases, however, in which the operation is quite inadequate.

So far nobody has mentioned continuous dilatation as a treatment of stricture. This method I have found highly satisfactory in difficult out-patient cases where intermittent dilatation was found to be inadequate. The patient is admitted to hospital and successively increasing sizes of instruments are placed in position during the course of a few days. In this way a bad stricture can be dilated up to a fairly large calibre within a week with the least possible traumatism resulting.

Excision of the stricture I reserve for certain traumatic cases of the bulbous or penile urethra. This operation is satisfactory with these cases because the constriction tends to be more localized than is sometimes the case in the extensive stricture resulting from inflammatory and other causes.

Mr. A. Wilfrid Adams: Post-prostatectomy Obliteration of Penile Urethra.

FIG. 1.—Pre-scrotal meatus for post-prostatectomy stenosis of urethra.

A patient was sent to me with permanent suprapubic drainage which he had had for a year since removal of his prostate. He was aged 66, healthy in general appearance but somewhat resentful in expression.

On examining the penis the meatal margins were seen to be normal but the opening was sealed and smooth, suggesting congenital absence of urethra. I examined the proximal urethra via the suprapubic opening and found tight stenosis of the internal meatus through which a sound could be passed as far as the root of the penis. The whole shaft of the penis was impermeable.

He was anxious to dispense with the tube so I divided the urethra at the penoscrotal junction, exteriorized it there, dilated the neck of the bladder and the suprapubic fistula healed. He is more than grateful for the restoration of micturition which is perfectly free still.

The aetiology of this case is, presumably, traumatic urethritis from an indwelling catheter during his prostatectomy. The surgeon avers that the catheter was not in the urethra unusually long. Such perfect obliteration of the distal few inches of the urethra in this connexion is unique in my experience.

Mr. A. W. Badenoch: The retropublic approach is undoubtedly the best when dealing with rupture of the prostatic urethra seen soon after injury. When a stricture has been established, however, I have found it impossible to expose the urethra on account of scarring from dense fibrous tissue, and certainly, in my experience, this approach has not helped in the treatment of a fully developed stricture of the prostatic urethra. In a recent case, a man of 26 years had had an injury nine months previously. This was treated by suprapubic cystotomy, and in spite of subsequent operations there had been complete failure to pass an instrument along the urethra since the injury. I exposed the prostatic urethra but it was impossible to identify the stricture. The bulbous urethra was exposed in the perineum, the torn distal end identified, and the urethra freed for about one inch. A metal bougie was passed retrogradely and the stricture broken through. The open end of a catheter was attached to the bougie and brought into the bladder. The pointed end was passed retrogradely along the bulbous urethra, and the torn end of the latter was sutured to the catheter. The catheter was then pulled up into the bladder, bringing the bulbous urethra with it to lie in the region of the prostatic urethra. This catheter was kept in position as a splint for ten days, the bladder being drained suprapubically. On removal of the suprapubic tube at the end of fourteen days, the patient was able to pass water. A full-sized instrument can now be passed.

It is interesting to note that while the patient had been impotent for the nine months between his injury and this operation, his potency has now returned.

shown in fig. 3. The tooth, it will be observed, is situated in a more vertical position than in fig. 2, but the slight inward inclination is still present. A further movement upwards impels the crown of the tooth along the posterior surface of the second molar and brings it into a vertical position. These stages are shown in figs. 4 and 5. In fig. 4 the anterior border of the occlusal surface has reached the crown of the second molar, in fig. 5 the tooth has moved into a vertical position.

It seems, therefore, that if the tooth is to take its normal place in the arch the tooth-bud must be given off from the tooth-band in a position which, at a certain stage of growth, will bring the convex surface of the anterior aspect of the crown into the concavity in the posterior surface of the second molar.

The mandibles with misplaced third molars are as follows:

(i) In the one shown in fig. 6, the crown of the third molar is impacted against the root of the second molar. This abnormality is probably due to the tooth-bud being given off from the tooth-band with such a forward inclination that the occlusal surface tends to reach the root of the second molar lower down than the concavity at a stage when the growth of the roots is complete.

Here, I think, is a convenient place to refer to the difficulty in deciding whether a growing third molar is likely to move into a correct position or into one where it will be impacted against the second molar. As long as the roots are not fully formed there is always the possibility that the apparently tilted tooth may right itself, but where the root is fully formed and the crown is in contact with the root of the second molar well below the concavity then the probability is that the tooth will become impacted.

(ii) In the second mandible the third molar has erupted with the occlusal surface directed well inwards and the external surface so much upwards that in occlusion it is this surface and not the occlusal surface which comes in contact with the maxillary tooth. This abnormality may be traced to an undue tilt inwards of the developing tooth (A. 72.58).

(iii) The third mandible is shown in fig. 7. The tooth has erupted on the inner aspect of the bone with the crown directed inwards and forwards. This abnormality may be regarded as a marked example of the type of variation present in the second mandible. The tooth has moved in its developmental direction and has failed to contact the root of the second molar and so has not rotated into a vertical position.

FIG. 6.—*Cercopithecus aethiops sabæus* (The Green Monkey). Right half of the mandible. The third molar is unerupted and impacted (A. 72.647).

FIG. 7.—*Cercopithecus aethiops sabæus* (The Green Monkey). Right half of the mandible, view of the inner surface. The third molar has erupted on the inner aspect of the bone (A. 72.6712).

FIG. 8.—*Cercopithecus aethiops sabæus* (The Green Monkey). Right half of the mandible. The third molar is much misplaced (A. 72.671).

(iv) The fourth and most interesting case is in the mandible of an old female. On first examining this specimen I thought it was an example of a missing molar but just posterior to the second molar there was a small hole and at the base of this the crown of a tooth could be detected. On removing the bone the third molar was found to be in a horizontal position in the base of the ramus as shown in fig. 8. The crown is directed downwards, a little inwards and is rotated slightly, the lower part which is the normal anterior surface facing upwards. Considerable difficulty was encountered in removing the bone which in places was closely adherent to the tooth, unfortunately a small portion of the anterior root was cut away by the drill. A curious feature about

Fusion of the roots of the mandibular first molar, which is an uncommon variation in monkeys, is present in one specimen (A. 72.6713). Unfortunately investigations of the roots of teeth often involve damage to the specimens and as several formed parts of collections in other museums the number available for examination was limited. In the 36 skulls it was possible to examine there were three with fusion of the roots of the maxillary third molar or 8.3% of the specimens.

In addition to this marked rate of variability in number and shape of the teeth there is also a high rate of variability in the position of the teeth. An abnormal arrangement of the maxillary incisors is present in just over one-quarter of the skulls; the abnormality consists in the protrusion of one or both first incisors beyond the line of the second incisors. In 8 cases the abnormality is well defined.

Positional variations of canines are rare in the apes and monkeys, the variation when present being almost entirely confined to the mandibular teeth. In this series of the Green Monkey there is a mandible in which the right canine has moved in a backward direction and in occlusion impinges against the inner surface of the maxillary tooth which it has displaced outwards (A. 72.639).

In 16 of the skulls there are variations in position of the premolars, the abnormality taking the form, in most cases, of rotation or displacement inwards of the maxillary second premolar; in four of the specimens the abnormality is marked. By far the most interesting variations are those of the third molar. There are four cases of misplaced mandibular teeth and one of a misplaced maxillary tooth. Before, however, describing these most interesting variations it may be instructive to glance at the positions of the third molar in the bone during the period of growth as, I think, they shed light upon the development of the misplaced third molar.

At an early stage in the growth of the mandibular third molar, as shown in fig. 2, the crown of the tooth is tilted well forwards with a slight inclination inwards, the anterior border of the occlusal surface being close to the posterior root of the second molar. With the growth of the root the crown moves upwards and the convex surface of the anterior portion passes into the hollow in the posterior aspect of the second molar; this stage is

FIG. 2.—*Cercopithecus aethiops sabaeus* (The Green Monkey). Right half of the mandible. An early stage in the growth of the third molar. The anterior border of the occlusal surface is close to the posterior surface of the second molar (A. 72.61).

FIG. 3.—*Cercopithecus aethiops sabaeus* (The Green Monkey). Right half of the mandible. The convex surface of the anterior portion of the crown of the third molar has moved into the concavity in the posterior surface of the second molar (A. 72.614).

FIG. 4.—*Cercopithecus aethiops sabaeus* (The Green Monkey). Right half of the mandible. The anterior border of the occlusal surface of the third molar has reached the crown of the second molar (A. 72.651).

FIG. 5.—*Cercopithecus aethiops sabaeus* (The Green Monkey). Right half of the mandible. The third molar is fully erupted (A. 72.665).

shown in fig. 3. The tooth, it will be observed, is situated in a more vertical position than in fig. 2, but the slight inward inclination is still present. A further movement upwards impels the crown of the tooth along the posterior surface of the second molar and brings it into a vertical position. These stages are shown in figs. 4 and 5. In fig. 4 the anterior border of the occlusal surface has reached the crown of the second molar, in fig. 5 the tooth has moved into a vertical position.

It seems, therefore, that if the tooth is to take its normal place in the arch the tooth-bud must be given off from the tooth-band in a position which, at a certain stage of growth, will bring the convex surface of the anterior aspect of the crown into the concavity in the posterior surface of the second molar.

The mandibles with misplaced third molars are as follows:

(i) In the one shown in fig. 6, the crown of the third molar is impacted against the root of the second molar. This abnormality is probably due to the tooth-bud being given off from the tooth-band with such a forward inclination that the occlusal surface tends to reach the root of the second molar lower down than the concavity at a stage when the growth of the roots is complete.

Here, I think, is a convenient place to refer to the difficulty in deciding whether a growing third molar is likely to move into a correct position or into one where it will be impacted against the second molar. As long as the roots are not fully formed there is always the possibility that the apparently tilted tooth may right itself, but where the root is fully formed and the crown is in contact with the root of the second molar well below the concavity then the probability is that the tooth will become impacted.

(ii) In the second mandible the third molar has erupted with the occlusal surface directed well inwards and the external surface so much upwards that in occlusion it is this surface and not the occlusal surface which comes in contact with the maxillary tooth. This abnormality may be traced to an undue tilt inwards of the developing tooth (A. 72.58).

(iii) The third mandible is shown in fig. 7. The tooth has erupted on the inner aspect of the bone with the crown directed inwards and forwards. This abnormality may be regarded as a marked example of the type of variation present in the second mandible. The tooth has moved in its developmental direction and has failed to contact the root of the second molar and so has not rotated into a vertical position.

FIG. 6.—*Cercopithecus aethiops sabæus* (The Green Monkey). Right half of the mandible. The third molar is unerupted and impacted (A. 72.647).

FIG. 7.—*Cercopithecus aethiops sabæus* (The Green Monkey). Right half of the mandible, view of the inner surface. The third molar has erupted on the inner aspect of the bone (A. 72.6712).

FIG. 8.—*Cercopithecus aethiops sabæus* (The Green Monkey). Right half of the mandible. The third molar is much misplaced (A. 72.671).

(iv) The fourth and most interesting case is in the mandible of an old female. On first examining this specimen I thought it was an example of a missing molar but just posterior to the second molar there was a small hole and at the base of this the crown of a tooth could be detected. On removing the bone the third molar was found to be in a horizontal position in the base of the ramus as shown in fig. 8. The crown is directed downwards, a little inwards and is rotated slightly, the lower part which is the normal anterior surface facing upwards. Considerable difficulty was encountered in removing the bone which in places was closely adherent to the tooth, unfortunately a small portion of the anterior root was cut away by the drill. A curious feature about

the tooth is a linear gap about the junction of the crown with the root on the anterior aspect of the tooth. This line is discernible in the illustration and is clearly seen in the radiograph which was taken of the tooth. The exact nature of the defect cannot very well be ascertained without destroying the tooth but the radiograph seems to point to some absorption of the dentine.

A rare variation of the second molar is present in this mandible. Both teeth are rotated, the anterior surfaces having swung inwards and the posterior outwards. In the maxillæ the third molars have the crowns tilted backwards and the antero-external roots of the third molars are overlapped by the postero-external roots of the second molars. The right second molar is displaced slightly inwards and is in abnormal occlusion with the mandibular tooth. The antero-external and internal roots of the maxillary third molars are joined by a web of cement.

The growth and eruption of the maxillary third molar is similar to that of the mandibular tooth. At the stage before the crown is fully formed the tooth is high up in the tuberosity with the occlusal surface directed downwards and slightly forwards. With the formation of the roots the tooth moves downwards and passes into the concavity in the posterior surface of the second molar and then rotates and assumes a vertical position in the arch with ample room between its antero-external root and the postero-external root of the second molar.

Impactions and other abnormalities of the tooth are much less common than is the case with the mandibular tooth and this is probably attributable to the less resisting character of the bone of the tuberosity which allows the crown to move freely backwards. The occlusal surface, even when there is ample room in the arch, is often directed a little backwards with ample room between the roots of the second and third molars. Impaction of the

crown of the maxillary third molar against the root of the second molar does occur but the usual form of positional variation is an exaggerated backward inclination of the crown accompanied by a corresponding forward movement of the roots so that the antero-external root passes under the postero-external root of the second molar. This condition is present in two of the skulls. The most marked example of a misplaced maxillary third molar in the series is shown in fig. 9. The crown of the right tooth is tilted towards the palate and is in abnormal occlusion with the mandibular tooth.

Amongst the skulls of animals from West Africa there was only one showing positional variation of the third molar and in that specimen the mandibular right tooth was slightly inverted.

The facts related above show (i) a marked variability of the teeth of the Green Monkey in

St. Kitts, and (ii) that it is varying more than the animal in its normal habitat. It is of interest to speculate whether this increased variability is due to the altered environment of the animal.

There is evidence that positional variations may be related to variations in number and shape¹. Examples of the relationship are seen in *Erythrocebus* amongst the Old World Monkeys and *Cebus* and *Ateles* in the New World Monkeys. This series of Green Monkeys from St. Kitts is another example of the relationship and the marked variability in the number of roots of the third molars and the comparatively large number of misplaced third molars is most instructive.

¹See Colyer, F. "Variations and Diseases of the Teeth of Animals", London, p. 465.

Section of Orthopædics

President—GEORGE PERKINS, M.C., F.R.C.S.

[May 4, 1948]

Paget's Disease Commencing at the Age of 30.—DAVID LEVAY, M.S., F.R.C.S.

A woman of 37, complaining of *backache*, was found on radiographic examination to have collapse of the second lumbar vertebra (fig. 1).

Further investigation showed changes due to *Paget's disease* in the skull and left femur but in no other bones (figs. 2 and 3).

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

There was a history of a pathological fracture of the left femur at the age of 30, and recourse to the original radiographs showed a typical fracture due to *osteitis deformans* (fig. 4).

The patient's father and a paternal uncle both suffered from the disease.

DEC.—ORTHOP. I

Fracture-Dislocation of Cervical Spine.—DAVID LEVAY, M.S., F.R.C.S.

On 13.6.47 a woman of 42 sustained a fracture-dislocation of the fifth on sixth cervical vertebra, as the result of a heavy cupboard falling on her head at work (fig. 1).

There was quadriparesis, mainly affecting the right arm, and respiratory embarrassment. Skull traction was applied, and reduction completed by manipulation under pentothal anaesthesia after forty-eight hours.

On 4.7.47 wiring and grafting were performed, with post-operative immobilization in a leather collar, which was retained for twenty weeks.

FIG. 1.

FIG. 2.

The neck is now painless and fusion is sound, though the radiograph shows that consolidation has taken place in a position of slight forward subluxation (fig. 2). Function in the right arm has improved considerably, and the other limbs are normal. She is doing most of her own housework.

Congenital Bowing of the Tibia.—J. A. CHOLMELEY, F.R.C.S.

R. W., male, born 4.9.38.

History.—Forward bowing of left tibia was first noticed at 15 months old. There was no history of injury.

September 1941: Admitted to Hertford County Hospital where a wedge osteotomy of

FIG. 1 (13.6.41).—Condition on this date.

FIG. 2 (1.5.43).—Showing plate and non-union.

the left tibia and fibula was carried out. The tibial osteotomy was fixed by a plate (two screws broke after insertion).

February 1942: Walking plaster applied.

May 1942: Plaster removed.

June 1942: Walking plaster reapplied as there was no sound bony union.

September 1943: Plate removed. Clinically and radiologically ununited fracture of tibia below the site of osteotomy.

FIG. 3 (11.1.44).—Showing non-union after removal of plate.

FIG. 4 (7.10.45).—Showing graft fixed by four vitallium screws.

November 1943: Admitted to Royal National Orthopædic Hospital, Stanmore, under my care.

February 1944: Bone grafting from right tibia fixed with four vitallium screws. Some sclerosed bone removed at the site of the pseudarthrosis. Lower end of fibula osteotomized.

July 1945: Caliper with moulded leather leg piece supplied. Discharged home.

October 1945: Upper two screws subcutaneous and painful.

November 1945: Upper two screws removed.

May 1946: Caliper omitted. Moulded leather below-knee splint substituted.

September 1946: Readmitted to Royal National Orthopædic Hospital, Stanmore, on

FIG. 5 (22.4.47).—Incomplete fracture without displacement.

FIG. 6 (5.8.47).—Cyst formation at site of fracture with displacement.

FIG. 7 (14.4.48).—Graft fixed by six vitallium screws, cyst cavity filled by bone chips.

account of pain in left leg following a fall three days previously. X-ray showed crack along the line of lowest screw.

October 1946: Lower two screws removed. Bone drilled at site of crack.

December 1946: Discharged wearing instrument.

April 1947: Fell off see-saw injuring left leg. X-ray shows small crack in left tibia below area of sclerosed bone, previous osteotomy and fracture. Below-knee walking plaster applied.

August 1947: Readmitted to Royal National Orthopædic Hospital, Stanmore. X-ray shows complete fracture of the left tibia with displacement and cyst formation (fig. 6). Clinically non-union was obvious but it was noticeable that there was singularly little pain or tenderness.

Operation.—Bone graft from tibia, fixing graft with six vitallium screws. Cyst curetted and tibial chips used to fill it. Above-knee plaster.

January 1948: Discharged home in plaster.

April 1948: Readmitted to Royal National Orthopædic Hospital, Stanmore.

Present state.—Bony union tibia and fibula with some angulation and sclerosis at fracture site. Left leg is $\frac{1}{2}$ in. short, foot is small and in some calcaneus.

May 1948: Screws removed.

Fracture of Femoral Neck Treated with a Godoy-Moreira Stud Bolt Screw.—J. D. CRONIN, F.R.C.S.

5.5.48: Mrs. L. B., aged 72. Was admitted to the Prince of Wales' Hospital with a history of having stumbled and hurt her right hip. She was unable to walk and complained of pain in the region of the hip-joint.

On examination.—External rotation deformity of right lower limb and tenderness over the neck of the femur.

X-ray: Transcervical fracture of the neck of the femur (right).

Operation (7.5.48).—Epidural anaesthesia; 4 in. longitudinal incision over the lateral aspect of the greater trochanter after reduction of fracture under X-ray control. Guide wire inserted into head and neck of femur in optimum position under X-ray control. Channel drilled through neck and head of femur with cannulated drill ($\frac{1}{4}$ in.) threaded over guide wire. Godoy-Moreira stud bolt screwed into head of femur. X-ray verified posi-

FIG. 1.

FIG. 2.

tion of screw bolt. Collar and nut applied to stud bolt and fracture powerfully impacted by tightening up. Wound closed. Uneventful recovery (figs. 1 and 2).

Two weeks after operation active movements of right hip-joint 45 degrees flexion, 35 degrees abduction, 30 degrees internal rotation, and 40 degrees external rotation.

Osteochondral Fracture of the Patella.—J. S. BATCHELOR, F.R.C.S.

FIG. 1.

On February 11, 1948, the patient, a lad aged 16 years, fell a short distance from a ladder, injuring his left knee. On examination the following day there was a large hæmarthrosis and joint movements were limited and painful. The collateral and cruciate ligaments were intact. X-ray examination (see fig. 1) revealed the presence of two loose bodies lying in the anterior compartment of the joint.

An arthrotomy was performed on March 16. A large fragment of articular cartilage with a thin layer of underlying bone was found loose in the joint cavity, with two smaller cartilaginous fragments. Examination of the patella showed that these fragments had come from the inferior part of its articular surface. There was no evidence of any damage to the femoral condyles.

The mechanism of injury was, no doubt, similar to that described by Coleman (*J. Bone Jt. Surg.*, 1948, 30B, 153). This consists essentially of a lateral subluxation of the patella, which probably occurred in this case whilst the knee was in a position of flexion and valgus. The inner border of the patella is caught by

the margin of the lateral femoral condyle and the fracture is produced by the tangential force applied by the pull of the quadriceps during the return of the patella to its normal position.

Actinomycosis Simulating Osteitis of the Pelvis.—J. S. BATCHELOR, F.R.C.S.

8.10.47: Housewife, aged 40. Admitted to hospital, 1947, with a history of pain in the region of the right iliac crest for three weeks. She looked ill and had a temperature of 101.2°, pulse 130. There was a large, fluctuating, tender swelling over the right iliac crest with marked induration of the tissues in the flank and iliac fossa. A diagnosis of osteitis of the pelvis was made.

The abscess was incised and over a pint of foul-smelling pus was evacuated. Exploration showed that the abscess cavity extended into the retroperitoneal tissues of the iliac fossa, but there was no evidence of bony disease. The cavity was packed with vaseline gauze and penicillin therapy instituted. Culture of the pus yielded a heavy growth of coliform organisms and a scanty growth of non-hæmolytic streptococci.

Following operation the induration of the tissues diminished considerably but there was a persistent discharge of pus from the abscess. Further X-ray examination did not reveal any evidence of bone infection.

On November 15 the patient's general condition had improved and she was allowed to go home. There was still a free discharge of pus from two or three sinuses in the region of the incision, and a diagnosis of actinomycosis was entertained at this time.

13.1.48: Patient readmitted. Her general condition was satisfactory but the sinuses were still discharging freely and there was a hard, tender swelling palpable in the right iliac fossa. Further X-ray examination showed no evidence of bony disease. By the end of January the mass in the right iliac fossa had increased in size and now extended into the right loin. On February 19 the sinuses were explored; a large abscess cavity extending into the true pelvis and filled with gelatinous granulation tissue and pus was found. Following this operation the pus was examined on numerous occasions for actinomycosis with negative results until, on April 15, the Department of Medical Mycology, London School of Hygiene and Tropical Medicine, confirmed the presence of *Actinomyces bovis*.

Since the operation in February, penicillin, 200,000 units eight-hourly, has been administered. There has been a slow but steady improvement in the local condition and the discharge from the sinuses is slowly diminishing.

Tomography in Surgical Tuberculosis

By VINCENT SNELL, F.R.C.S.

TOMOGRAPHY is now of established value in pulmonary tuberculosis, but its value in "surgical tuberculosis" is still undecided. A number of cases have been investigated at Harefield where patients with combined pulmonary and surgical tuberculosis are under treatment, and we have reached the following conclusions, which we feel may be of use.

Tuberculosis of the spine.—Tomography is of considerable assistance in judging the extent

account of pain in left leg following a fall three days previously. X-ray showed crack along the line of lowest screw.

October 1946: Lower two screws removed. Bone drilled at site of crack.

December 1946: Discharged wearing instrument.

April 1947: Fell off see-saw injuring left leg. X-ray shows small crack in left tibia below area of sclerosed bone, previous osteotomy and fracture. Below-knee walking plaster applied.

August 1947: Readmitted to Royal National Orthopædic Hospital, Stanmore. X-ray shows complete fracture of the left tibia with displacement and cyst formation (fig. 6). Clinically non-union was obvious but it was noticeable that there was singularly little pain or tenderness.

Operation.—Bone graft from tibia, fixing graft with six vitallium screws. Cyst curetted and tibial chips used to fill it. Above-knee plaster.

January 1948: Discharged home in plaster.

April 1948: Readmitted to Royal National Orthopædic Hospital, Stanmore.

Present state.—Bony union tibia and fibula with some angulation and sclerosis at fracture site. Left leg is $\frac{1}{2}$ in. short, foot is small and in some calcaneus.

May 1948: Screws removed.

Fracture of Femoral Neck Treated with a Godoy-Moreira Stud Bolt Screw.—J. D. CRONIN, F.R.C.S.

5.5.48: Mrs. L. B., aged 72. Was admitted to the Prince of Wales' Hospital with a history of having stumbled and hurt her right hip. She was unable to walk and complained of pain in the region of the hip-joint.

On examination.—External rotation deformity of right lower limb and tenderness over the neck of the femur.

X-ray: Transcervical fracture of the neck of the femur (right).

Operation (7.5.48).—Epidural anaesthesia; 4 in. longitudinal incision over the lateral aspect of the greater trochanter after reduction of fracture under X-ray control. Guide wire inserted into head and neck of femur in optimum position under X-ray control. Channel drilled through neck and head of femur with cannulated drill ($\frac{1}{4}$ in.) threaded over guide wire. Godoy-Moreira stud bolt screwed into head of femur. X-ray verified posi-

FIG. 1.

FIG. 2.

tion of screw bolt. Collar and nut applied to stud bolt and fracture powerfully impacted by tightening up. Wound closed. Uneventful recovery (figs. 1 and 2).

Two weeks after operation active movements of right hip-joint 45 degrees flexion, 35 degrees abduction, 30 degrees internal rotation, and 40 degrees external rotation.

and in front of it is poorer than expected from the plain film. There is also cavitation of the lower half of D.7. and extensive disease involving the adjacent portions of D.9 and D.10 (figs. 1a and 1b).

CASE II.—S. S., female, aged 26. Bilateral pulmonary disease. Plain X-ray (fig. 2) shows involvement of D.6 with loss of joint space above. D.5 shows a number of shadows the situation of which is uncertain.

Tomogram (fig. 2a) shows involvement of D.3, 4, 5, 6 and 8.

In this case it would never have been possible to determine the situation and degree of the bone involvement without tomography.

CASE III.—J. P., male, aged 22. Plain X-ray (fig. 3)—lateral view of D.10 is obscured by the diaphragm. Tomogram (fig. 3a) shows the cavity to be considerably larger and the cartilage and disc are entirely destroyed.

FIG. 3.—Plain view.

FIG. 3A.—Tomogram, disease more extensive than expected.

FIG. 4.—Tarsal Scaphoid. Plain view.

FIG. 4A. Tomogram.

of bone destruction and the number of vertebræ involved. This particularly applies to the lower cervical and upper dorsal vertebræ, and also to the lower dorsal vertebræ where the structures of the shoulder and the diaphragm respectively may make plain radiographs difficult to interpret.

It is of value throughout the dorsal spine when pulmonary disease is present. In such cases it is often uncertain whether markings on the radiographs are in the bone or the overlying lung tissue.

CASE I.—A. L., female, aged 28. Bilateral pulmonary disease. Plain lateral view shows collapse of D.8 and D.9 with cavitation of posterior two-third of both bodies (fig. 1). Tomograms confirm the collapse; they show the cavity to be larger than suspected. The bone reaction surrounding the cavity

FIG. 1.—Plain view shows disease of D.8, D.9.

FIGS. 1A and 1B.—Tomograms show disease of D.7, 8, 9 and 10. The posterior wall of the cavity is very thin.

FIG. 2.—Plain view shows two vertebræ affected.

FIG. 2A.—Tomogram (part of which is reproduced above) shows five vertebræ affected.

and in front of it is poorer than expected from the plain film. There is also cavitation of the lower half of D.7. and extensive disease involving the adjacent portions of D.9 and D.10 (figs. 1a and 1b).

CASE II.—S. S., female, aged 26. Bilateral pulmonary disease. Plain X-ray (fig. 2) shows involvement of D.6 with loss of joint space above. D.5 shows a number of shadows the situation of which is uncertain.

Tomogram (fig. 2a) shows involvement of D.3, 4, 5, 6 and 8.

In this case it would never have been possible to determine the situation and degree of the bone involvement without tomography.

CASE III.—J. P., male, aged 22. Plain X-ray (fig. 3)—lateral view of D.10 is obscured by the diaphragm. Tomogram (fig. 3a) shows the cavity to be considerably larger and the cartilage and disc are entirely destroyed.

FIG. 3.—Plain view.

FIG. 3A.—Tomogram, disease more extensive than expected.

FIG. 4.—Tarsal Scaphoid. Plain view.

FIG. 4A. Tomogram.

In other regions of the spine tomography is of little value. In the cervical region and the lumbar region the additional evidence gained is not justified by the expense. In the lumbosacral region it is ineffective owing to the degree of penetration required.

Tuberculosis of other bones and joints.—There is little advantage in tomography compared with plain radiographs to compensate for the added expense.

CASE IV.—N. P., male, aged 16. Tomograms of the tarsal scaphoid show cavitation, the largest cavity extending into the joint behind. This is quite clearly shown in one plain view (fig. 4) whereas at least three tomograms must be taken to obtain a comparable result (see fig. 4a).

[July 10, 1948]

MEETING HELD AT ESSEX COUNTY COUNCIL HOSPITAL, BLACK NOTLEY

Tomography of Bones and Joints

By FRANKLIN G. WOOD, M.B., D.M.R.E.

In this paper the value of tomography in the X-ray examination of the spine, ribs, sternum and hip-joints was discussed, the skull being omitted.

Since the introduction of the modern tomography by Grossmann of Berlin in 1935, the method has been applied very generally to the lungs, especially in the demonstration of cavities, but it has not been used universally for bone conditions apart from a few workers who have become interested in the method and convinced of its value.

It is not proposed to go into the theory of tomography in any detail except in regard to

FIG. 1.

FIG. 2.

the question of the thickness of the section made; or put in another way, how far can objects be blurred out by the movement of the tube? This will depend firstly on their position relative to the line of travel, and secondly on the density of the shadow they cast in the film. The best effect is obtained in the case of a long bone when the long axis of the bone lies at

right angles to the line of travel; thus when the tube runs lengthways to the body, the ribs are fairly easily blotted out. On the other hand, when the long axis of the bone lies parallel to the line of travel, the structure tends to be drawn out into straight lines, which persist in several sections and tend to spoil the radiographic appearance. As regards the density of the shadow, soft structures, such as the lungs, are blurred very easily. Dense structures, such as calcified nodes and calcified glands, blur with difficulty, and tend to appear in more than one section.

Tomograms of the spine.—In the case of children the difficulty experienced in ordinary radiography occurs when tuberculous disease affects the lower cervical and upper dorsal vertebrae. In such a condition the child may be unable to sit up, and lies with the shoulders hunched, and the neck rigid; ordinary radiographs will fail to show the extent of the disease. By tomography this may readily be shown. Fig. 1 shows the lateral film of a child aged 2½ years, suffering from tuberculous disease of the first four dorsal vertebrae. The film was taken shortly after admission, and was the best view we were able to obtain by ordinary methods. The area of disease is very poorly defined. In the lateral tomogram, fig. 2, taken at a later date, the extent of the disease is very clearly seen. There is caries of the first four dorsal vertebrae with considerable bone destruction and an unstable spine.

As regards the upper cervical region, it can of course be shown successfully in a lateral film, but the antero-posterior view may be very difficult owing to the lower jaw, which obscures this area. A view through the mouth is difficult to obtain, especially where abscess or dislocation is present. Tomograms made in the antero-posterior position will, however, give a reasonable picture of the region.

In the adult we have used tomography more for the X-ray examination of the thoracic spine, partly as an aid in the differential diagnosis of new growth and tuberculous disease, and also to show the condition of the spinal canal in patients with actual or threatened paraplegia. In such a patient, where there is usually marked kyphosis and considerable bone changes, the spinal canal cannot be seen in the ordinary films. By tomography a much clearer picture is obtained. Also in radiographs of the spine, as indeed elsewhere in the body, there is usually more disease present than is suspected from examination of the ordinary films. Thus, if tomograms are made of the dorsal spine, areas of disease may be disclosed which were not clearly shown in the routine films.

Ribs.—Tumours of the ribs can be demonstrated in greater detail by tomography than by any other method. The patient is turned so that the affected portion of the rib lies parallel to the top of the X-ray couch, and sections are made at the appropriate level.

Sternum.—The sterno-clavicular joints may be very easily shown by the method used for routine lung tomography with the patient either prone or supine. This will show both sterno-clavicular joints and the manubrium sterni. The sternum itself is one of the most elusive bones from the radiologist's point of view. In the lateral position fairly good definition of the sternum may be obtained, unless the bone is depressed and lies in a groove, when it will be overlapped by the ribs. Other views may be taken in one of the oblique positions, with varying success as the ribs and mediastinal shadows obscure the picture. Tomography solves the problem because the rib shadows can be obliterated, and by careful positioning the sternum may be shown unobscured. The patient is placed face downwards in the left semi-oblique position and rotated so that the sternum is 5 to 7 cm. from the table. The tube is angled 10 degrees to the right, and the cassette moved 3 in. to the right in compensation. The central ray is directed just to the right of the spine. In small children the tube tilt is not recommended. By this means quite a good view of the whole of the sternum can be obtained in most cases. Fig. 3 shows a tomogram of the sternum of a boy aged 12½. It will be noticed that the first and second segments of the body are in process of uniting, whilst the second and third segments have already fused. Consideration of a short series of tomograms of the sternum in children suggests that union of these segments takes place earlier than is commonly supposed, and is complete in the case of the first and second by puberty, whilst the second and third segments unite about two years before this.

Hip-joints.—It is not claimed that tomography has any great contribution to make to the radiology of the hip-joint, but it may be used to show tuberculous foci in the acetabulum or neck of the femur in conjunction with the usual anteroposterior and lateral films.

FIG. 3.

The Late Results of Tuberculosis of the Spine in Children, with Special Reference to Spinal Grafting

By D. M. DUNN, F.R.C.S.

THE total number of cases under the age of 15, and of which a reasonably satisfactory follow-up is available is 84—not all of these had all their treatment at Black Notley. Four of these cases had demonstrable radiological lesions in two distinct areas of the spine, making the total number of lesions 88. In the tables which follow the number of lesions is considered and not the number of patients. Moreover, a case may occur in both the non-grafted series as a failure of conservative treatment and later in the grafted series.

Fifteen of these cases had spinal fusion of the Albee type but not all were operated upon in this hospital. Some had their graft at the end of the first period of conservative treatment, others only after two, or even three attempts to arrest the disease by recumbency. In some cases an attempt was made to fuse the spinous processes only of the affected vertebrae, and in others to include the spinous processes of the bodies above and below the affected area.

In dividing the cases into satisfactory and unsatisfactory results, I have been guided entirely as to whether, after an adequate period of conservative treatment, the patient, having been discharged from hospital as clinically quiescent, had or had not to be re-admitted because of further symptoms referable to the spinal lesion.

The degrees of deformity have been assessed in three grades—slight, being those with or no deformity up to 45 degrees; moderate, being those with from 45 to 90 degrees deformity; and gross, being those with deformity of more than 90 degrees.

TABLE I.

Level of lesion			Average duration of primary treatment in years	Length of follow-up in years		
				Max.	Min.	Average
Cervical and upper dorsal						
Total 10	Satisfactory	9	2 2/12 Died	11	1 4/12	5 4/12
	Unsatisfactory	1				
Dorsal and dorso-lumbar						
Total 45	Satisfactory	13	2 4/12	9	1 2/12	4 3/12
	Unsatisfactory	32	2 3/12	15	1	7 3/12
Lumbar						
Total 24	Satisfactory	18	2 2/12	9	1 2/12	4 3/12
	Unsatisfactory	6	2	15	1	7 3/12

It will be noticed that the average follow-up period of unsatisfactory results is appreciably longer than the satisfactory results, indicating the late incidence of further activation.

TABLE II.—MORTALITY

	Total No. cases	Died	%
Non-graft	79	9	11.4
Graft	15	3	20

Of the cases not grafted, except for one boy who died at the age of about 25 with Parkinson's disease, not one survived beyond the age of 7 and five had died at the age of 4 or sooner. Seven of these cases died of tuberculous meningitis and one of military tuberculosis. Two developed the meningitis within three months of operation on a tuberculous focus. Two others died following a mis-diagnosis and failed initial treatment. It seems, therefore, that if the child survives the bacillæmic stage of the illness till he is 7 or 8 years old he is unlikely to die as a result of his tuberculosis. Of the three cases which were grafted and later died, one was grafted at the age of 9 and died of pulmonary tuberculosis at the age of 17. Another was grafted at the age of 7, but at about the age of 11 developed a partial paraplegia. This fluctuated considerably in degree, and when he was 14 a costotransversectomy was performed and the vertebral bodies curetted, bone chips from the adjacent rib being packed into the affected region. This child died of tuberculous meningitis about three months later. The third case died at home, aged 19; the cause of

death is unrecorded, but she had been discharged three years earlier with an unrelieved paraplegia.

Of the ungrafted cases 29, i.e. 36%, were readmitted, with the following leading symptoms—8 had local reactivation, 8 had increasing deformity, 7 had paraplegia, 3 had sinuses, 2 had abscesses and 1 had urinary tuberculosis. Of the 15 grafted cases 6, or 40% were readmitted—4 had paraplegia, 3 had increasing deformity, 1 had sinuses and 1 had pulmonary tuberculosis. The rate for readmission and the reason for readmission are similar in the grafted and the ungrafted cases. Moreover, it seems to make little difference whether the graft had been done at the end of the initial treatment or later. Of the 7 cases on which bone grafting was performed at the end of the first period of conservative treatment, 3 were readmitted, of which one later died. Furthermore, it can be shown that of the grafted cases which had a satisfactory result, in several the graft was unsatisfactory from a mechanical point of view; in fact the main function of a posterior bone graft seems to be to ensure that anterior bony fusion does not occur between the bodies, which is the patient's main insurance against reactivation.

Of the 9 cases grafted and appearing in the table as a satisfactory result, in one case the graft was too low and the degree of deformity increased from 50 to about 85 degrees. In another case the graft failed to unite at the upper part of the diseased area and there was some increase of deformity. In a third there was complete failure of the fusion and in a fourth the graft fractured near its upper end. Of the unsatisfactory results following grafts, two had increasing deformity associated with paraplegia since the graft, and a third had increasing deformity and abscess formation.

TABLE III.—DEGREE OF DEFORMITY. UNGRAFTED

			0-45 degrees	45-90 degrees	90+ degrees	Unknown
Cervical and upper dorsal	} Total 10	Satisfactory ..	7	1	1	1 (died)
		Unsatisfactory	—	—	—	
Dorsal and lumbo-dorsal	} Total 45	Satisfactory ..	5	5	3	0
		Unsatisfactory	—	5	19	8
Lumbar	} Total 24	Satisfactory ..	12	3	0	3
		Unsatisfactory	2	2	1	1

TABLE IV.—DEGREE OF DEFORMITY. GRAFTED*

			0-45 degrees	45-90 degrees	90+ degrees
Dorsal and upper lumbar	(a) 1st admission	Satisfactory ..	—	2	0
		Unsatisfactory	—	1	1
	(b) Later	Satisfactory ..	—	1	2
		Unsatisfactory	—	—	2
Lumbar	(a) 1st admission	Satisfactory ..	2	—	—
		Unsatisfactory	1	—	—
	(b) Later	Satisfactory ..	1	—	1
		Unsatisfactory	—	—	—

*In one unsatisfactory case the degree of deformity is not recorded.

TABLE V.—TYPE OF ANTERIOR FUSION

			Bone	Fibrous	Unknown
Cervical and upper dorsal	Satisfactory		2	3	4
	Unsatisfactory		—	—	—
Dorsal and lumbo-dorsal	Satisfactory	No graft	4	5	4
		Graft ..	0	5	0
	Unsatisfactory	No graft	0	12	20
		Graft ..	0	2	2
Lumbar	Satisfactory	No graft	7	5	6
		Graft ..	1	3	1
	Unsatisfactory	No graft	0	6	1
		Graft ..	0	1	1

In only one case that was grafted did anterior bony fusion occur. None of the cases with bony fusion gave an unsatisfactory result.

TABLE VI.—AVERAGE NUMBER OF BODIES INVOLVED

				C. and Upper D.	D. and D. L.	L.
Grafts	{ Satisfactory	—	4.8	2.5
	{ Unsatisfactory	—	4.3	2.5
Non-grafts	{ Satisfactory	3.6	3.3	2.3
	{ Unsatisfactory	4.0	4.6	2.5

It will be seen that the average number of bodies affected is very little greater in the grafted than in the ungrafted series. In other words, the poor results of grafting cannot be explained adequately by saying that the worst cases only were grafted.

SUMMARY

There is no evidence here that spine grafting in children reduces the mortality or the incidence of readmission because of complications or later reactivation, nor does it control the development of a kyphosis. Though the number of cases is few, it does suggest that grafting prevents the formation of anterior bony fusion between the vertebral bodies. What then is needed—bigger and better grafts? It seems that this would be more likely to keep the disease in the bodies active rather than preserve its quiescence. Or should the operation be directed against the disease focus in the bodies in an attempt to eradicate the caseous material and sequestered bone and replace it with cancellous bone chips? Obviously there is a greater operative risk with this type of operation than with the Albee grafts, though this could be lessened by making use of bone from a bone bank. Moreover there seems to be a very definite risk of tuberculous meningitis following a direct approach to the bodies, which must necessarily cut across the perivertebral plexus of veins; there is also some risk of tuberculous pleurisy. Can we yet say that the streptomycin treatment of meningitis is sufficiently satisfactory to justify the risk? Until this is so, the indication is for earlier diagnosis and immobilization until the bacillæmic stage of the disease is over and the refraining from a posterior graft which is all too likely to prevent anterior consolidation of the bodies.

Section of Pædiatrics

President—W. G. WYLLIE, M.D., F.R.C.P.

[May 22, 1948]

MEETING HELD AT THE ROYAL INFIRMARY, CARDIFF

Periodic Familial Paralysis.—W. G. WYLLIE, M.D., F.R.C.P., and A. G. WATKINS, F.R.C.P.

Mrs. M. has had attacks of paralysis since 3 years old, but of late the attacks have been lasting more or less continuously for three to four days or even up to a week. She complains of aching and weakness of the muscles of the legs; the arms are unaffected.

April 1946: Blood potassium 18.9 mg. %.

Mrs. M. says she is worse after taking potassium.

D. M., male, aged 5½ years. Mrs. M.'s son. Becomes "completely helpless" at times. Attacks last ten to fifteen minutes and may be brought on by sudden cooling after exercise or after prolonged rest. Onset at 8 months old.

J. M., female, aged 2½ years. Mrs. M.'s daughter. Free from attacks. (see fig. 1).

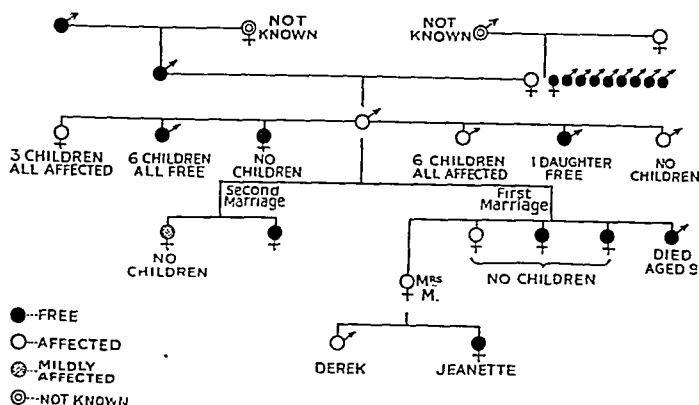

FIG. 1.—Periodic familial paralysis.

Cerebellar Atrophy.—J. D. SPILLANE, M.D.

Miss I. R., aged 16 years. Admitted to this hospital in March 1948. Symptoms began in April 1946 with shakiness of the left hand followed shortly afterwards by changes in speech. An ataxia of all voluntary movement gradually spread and increased in intensity producing her present state of marked asynergia.

Family history.—The maternal grandfather committed suicide and his brother was psychotic. There was no other family neuropathy.

On examination the general state of nutrition was good. There was a gross speech defect making her almost unintelligible. She showed a spontaneous rotatory coarse nystagmus, and a gross cerebellar ataxia of gait and all voluntary movement. She had all the other signs of a pure cerebellar lesion. There was no evidence of involvement of the pyramidal or posterior column tracts. Lumbar puncture showed no abnormality of itself or in the fluid. W.R. was negative in blood and cerebrospinal fluid. Air encephalography showed a little excess air over the cerebral cortex with cerebellar atrophy as judged by increased size of the fourth ventricle, the excess of inter-folial air and a general increase of air in the posterior cranial fossa.

Female Epispadias.—R. A. MOGG, F.R.C.S.

S. H., aged 6 years. Incontinence of urine since birth. No relevant past history.

8.9.47: General condition good. Excoriation of vulva and vagina. Abdomen normal. Clitoris split along the dorsum; the urethra shows the female type of epispadias. Palpable depression in the region of the mons pubis due to separation of the symphysis pubis.

Cystoscopy.—No resistance to passage of cystoscope. Bladder sphincter appeared to be deficient. Bladder normal apart from gross congestion of trigone.

Treatment.—Bilateral transplantation of ureters performed in two stages using the extra-peritoneal technique. Convalescence uneventful. Rectal control good.

DEC.—PÆDIAT. 1

Complete Double Right Ureter with Ectopic Insertion of the Upper Ureter. Ureterocele of the Ectopic Ureter causing Left Hydro-ureter and Hydronephrosis.—R. A. MOGG, F.R.C.S.

J. C., male, aged 9 years.

First seen at the age of 5 years suffering from pyuria, hæmaturia and albuminuria following measles. Improved but relapsed. I.V.P. showed dilatation of left ureter and renal pelvis and no secretion from the right side after one and a half hours.

Cystoscopy 23.10.46 showed an unexplained elevation of the trigone; the ureteric orifices were normal in position but patulous and could not be catheterized.

Exploration of bladder 30.10.46 showed a greatly hypertrophied wall and a complete double ureter on the right side, the upper ureter opening ectopically at the bladder neck with an associated ureterocele. The whole of the trigonal mucosa was elevated by this dilated ectopic ureter to such a degree that it obstructed the left ureteric orifice causing hydro-ureter. The ureterocele and the lower part of the right ectopic ureter were resected, indwelling ureteric catheters were passed up the right ureters, pyelography was performed and the bladder closed round a suprapubic tube.

Convalescence was uneventful and he was discharged symptom free. There is an occasional *B. coli* infection of the urine; there was a mild hæmaturia on 25.3.47, but the child remains fit and well and attends school regularly.

Subdural Hæmatoma—Two Cases.—H. R. I. WOLFE, F.R.C.S. (Surgical Unit).

CASE I.—M. E., male, aged 13 months, was referred as a case of hydrocephalus.

History.—Fourth child of rhesus positive parents. Both brothers alive and well. Sister alive but thought to be a mongol. Full-term pregnancy, normal delivery. Slightly jaundiced at birth but this rapidly cleared. At age of 6 months it was noticed the head was abnormally large. Progress had been otherwise normal and there was no history of injury to the head.

Clinically.—Pale, anæmic and fretful child who could not sit up without support (*see fig.*). The head was abnormally large—maximum circumference 23 in.—and the anterior fontanelle was enlarged and tense. Intelligence did not appear to be impaired. No other abnormal physical signs.

Special investigations.—R.B.C. 2,620,000. Hb 28%. C.I. 0.53. W.B.C. 8,000. Platelets 80,000. Clotting time 6 minutes.

Slightly raised resistance of red cells to hypotonic saline. W.R. negative. C.S.F.—Clear fluid, pressure 300 mm. 2 lymphocytes per c.mm. Protein 40 mg.%. R.B.C. 146 per c.mm.

Encephalography: Symmetrical slight dilatation of ventricular system which appears to be displaced downwards.

Bilateral subdural tap through anterior fontanelle.—Subdural collection of orange fluid on right side: protein content 4,400 mg.%. Subdural collection of brown fluid on left side: protein content 5,600 mg.%.

Treatment.—By transfusion, fersolate, vitamin C and further subdural taps.

Operation (Professor Lambert Rogers, 31.1.48).—A 1½ in. trephine disc was removed just anterior to the parietal eminence on the right side and the dura opened. A thick green membrane lightly adherent to the dura was incised and removed. Dark blood-stained fluid was evacuated from the subdural space. A thin smooth green membrane over the cerebral cortex was incised and removed. The underlying cortex appeared normal. A small rubber tube was placed through the centre of the trephine disc which was then replaced and the wound closed.

Convalescence was uneventful and the patient discharged on 10.3.48. Readmitted 8.5.48. Circumference of skull 22 in. General condition excellent. Bright, intelligent child. Able to walk.

ADDENDUM

Operation (Professor Lambert Rogers, 30.6.48).—Operation carried out on the left side similar to that on the right. Subdural collection of brown fluid and blood clot removed. Membranes removed. Cavity filled with Ringer's solution. Bone disc replaced and wound closed without drainage.

Convalescence uneventful and patient discharged 12.7.48.

Follow-up, 18.12.48: Very satisfactory progress. The child is of normal intelligence.

CASE II.—T.S., male, aged 8 months.

History.—Father, mother, brother and sister alive and well. Full term pregnancy, normal delivery, birth-weight 7½ lb. "Operation for gland of neck" when 3 months old.

M. E., aged 13 months.

Admitted to City Hospital, Plymouth, when 7 months old in status epilepticus. Prior to admission feeds had been taken reluctantly and there had been copious vomiting. No history of injury to head.

Examination.—Bilateral retinal hæmorrhages. Minor degree of spinal rigidity and hydrocephalus (circumference of head 18½ in.).

Investigations.—Lumbar puncture: Xanthochromic fluid not under pressure. Protein 45 mg. %. Globulin—faint trace. R.B.C. 50. Lymphocytes 12.

Blood W.B.C. 29,600. Platelet count and bleeding and clotting time normal.

Wassermann reaction of blood and C.S.F. negative.

Progress.—Epileptic fits ceased three hours after admission. Occasional generalized twitching during next two weeks, when right-sided hemiplegia noted. Signs of increased intracranial pressure—papillædema and bulging of anterior fontanelle—present on admission. These subsided and child regained consciousness five days after admission, but was apparently blind.

Admitted to Royal Infirmary, Cardiff, when 8 months old.

Examination.—Healthy, good-tempered, rosy-cheeked child (see fig.). Slight eczema of scalp. Head large. Anterior fontanelle open, tense and bulging slightly. Right-sided hemiparesis. Pupils equal and react to light. No ophthalmoplegia. Child apparently blind, for gaze does not fix on bright light or feeding bottle and no reaction to brisk movement in line of vision. Optic discs flat and of fairly normal colour. Extensive central area of retinal hæmorrhage in right eye.

Investigations.—Bilateral subdural tap through anterior fontanelle. Right side—dark blood-stained fluid, protein 1,600 mg. %. Left side—orange fluid, protein 1,500 mg. %. Blood-count: R.B.C. 2,690,000. Ascorbic acid 0.6 mg. %.

Treatment.—Transfusion, fersolate and vitamin C, and repeated bilateral subdural tapping.

T. S., aged 8 months.

ADDENDUM

Operation (Mr. Wolfe, 3.7.48).—Removal of trephine disc in left parietal region. Dura incised and blue-grey external membrane stripped and removed from dura. Cyst emptied, and thin smooth greenish inner membrane removed from cortex. The inner membrane stripped with ease except at one point where an oozing vascular adhesion was found to traverse the subdural space from the inner to the outer membrane 1½ in. lateral to the superior longitudinal sinus. Portion of inner membrane the size of a postage stamp was left adherent to the cortex at the base of this adhesion, which was then severed and removed with a portion of the outer membrane for histology. The cerebral cortex, initially pale and rather flattened, within a minute following the removal of the inner membrane became vascular and of normal appearance. The cavity was filled with Ringer's solution, the dural defect closed, the bone disc replaced and the wound sutured without drainage.

Convalescence uneventful.

Pathological report on portion of outer wall of subdural cyst with vascular pedicle: The tissue is composed of proliferating blood-vessels with a stroma of collagen. Around some of the vessels is a concentric proliferation of cells giving the appearance similar to that seen in a meningioma. The cyst has a dense fibrous wall in which there are deposits of hæmosiderin. The condition is possibly a hæmangioma of the meninges, but it probably represents organization in the wall of a subdural hæmatoma.

14.8.48: *Operation* carried out on right side similar to that on left. A thick gelatinous green outer membrane was stripped without difficulty from the dura. A subdural collection of dark reddish brown fluid was removed. The pearly white semi-translucent inner membrane was then removed from the cortex. Convalescence was uneventful and the patient discharged from hospital on 3.9.48.

Follow-up, 18.12.48: Satisfactory progress. There would appear to be some degree of recovery of vision for the child will now respond to the stimulus of a bright light.

Comment.—In both these cases the inner membrane of the subdural cyst was found to be semi-permeable when the cyst fluid was placed within the membrane and tested against the patient's blood. It is noteworthy that in Case I, which was referred as a case of hydrocephalus (a diagnosis which might have been accepted but for ventriculography), there were no abnormal neurological signs, and that in Case II, where the head was only slightly enlarged, neurological symptoms were pronounced.

Complete Double Right Ureter with Ectopic Insertion of the Upper Ureter. Ureterocele of the Ectopic Ureter causing Left Hydro-ureter and Hydronephrosis.—R. A. MOGG, F.R.C.S. J. C., male, aged 9 years.

First seen at the age of 5 years suffering from pyuria, hæmaturia and albuminuria following measles. Improved but relapsed. I.V.P. showed dilatation of left ureter and renal pelvis and no secretion from the right side after one and a half hours.

Cystoscopy 23.10.46 showed an unexplained elevation of the trigone; the ureteric orifices were normal in position but patulous and could not be catheterized.

Exploration of bladder 30.10.46 showed a greatly hypertrophied wall and a complete double ureter on the right side, the upper ureter opening ectopically at the bladder neck with an associated ureterocele. The whole of the trigonal mucosa was elevated by this dilated ectopic ureter to such a degree that it obstructed the left ureteric orifice causing hydro-ureter. The ureterocele and the lower part of the right ectopic ureter were resected, indwelling ureteric catheters were passed up the right ureters, pyelography was performed and the bladder closed round a suprapubic tube.

Convalescence was uneventful and he was discharged symptom free. There is an occasional *B. coli* infection of the urine; there was a mild hæmaturia on 25.3.47, but the child remains fit and well and attends school regularly.

Subdural Hæmatoma—Two Cases.—H. R. I. WOLFE, F.R.C.S. (Surgical Unit).

CASE I.—M. E., male, aged 13 months, was referred as a case of hydrocephalus.

History.—Fourth child of rhesus positive parents. Both brothers alive and well. Sister alive but thought to be a mongol. Full-term pregnancy, normal delivery. Slightly jaundiced at birth but this rapidly cleared. At age of 6 months it was noticed the head was abnormally large. Progress had been otherwise normal and there was no history of injury to the head.

M. E., aged 13 months.

Clinically.—Pale, anæmic and fretful child who could not sit up without support (see fig.). The head was abnormally large—maximum circumference 23 in.—and the anterior fontanelle was enlarged and tense. Intelligence did not appear to be impaired. No other abnormal physical signs.

Special investigations.—R.B.C. 2,620,000. Hb 28%. C.I. 0.53. W.B.C. 8,000. Platelets 80,000. Clotting time 6 minutes.

Slightly raised resistance of red cells to hypotonic saline. W.R. negative. C.S.F.—Clear fluid, pressure 300 mm. 2 lymphocytes per c.mm. Protein 40 mg.%. R.B.C. 146 per c.mm.

Encephalography: Symmetrical slight dilatation of ventricular system which appears to be displaced downwards.

Bilateral subdural tap through anterior fontanelle.—Subdural collection of orange fluid on right side: protein content 4,400 mg.%. Subdural collection of brown fluid on left side: protein content 5,600 mg.%.

Treatment.—By transfusion, fersolate, vitamin C and further subdural taps.

Operation (Professor Lambert Rogers, 31.1.48).—A 1½ in. trephine disc was removed just anterior to the parietal eminence on the right side and the dura opened. A thick green membrane lightly adherent to the dura was incised and removed. Dark blood-stained fluid was evacuated from the subdural space. A thin smooth green membrane over the cerebral cortex was incised and removed. The underlying cortex appeared normal. A small rubber tube was placed through the centre of the trephine disc which was then replaced and the wound closed.

Convalescence was uneventful and the patient discharged on 10.3.48. Readmitted 8.5.48. Circumference of skull 22 in. General condition excellent. Bright, intelligent child. Able to walk.

ADDENDUM

Operation (Professor Lambert Rogers, 30.6.48).—Operation carried out on the left side similar to that on the right. Subdural collection of brown fluid and blood clot removed. Membranes removed. Cavity filled with Ringer's solution. Bone disc replaced and wound closed without drainage.

Convalescence uneventful and patient discharged 12.7.48.

Follow-up, 18.12.48: Very satisfactory progress. The child is of normal intelligence.

CASE II.—T.S., male, aged 8 months.

History.—Father, mother, brother and sister alive and well. Full term pregnancy, normal delivery, birth-weight 7½ lb. "Operation for gland of neck" when 3 months old.

demonstrates the typical appearance of Ehlers-Danlos syndrome differing only in that there does not appear to be any crackling of the skin or a tendency to undue hæmorrhage.

The child's mother would appear to suffer in a mild degree from the same condition.

The following seven cases were shown by Dr. A. G. WATKINS and the Staff of the Pædiatric Department, Cardiff Royal Infirmary.

Cases I to III. Chondrodysplasia in a Family of Three Children.

M. A., male, aged 8 years. Height 3 ft. 2 in. Weight 38½ lb.

J. A., female, aged 7 years. Height 2 ft. 6½ in. Weight 24 lb.

J. A., male, aged 5½ years. Height 2 ft. 8 in. Weight 26 lb.

No other children. Parents healthy; no consanguinity. Family history nil. All three children normal mentally and of good general health.

X-ray films demonstrated typical bony changes.

Case IV. Calcinosis Universalis.

R. G., male, aged 6½ years.

Lumps in lower end of right upper arm first noted at 2 years of age. They later developed on left arm and behind knees. The lumps vary in size and almost disappear at times; there is no discharge.

A small patch of dermatitis is present on outer side of right arm. General health good. Family history: nothing relevant.

Blood-count normal. Serum calcium 11.2 mg.%; serum phosphate 5 mg.%; alkaline phosphatase 24 units.

X-ray films demonstrated calcified subcutaneous areas opposite lower end of both humeri, also large calcified area over left psoas muscle.

Case V. Hypertrophy of Left leg.

F. B., male, aged 6½ years. Left leg first noticed to be bigger than right at 1 year. Increasing disability and unable to walk far.

	Left	Right
Circumference of leg 3 in. above patella ..	12 in.	12 in.
Circumference of leg 5 in. below patella ..	10½ in.	8½ in.
Circumference of leg at ankle ..	8½ in.	7 in.
Anterior iliac spine to patella ..	11½ in.	10½ in.
Tibial spine to lateral malleolus ..	13 in.	11 in.

No alteration in limb temperature. No alteration in cardiac rate on occluding left femoral. Blood-pressure equal in both legs. Femoral vein puncture shows equal oxygenation in both legs. X-ray films demonstrated simple enlargement of femur and tibia.

Case VI. ? Bilateral Arteriovenous Anastomosis.

E. D., female, aged 15 years.

Surface nævi on both legs extending to buttocks. Varicose veins of both legs. Intermittent swelling of feet. On two occasions discharge from pin-point openings behind right knee, ? chyle. Blood-pressure equal in both limbs. No cardiac lesion. No investigations done.

Case VII. Arteriovenous Anastomosis.

D. P., female, aged 14½ years.

First seen in May 1941 because of a "milky discharge" from the inner side of right thigh of two days' duration. The discharge was chylous fluid from a pin-point opening approximately at the apex of Scarpa's triangle. There has been no recurrence from that site but two years later she had a similar discharge *per vaginam* and this has occurred intermittently since. It is always better when she is at rest. Right leg was noted to be longer, fatter and hotter than left. Occlusion of right femoral slowed pulse after an interval of six beats.

April 1943: Subarachnoid hæmorrhage—attack while in hospital.

October 1945: Considerable lengthening of right limb with gross compensatory scoliosis. Spasticity of both limbs, more marked on right side; double Babinski. Groin temperature half a degree higher on right side.

November 1947: Blood-pressure normal and equal on both sides in arm and leg. Right leg 3 in. longer than left. Right leg 1½ in. greater in circumference than left. Right leg 5½ in. cephalic in Nélaton's line.

larged, neu.

Congenital Webbing of the Lower Limbs.—EMLYN LEWIS, F.R.C.S.

E. N., girl, aged 7 years. Referred because of inability to walk without crutches and suffering from congenital contractures of the lower limbs. The child is one of a family of four, the father has a harelip and cleft palate, and a brother a cleft palate and similar congenital web formation of the lower limbs. Patient has a bilateral incomplete harelip and a posterior two-thirds cleft palate.

The webs extend from the region of the tuber ischii down to the heels. They limit extension of the knee-joint by 40 degrees and the ankle-joints very considerably. The webs had been previously explored elsewhere and a neurovascular bundle was encountered in the free margin of the web. At operation the above findings were corroborated but in addition it was found that there were large muscle sheets extending from the tuber ischii to the heel region which were responsible for the web formation. Presumably these muscle sheets had failed to gain their intermediate attachments either below to the upper end of the tibia or above to the lower end of the femur. The muscle sheets were divided and secondarily attached to the tibia and femur in order to reproduce something like normal anatomical distribution. Z-plastics were performed on the skin folds and in this way considerable elongation obtained. After operation gradual extension of the knee-joint was obtained by means of a spring extension apparatus in order slowly to elongate the neurovascular bundle.

The patient is now able to walk unaided. The left lower limb now functions correctly and the right limb is being restored to normal position.

Following these procedures the development of the heel portion of the os calcis has been very considerable.

Leontiasis Ossea.—EMLYN LEWIS, F.R.C.S.

M. T., a boy, aged 11 years. Referred as a case of sarcoma of the right maxilla with right nasal obstruction. It was noted at this time that in addition to the swelling of the right maxilla there was also expansion of the frontal and temporo-parietal regions. Nasal obstruction was corroborated and the right eye was elevated.

X-ray examination: Bony expansion of the superior maxilla, right frontal bone and right temporal region. No other bony abnormalities were found in the long bones.

Blood: Hb and cells normal. Blood calcium 8 mg. %, phosphorus 5.5 mg. %, phosphatase 25 units.

At examination it was decided that the symptoms did not warrant operative interference, but it is proposed that when the symptoms, due to mechanical factors, warrant it, bony reduction should be carried out and specimens of the bone examined histologically.

Osteopetrosis (Marble Bones).—EMLYN LEWIS, F.R.C.S., and Pædiatric Dept.

A. W., boy, aged 9 years. Referred because of osteomyelitis of the lower jaw, which started in February 1947. Three years previously he had fractured his femur and examination showed that he had a large spleen but the blood picture was normal at that time. Routine X-ray examination revealed condition of marble bones.

X-ray examination for osteomyelitis of the jaw showed typical marble bone appearance together with extensive osteomyelitis of the right side of the mandible. Intra-oral examination showed presence of dead bone. Spleen considerably enlarged. Some ascites.

Blood examination.—R.B.C. 3,250,000; Hb 50%; C.I. 0.8; W.B.C. 12,800 (polys. 43%, lymphos. 30%, myelos. 13%, monos. 9%, eosinos. 5%). Nucleated reds 8 per 100 W.B.C. Polychromasia with stippling. Film was said to show a leuco-erythroblastic anæmia. W.R. and Kahn negative.

When operation was performed on the lower jaw it was found that the greater part of the horizontal ramus was necrotic and surrounded by a large mass of vascular fibrous bone, which when drilled produced a cloud of dust. The new bone was very brittle and fractured in removing the dead bone. The fragments were wired and the wound closed with drainage. It is interesting to note that osteomyelitis of the jaw appears to be a frequent terminal condition in these children. Presumably it arises via carious milk teeth and when combined with the relative avascular condition of the bone assumes severe proportions.

Repeated transfusions were given and his Hb is now 75% with R.B.C. 4,250,000.

Cutis Laxa.—EMLYN LEWIS, F.R.C.S.

P. T., aged 7, girl. Referred because of appearance. The girl presented a facial and neck appearance of an elderly person and it was found that she was referred to by her classmates as "Granny." A bilateral face-lifting operation was performed, which considerably improved her appearance. Since performing the operation it is apparent that she has ^{sy.} notably aged and it may be worth while repeating the surgical procedure. The skin of her ^{abdomen} ^{retched} ^{ed.}

demonstrates the typical appearance of Ehlers-Danlos syndrome differing only in that there does not appear to be any crackling of the skin or a tendency to undue hæmorrhage.

The child's mother would appear to suffer in a mild degree from the same condition.

The following seven cases were shown by Dr. A. G. WATKINS and the Staff of the Pædiatric Department, Cardiff Royal Infirmary.

Cases I to III. Chondrodysplasia in a Family of Three Children.

M. A., male, aged 8 years. Height 3 ft. 2 in. Weight 38½ lb.

J. A., female, aged 7 years. Height 2 ft. 6½ in. Weight 24 lb.

J. A., male, aged 5½ years. Height 2 ft. 8 in. Weight 26 lb.

No other children. Parents healthy; no consanguinity. Family history nil. All three children normal mentally and of good general health.

X-ray films demonstrated typical bony changes.

Case IV. Calcinosis Universalis.

R. G., male, aged 6½ years.

Lumps in lower end of right upper arm first noted at 2 years of age. They later developed on left arm and behind knees. The lumps vary in size and almost disappear at times; there is no discharge.

A small patch of dermatitis is present on outer side of right arm. General health good. Family history: nothing relevant.

Blood-count normal. Serum calcium 11.2 mg.%; serum phosphate 5 mg.%; alkaline phosphatase 24 units.

X-ray films demonstrated calcified subcutaneous areas opposite lower end of both humeri, also large calcified area over left psoas muscle.

Case V. Hypertrophy of Left leg.

F. B., male, aged 6½ years. Left leg first noticed to be bigger than right at 1 year. Increasing disability and unable to walk far.

	Left	Right
Circumference of leg 3 in. above patella ..	12 in.	12 in.
Circumference of leg 5 in. below patella ..	10½ in.	8½ in.
Circumference of leg at ankle ..	8½ in.	7 in.
Anterior iliac spine to patella ..	11½ in.	10½ in.
Tibial spine to lateral malleolus ..	13 in.	11 in.

No alteration in limb temperature. No alteration in cardiac rate on occluding left femoral. Blood-pressure equal in both legs. Femoral vein puncture shows equal oxygenation in both legs. X-ray films demonstrated simple enlargement of femur and tibia.

Case VI. ? Bilateral Arteriovenous Anastomosis.

E. D., female, aged 15 years.

Surface nævi on both legs extending to buttocks. Varicose veins of both legs. Intermittent swelling of feet. On two occasions discharge from pin-point openings behind right knee, ? chyle. Blood-pressure equal in both limbs. No cardiac lesion. No investigations done.

Case VII. Arteriovenous Anastomosis.

D. P., female, aged 14½ years.

First seen in May 1941 because of a "milky discharge" from the inner side of right thigh of two days' duration. The discharge was chylous fluid from a pin-point opening approximately at the apex of Scarpa's triangle. There has been no recurrence from that site but two years later she had a similar discharge *per vaginam* and this has occurred intermittently since. It is always better when she is at rest. Right leg was noted to be longer, fatter and hotter than left. Occlusion of right femoral slowed pulse after an interval of six beats.

April 1943: Subarachnoid hæmorrhage—attack while in hospital.

October 1945: Considerable lengthening of right limb with gross compensatory scoliosis. Spasticity of both limbs, more marked on right side; double Babinski. Groin temperature half a degree higher on right side.

November 1947: Blood-pressure normal and equal on both sides in arm and leg. Right leg 3 in. longer than left. Right leg 1½ in. greater in circumference than left. Right leg 5½ in. difference in Nélaton's line.

Congenital Webbing of the Lower Limbs.—EMLYN LEWIS, F.R.C.S.

E. N., girl, aged 7 years. Referred because of inability to walk without crutches and suffering from congenital contractures of the lower limbs. The child is one of a family of four, the father has a harelip and cleft palate, and a brother a cleft palate and similar congenital web formation of the lower limbs. Patient has a bilateral incomplete harelip and a posterior two-thirds cleft palate.

The webs extend from the region of the tuber ischii down to the heels. They limit extension of the knee-joint by 40 degrees and the ankle-joints very considerably. The webs had been previously explored elsewhere and a neurovascular bundle was encountered in the free margin of the web. At operation the above findings were corroborated but in addition it was found that there were large muscle sheets extending from the tuber ischii to the heel region which were responsible for the web formation. Presumably these muscle sheets had failed to gain their intermediate attachments either below to the upper end of the tibia or above to the lower end of the femur. The muscle sheets were divided and secondarily attached to the tibia and femur in order to reproduce something like normal anatomical distribution. Z-plastics were performed on the skin folds and in this way considerable elongation obtained. After operation gradual extension of the knee-joint was obtained by means of a spring extension apparatus in order slowly to elongate the neurovascular bundle.

The patient is now able to walk unaided. The left lower limb now functions correctly and the right limb is being restored to normal position.

Following these procedures the development of the heel portion of the os calcis has been very considerable.

Leontiasis Ossea.—EMLYN LEWIS, F.R.C.S.

M. T., a boy, aged 11 years. Referred as a case of sarcoma of the right maxilla with right nasal obstruction. It was noted at this time that in addition to the swelling of the right maxilla there was also expansion of the frontal and temporo-parietal regions. Nasal obstruction was corroborated and the right eye was elevated.

X-ray examination: Bony expansion of the superior maxilla, right frontal bone and right temporal region. No other bony abnormalities were found in the long bones.

Blood: Hb and cells normal. Blood calcium 8 mg. %, phosphorus 5.5 mg. %, phosphatase 25 units.

At examination it was decided that the symptoms did not warrant operative interference, but it is proposed that when the symptoms, due to mechanical factors, warrant it, bony reduction should be carried out and specimens of the bone examined histologically.

Osteopetrosis (Marble Bones).—EMLYN LEWIS, F.R.C.S., and Pædiatric Dept.

A. W., boy, aged 9 years. Referred because of osteomyelitis of the lower jaw, which started in February 1947. Three years previously he had fractured his femur and examination showed that he had a large spleen but the blood picture was normal at that time. Routine X-ray examination revealed condition of marble bones.

X-ray examination for osteomyelitis of the jaw showed typical marble bone appearance together with extensive osteomyelitis of the right side of the mandible. Intra-oral examination showed presence of dead bone. Spleen considerably enlarged. Some ascites.

Blood examination.—R.B.C. 3,250,000; Hb 50%; C.I. 0.8; W.B.C. 12,800 (polys. 43%, lymphos. 30%, myelos. 13%, monos. 9%, eosinos. 5%). Nucleated reds 8 per 100 W.B.C. Polychromasia with stippling. Film was said to show a leuco-erythroblastic anaemia. W.R. and Kahn negative.

When operation was performed on the lower jaw it was found that the greater part of the horizontal ramus was necrotic and surrounded by a large mass of vascular fibrous bone, which when drilled produced a cloud of dust. The new bone was very brittle and fractured in removing the dead bone. The fragments were wired and the wound closed with drainage. It is interesting to note that osteomyelitis of the jaw appears to be a frequent terminal condition in these children. Presumably it arises via carious milk teeth and when combined with the relative avascular condition of the bone assumes severe proportions.

Repeated transfusions were given and his Hb is now 75% with R.B.C. 4,250,000.

Cutis Laxa.—EMLYN LEWIS, F.R.C.S.

P. T., aged 7, girl. Referred because of appearance. The girl presented a facial and neck appearance of an elderly person and it was found that she was referred to by her classmates as "Granny." A bilateral face-lifting operation was performed, which considerably improved her appearance. Since performing the operation it is apparent that she has not aged again and it may be worth while repeating the surgical procedure. The skin of her face

(1) *Death due to a "congenital defect".*—12 cases. In one case a previously symptomless infundibular cyst produced an acute fatal hydrocephalus. In another a large intrathoracic cyst was present, considered on histological grounds to be derived from enteric epithelium. The remainder of the group comprised gross cardiac defects (5), pulmonary atelectasis (3), neonatal hæmorrhagic disease (1) and an instance of asphyxiation produced by a grossly mobile tongue.

The cases thus grouped died almost exclusively in the first month of life (fig. 2) and indeed 9 of them were aged 1 week or under. Thus concentrated they represent an important proportion of the total deaths encountered in the neonatal period.

(2) *Death due to an infectious process.*—Infection was the major cause of death, accounting for about a third of all cases (fig. 3). In two-thirds of these (21 out of 30) the site of infection was respiratory (viz. upper respiratory infection (7), suppurative bronchopneumonia¹ (9) and acute interstitial pneumonia (5)).

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 7.

Other conditions responsible for death in this group included single cases of encephalitis, meningitis and acute hepatitis.

(3) *Death due to mechanical suffocation.*—In 30 of the cases studied, death had occurred while the infant was in a bed with one or more other occupants. At autopsy, however, only 9 of these infants presented signs of asphyxiation which could have been ascribed to overlaying—the remainder showed another adequate cause for death. The striking difference between the incidence of suspected overlaying and substantiated mechanical asphyxiation is shown in fig. 4.

The remaining 51 cases died when alone in bed, and of these 7 were considered to have died from asphyxiation as the result of pressure from bedclothes. Thus of the 81 cases investigated in this paper a total of 16 only appeared to have suffered mechanical asphyxiation (fig. 5).

It has perhaps been the tendency in the past for practitioners and coroners to assume that sudden death in an infant is likely to be due to unnatural causes, notably suffocation, sometimes with the result that investigations have not included autopsy. From the present study, the author is in complete agreement with Davidson [1] that such examination is an indispensable routine; moreover it should include histological studies, for especially in infancy, organs which appear normal to the naked eye not infrequently show a well-defined lesion microscopically.

¹An unsuspected duodenal ulcer found in one case of bronchopneumonia was exhibited at the meeting.

Sudden Death in Infancy (A Preliminary Communication)

By LESLIE L. R. WHITE, M.B., B.Ch.,¹D.C.H.

Department of Pathology and Bacteriology, Welsh National School of Medicine, Cardiff

SUDDEN death in infancy presents a problem of considerable importance to the coroner and medico-legal pathologist. It also merits the interest of those concerned with child health, at least in so far as certain of the deaths are ascribable to accidental and presumably avoidable causes.

Source of material.—The term "sudden death" may be used with varying implications. For the purpose of the present study the criterion adopted was that death occurred unexpectedly, an antecedent state of illness being admissible, but only when there was no suspicion of impending decease. The cases studied were all subjected to post-mortem examinations at the Pathology Department of the Welsh National School of Medicine, during the period January 1941 to May 1948.

The yearly incidence of the autopsies performed during the period selected shows a steady and significant increase (Table I).

TABLE I

Year	1941-2	1942-3	1943-4	1944-5	1945-6	1946-7	1947-8	1948 Jan.-May
No. of cases	1	5	7	12	12	14	19	11

It would seem probable that this increase is to a large extent the result of greater cautiousness on the part of the practitioner and coroner, with more frequent appeal to autopsy in verifying the cause of death.

Post-mortem examinations were conducted on 81 cases of unexpected death occurring during infancy. The age distribution (fig. 1) reveals that nearly one-third of these took place

FIG. 1.

FIG. 2.

FIG. 3.

in the neonatal period and that thereafter there was a fairly uniform decrease in the incidence with increasing age.

A preliminary case analysis was made into four main divisions (Table II).

TABLE II

Cause of death	No. of cases	Cause of death	No. of cases
Infectious process	30	Mechanical suffocation	16
Aspiration of regurgitated food	23	"Congenital defect"	12

Charles Creighton, M.A., M.D. (1847-1927): Scholar, Historian and Epidemiologist

By E. ASHWORTH UNDERWOOD, M.A., B.Sc., M.D., D.P.H.

TWENTY years ago, on July 18, 1927, there died in a little cottage in the village of Upper Boddington near Rugby a man who had for eight years been regarded by the villagers with respect and affection. He never spoke of his life before he had come at the age of 70 to reside amongst them. Few—perhaps only one—of his former friends ever visited him. The man was Charles Creighton—described as the greatest medical scholar this country produced during the nineteenth century. Yet for nearly forty years he had been ostracized by the medical profession, not because of any crime or misdemeanour, but because he had dared to hold heterodox opinions on a procedure which in England is peculiarly liable to set the doctor and his patients off on different paths. When he died few voices were raised to pay him homage. *The Times* was discreetly silent. Professor William Bulloch, his oldest and most intimate friend, contributed sympathetic obituaries to the *Lancet* [1] and the *Aberdeen University Review* [2] and in the *British Medical Journal* Professor Greenwood [3] summed up in richly suggestive phrases the manner of Creighton's greatness. Eight months later Fielding Garrison in America contributed a more extensive review of Creighton's epidemiology [4]. He called his article "A Neglected Medical Scholar".

CHARLES CREIGHTON

That was twenty years ago. The object of this paper is not to review the work of Creighton in the detailed and critical manner which it undoubtedly merits. Its sole object is to point out that Creighton—to whom many have paid service from the lip and from the heart—is *still* neglected. Apart from the other writings of Professor Greenwood I have been unable to trace a single communication dealing with Creighton since Garrison's article in 1928. From one aspect that does not matter, since his best work has a lasting quality which defies time. But the man is part of his work, and the circle, never large, of those who knew Creighton in his lifetime shrinks at a dangerous rate as the years pass. It seems a safe bet that the man who wrote the book which Garrison refers to as the most considerable work in medical history which has yet come out of Great Britain will receive more than passing attention from the historian of the future. He will be interested in the *man*, as well as in the *History of Epidemics*. Except to a few the man is to-day a mere shadow. *Now* seems to be the time for those few to commit their recollections to print. The centenary of Creighton's birth is a fitting occasion to

make this appeal, and these remarks on his life and work are intended merely to drive this point home.

CREIGHTON'S EARLY LIFE

Charles Creighton, according to Bulloch, was the son of Alexander Creighton, a saw-miller and timber merchant of Peterhead. There Creighton was born on November 21, 1847. From the local school he went to the Gymnasium in Old Aberdeen. He gained ninth place in the bursary competition, and from King's College he graduated in Arts in 1867. His medical course was begun at Marischal College, but he seems to have finished

In occasional instances, however, autopsy results may lead to a mistaken presumption of mechanical suffocation, e.g. where an unobserved convulsion has occurred. In one instance a 2-day old baby was found at post-mortem to have visceral manifestations of asphyxia, with signs of facial pressure and anterior lividity. Death had actually taken place during a convulsion, and the signs suggesting suffocation from facial pressure were the result of subsequent deposition of the body in a package face-downwards. Had the convulsion not been noted death might have been attributed to mechanical asphyxia.

(4) *Death due to aspiration of regurgitated food*.—Twenty-three infants were considered to have died from asphyxia due to aspiration of regurgitated food (fig. 6).

Most pathologists would accept the finding of regurgitated material distributed throughout the lower airway as a sufficient explanation for asphyxial death. Simpson [2] has recently asserted that this is, in fact, a reversal of cause and effect, in that a state of asphyxiation induces vomiting, and subsequently inhalation of the vomitus may occur. He offers this theory without accompanying evidence.

It was noted in 10 cases, or nearly half of those with aspiration, that an underlying lesion was present which might reasonably be expected to produce vomiting rather than asphyxiation, viz. gastro-enteritis, otitis media, upper respiratory infection, &c. Further, though the series is admittedly a small one, the cases of undoubted mechanical suffocation (fig. 5) and those of aspiration of vomit show no correlation in age-incidence. Certainly many instances of asphyxia were unaccompanied by vomiting. Thus the evidence does not support Simpson's contention.

Another study of aspiration of vomit by Gardner [3] suggests that it is almost exclusively limited to artificially fed babies. He observes the small compact nature of the stomach of breast-fed infants at post-mortem and the liability to gross gastric distension in bottle-fed babies, presumably due [*sic*] to incidental aerophagy. Hence he deduces that an endeavour to regurgitate the gastric air-cap in the latter group leads to a possibility of inhalation of vomitus. In the present series, the mode of feeding was ascertainable in 12 out of the 23 cases showing aspiration and of these 4 were breast fed. Further, in those cases in which no underlying lesion was established (fig. 7) and where dietetic causes might possibly be of greater significance, 3 out of 7 cases were breast fed. Aspiration of stomach contents in breast-fed babies does not therefore seem to be a rare occurrence as Gardner has asserted. The apparently increasing incidence of aspiration of regurgitated food was the subject of a recent annotation in the *Lancet* [4] and subsequent correspondence [5, 6, 7] and certainly merits close attention, especially in view of the possibilities of preventing such a catastrophe. Regurgitation of food is prevalent in infants, but the factors leading to inhalation of the vomitus are as yet ill-defined.

Conclusion.—There appear to have been few extensive studies of sudden death in infancy, a problem which is of peculiar importance in relation to the present attempts to achieve further reduction in infant mortality. Detailed investigation and correlation of the social and pathological aspects are required, and for the latter it is essential to have the service of pathologists who are experienced in this branch of medico-legal work.

Summary.—(1) A preliminary study of the autopsy findings in 81 cases of sudden death in infancy is presented. (2) Of 30 deaths suspected from circumstantial evidence as due to overlaying, 9 were the result of mechanical suffocation; the remaining 21 were ascribable to other causes. (3) Asphyxia due to aspiration of regurgitated food as a cause of death is discussed.

The author is grateful to Professor Jethro Gough for his interest and helpful criticism, and for permission to make use of the autopsy records of the Welsh National School of Medicine, Pathology Department; also to Dr. A. G. Watkins, Pædiatrician to the Cardiff Royal Infirmary, for his encouragement.

Charles Creighton, M.A., M.D. (1847-1927): Scholar, Historian and Epidemiologist

By E. ASHWORTH UNDERWOOD, M.A., B.Sc., M.D., D.P.H.

TWENTY years ago, on July 18, 1927, there died in a little cottage in the village of Upper Boddington near Rugby a man who had for eight years been regarded by the villagers with respect and affection. He never spoke of his life before he had come at the age of 70 to reside amongst them. Few—perhaps only one—of his former friends ever visited him. The man was Charles Creighton—described as the greatest medical scholar this country produced during the nineteenth century. Yet for nearly forty years he had been ostracized by the medical profession, not because of any crime or misdemeanour, but because he had dared to hold heterodox opinions on a procedure which in England is peculiarly liable to set the doctor and his patients off on different paths. When he died few voices were raised to pay him homage. *The Times* was discreetly silent. Professor William Bulloch, his oldest and most intimate friend, contributed sympathetic obituaries to the *Lancet* [1] and the *Aberdeen University Review* [2] and in the *British Medical Journal* Professor Greenwood [3] summed up in richly suggestive phrases the manner of Creighton's greatness. Eight months later Fielding Garrison in America contributed a more extensive review of Creighton's epidemiology [4]. He called his article "A Neglected Medical Scholar".

That was twenty years ago. The object of this paper is not to review the work of Creighton in the detailed and critical manner which it undoubtedly merits. Its sole object is to point out that Creighton—to whom many have paid service from the lip and from the heart—is *still* neglected. Apart from the other writings of Professor Greenwood I have been unable to trace a single communication dealing with Creighton since Garrison's article in 1928. From one aspect that does not matter, since his best work has a lasting quality which defies time. But the man is part of his work, and the circle, never large, of those who knew Creighton in his lifetime shrinks at a dangerous rate as the years pass. It seems a safe bet that the man who wrote the book which Garrison refers to as the most considerable work in medical history which has yet come out of Great Britain will receive more than passing attention from the historian of the future. He will be interested in the *man*, as well as in the *History of Epidemics*. Except to a few the man is to-day a mere shadow. Now seems to be the time for those few to commit their recollections to print. The centenary of Creighton's birth is a fitting occasion to

CHARLES CREIGHTON

make this appeal, and these remarks on his life and work are intended merely to drive this point home.

CREIGHTON'S EARLY LIFE

Charles Creighton, according to Bulloch, was the son of Alexander Creighton, a saw-miller and timber merchant of Peterhead. There Creighton was born on November 21, 1847. From the local school he went to the Gymnasium in Old Aberdeen. He gained ninth place in the bursary competition, and from King's College he graduated in Arts in 1867. His medical course was begun at Marischal College, but he seems to have finished

his training in Edinburgh. Having graduated M.B. at Aberdeen in 1871, he set out for the Continent, where he spent most of his time with Virchow in Berlin, and with Rokitsky and Skoda in Vienna. Virchow, at that time 50 years of age, was at the height of his powers as a pathologist and was active in the political field. Rokitsky was within four years of his retirement, and his dyscrasia theory was widely accepted. It is small wonder that, with the recollection of two such teachers in his mind, Creighton early decided to be a pathologist. Rokitsky indeed implanted his views so firmly in Creighton that they stuck with him during the remainder of his life. Creighton must have spent about a year abroad, and on his return he was successively medical registrar at Charing Cross Hospital, and surgical registrar at St. Thomas's Hospital. In 1873 he began work on cancer research under Burdon-Sanderson at the Brown Institution. I have been in touch with Professor Twort, who has very kindly gone through the annual reports and the correspondence of the Brown Institution from its foundation in 1871 to his appointment in 1909. No record of Creighton's name appears anywhere, and Professor Twort does not remember Creighton having visited the Institution after 1909 [5]. There is, however, some evidence [6] that he was really engaged by the Medical Department of the Local Government Board, to which John Simon was the medical officer. In 1874 there appeared in a volume of special reports of that department a communication of eighteen pages by Creighton [7]. It is entitled *Anatomical Research towards the Aetiology of Cancer*, and it deals with the earlier signs of cancerous invasion in the ultimate anatomical elements of the secondarily affected organs. The investigation involved a study of secondary tumours in the liver. In his preface to the collected reports Simon refers to this paper as "a contribution of much interest". This is the earliest paper by Creighton which I have been able to find. The *Index Medicus* was not started until five years later; there may be earlier papers, but I do not think there can be many. This paper seems to me to be a competent bit of work, bearing some traces of Virchow's influence. During the next two years Creighton had several other papers on physiological and pathological processes in the breast published in the Privy Council Reports, and these and certain other papers were collected to form his first book—*Contributions to the Physiology and Pathology of the Breast and its Lymphatic Glands*—which was published in 1878. He was then 31 years of age, and a brilliant and successful career was apparently just round the corner.

Meanwhile, in 1877, Creighton had been appointed Demonstrator of Anatomy at Cambridge under Sir George Murray Humphry. He was attached to King's College, of which Humphry later became a Professorial Fellow. The next few years in Creighton's life form an interesting exercise in speculation. In 1877, the year in which he went to Cambridge, he had an article "On the Development of the Mamma" in the *Journal of Anatomy and Physiology*. This was volume XI. Between then and the publication of volume XV for 1880-81 Creighton had ten more articles—a very respectable output. On the title page of volume XI for 1877 the editors are given as Humphry, Professor of Anatomy at Cambridge; William Turner, Professor of Anatomy at Edinburgh; Michael Foster, Professor of Physiology at Trinity College, Cambridge; and William Rutherford, Professor of the Institutes of Medicine at Edinburgh. For volume XII the editors were Humphry, Turner, and J. G. M'Kendrick, Professor of the Institutes of Medicine at Glasgow. For volume XIII (1879) the editors were Humphry, Turner and M'Kendrick; but a fourth editor was again added. This was Charles Creighton. Thus, at the age of 32, he had become a joint editor of a leading scientific journal, in very exalted company. For the next two years he remained a joint editor, and Cambridge University had meanwhile (1880) conferred the degree of M.A. *propter merita* upon him. He had certainly "arrived". Then, in 1881, he left Cambridge and came to London. No further papers ever appeared from his pen in the *Journal* after volume XV, and in volume XVI his name was dropped from the list of editors. A crisis had evidently occurred. Bulloch covers it with the phrase "He left Cambridge with some sort of a grievance and came to London". The crisis must have been great to warrant Creighton sacrificing such a brilliant future, and to encourage the editors to drop such an outstanding and enthusiastic colleague.

Creighton now came to London, and the Metropolis seems to have swallowed him up. He lived in it for thirty-seven years, and as the years went by he became more and more a shadowy figure, until many acquaintances had forgotten him completely. At first he tried general practice in Savile Row, and later in New Cavendish Street, but his attempt was unsuccessful. Bulloch, who knew him well for twenty years, said that "he was by nature totally unfitted for this branch of medical activity". During the greater part of his time in London—he left it in 1917—Creighton lived in chambers in Great Ormond Street. After his failure in practice he seems to have decided, possibly without reluctance, to devote himself to a life of literature and scholarship, and his time during this long period was divided between the British Museum, or some other great library, and his home. It was then that his great work was done. His last medical work during this period appeared in

1908—a book entitled *Contributions to the Physiological Theory of Tuberculosis*. During the next twelve years there was silence until, at the age of 73, he emerged from obscurity once again with *Some Conclusions on Cancer*—his last work.

SUMMARY OF CREIGHTON'S LABORATORY AND LITERARY WORK IN THE MEDICAL FIELD

In the following table I have grouped his writings to show the development of his thought and interests.

(a) Early pathological work ..	<ul style="list-style-type: none"> (i) Early papers: Privy Council, &c. (ii) <i>Contributions to the Physiology and Pathology of the Breast</i>, 1878. (iii) Other writings on the breast, cancer and bovine tuberculosis.
(b) Infectious disease and historical epidemiology.	<ul style="list-style-type: none"> (i) <i>On the Autonomous Life of the Specific Infections</i>, 1883. (ii) Translation of Hirsch's <i>Handbuch der historisch-geographischen Pathologie</i>, 3 vols., 1883–86.
(c) <i>Unconscious Memory in Disease</i> , 1886.	
(d) The vaccination question ..	<ul style="list-style-type: none"> (i) <i>Cow-pox and Vaccinal Syphilis</i>, 1887. (ii) <i>Encyclopædia Britannica</i>. Article on Vaccination, 1888. (iii) <i>Jenner and Vaccination</i>, 1889.
(e) The <i>Encyclopædia Britannica</i> (Ninth edition).	<ul style="list-style-type: none"> Articles on Malaria, Medicine, Morgagni, Pathology, Pellagra (Vaccination, see (d)).
(f) Historical epidemiology ..	<i>History of Epidemics</i> , 1891–4.
(g) History of public health ..	In Traill's <i>Social England</i> , 1894.
(h) Late pathological work ..	<ul style="list-style-type: none"> (i) <i>Formative Property of Glycogen</i>, 1896–9. (ii) <i>Cancer and Other Tumours of the Breast</i>, 1902.
(i) Plague	<i>Plague in India</i> , 1906.
(j) Tuberculosis	<i>Contributions to the Physiological Theory of Tuberculosis</i> , 1908.
(k) Cancer	<i>Some Conclusions on Cancer</i> , 1920.

I now propose to group these writings and to deal with some of them very briefly under a few headings.

(a) *Pathological writings*.—His earliest paper (1874) was concerned, as has been stated, with secondary growths in the liver. He reached a hypothesis that the secretory function of mucous membranes is performed by means of a process in the epithelial cells identical with the process known as endogenous cell-formation, and he thought this theory was of significance as regards the malignant tumours of epithelial parts. He took the mammary gland as an illustration of his theory, and his next papers were devoted to that gland. He first tackled the normal processes of development of the mammary function, involution and evolution, and then applied his results to what he called "the grand disease of the breast"—the tumour disease. He concluded that centres of different types of cancer cells may each infect with its own type of structure different glands in the same pocket. He admitted that this research had not taken him very far.

It would be fruitless to follow these researches further. Creighton always considered himself as a pathologist, and rated his pathological work higher than the historical researches which have made his name.

In the library of the Royal Society of Medicine there is a bound volume of reprints on pathological subjects by Creighton. A carefully written list of contents at the beginning of the volume is subscribed "C.C. June 1884" (see next page). This makes it fairly certain that the book belonged to him. So far this is one of the very few specimens of his handwriting which I have discovered.

To this group belongs the article on "Pathology" which Creighton contributed to the ninth edition of the *Encyclopædia Britannica*. This volume appeared in 1885. The article consists of 46 pages, and appears to be a competent piece of work. The preponderance of references to German pathologists, especially to Virchow, Cohnheim and their schools, is noteworthy.

The *Microscopic Researches on the Formative Property of Glycogen*, which he published in 1896, are of interest as illustrating one side of his character. From the preface he had obviously been refused a publication grant from some scientific body. He then turned to the Leigh Browne Endowment. This trust was founded "for the promotion of original research in the biological sciences without any recourse to experiments upon living animals"

Creighton's work was microscopic and did not involve animal experiments. Hence he had no hesitation in accepting the assistance offered.

(b) *Writings on tuberculosis*.—Creighton's early writings had dealt to a considerable extent with the pathology of bovine tuberculosis. In the tuberculosis field he was a heretic, out and out. His theories are now as dead as the dodo, but in any study of Creighton the man they are significant. Perhaps the best short statement of his early views is found in the *Encyclopædia Britannica* article on pathology. In referring to experiments to produce tuberculosis by inoculating or feeding tuberculous matter, he says that a suggestive proportion of all such experiments have succeeded. Then he goes on: "It has been boldly alleged by Koch that the active agent in the inoculative production of tubercle is not the tuberculous matter from a previous case, but a minute rod-like living parasite belonging to the order of schizomycetes. According to this view tubercle is from first to last an affair of a parasite". He then says that the weak point is that one cannot be assured that the inoculated parasites have been completely freed from the original tuberculous matter! This is a very good rock for a heretic to take his stand on.

This article was published in 1885, and twenty-three years later Creighton was still fighting a magnificent rearguard action—though he would not have admitted, or even realized, that it was a rearguard action. It was a case of everyone else being out of step but himself. In 1908 he published his *Contributions to the Physiological Theory of Tuberculosis*. In this work he acknowledged the assistance of William Bulloch in obtaining for him inoculation material and the brains of patients who had died from tuberculous meningitis. He carried out a series of injections of tubercle bacilli into rabbits, and from the histological features he concluded that the resulting neoplasm was formed to get rid of the waste of disintegrated old blood corpuscles. He thought that bovine tuberculosis was a chronic disorder of nutrition, to which breeding might predispose in a very high degree. The same applied to a large part of human tuberculosis. As a cause of the tuberculosis of infants he suggested the absorption of milk from anæmic cows, which produced a state of the blood favouring the formation of minute multiple thrombi in the meningeal arterioles. There was nothing specifically infective common to human and bovine tuberculosis. He denied that tuberculosis was of the nature of a specific fever. Though cases of acute miliary tuberculosis often ran the course of a specific fever, it differed from other forms of tuberculosis only "in the insidiousness of the prodromata (in a scrofulous constitution) and the suddenness with which the actual crisis arises".

A man who could assert such views on experimental evidence in 1908, and have them published by a reputable publisher, must have been a very extraordinary character indeed.

(c) *Cow-pox and smallpox*.—Creighton's first work on this subject, *The Natural History of Cow-pox and Vaccinal Syphilis*, was published in 1887. There is no preface, and it is not clear when or for what reason he first embarked on the Jennerian question. In this work Creighton discusses the origin of vaccine lymph from the first stocks. He implied that Jenner had no justification for calling cow-pox "smallpox of the cow", and asserted that cow-pox had stronger relations with "the great pox" (syphilis) than it had with smallpox. He differentiated what he called "vaccinal syphilis" from "venereal syphilis" in the infant. In the following year Creighton's article on "Vaccination" appeared in the ninth edition of the *Encyclopædia Britannica*. Creighton re-emphasized his views on the identity of "vaccinal syphilis" with vaccinia of a severe type, and he regarded various sequelæ of vaccination—such as erysipelas, jaundice, skin eruptions, ulcers, and "vaccinal syphilis"—not as evidence of secondary infection, but as a reversion to type of certain manifestations produced by primary inoculation from the cow. Holding as he did such views regarding the nature of vaccinia and of vaccine matter, it was inevitable that Creighton should have cast doubt upon the practice of vaccination. This article, appearing in an authoritative publication which should, as a reviewer pointed out, have stood for a generation, raised much adverse comment in the medical press, and one reviewer stigmatized Creighton's views on the pathogenesis of cow-pox and of smallpox as "pathological transcendentalism". In the following year (1889) Creighton returned to the attack with his book on *Jenner and Vaccination: a Strange Chapter of Medical History*. Creighton was a tactician of a high order, and at the start of the book he proceeded to discredit Jenner's observational acumen. He suggested that Jenner's observation of the young cuckoo ejecting its foster brothers from the nest is a "tissue of inconsistencies and absurdities". Creighton then discussed the history of the whole question of vaccination in this country and in Germany, France and Italy. His concluding chapter summed up his views and gave more fuel to those who had called him an anti-vaccinationist. Greenwood [8] has reviewed the position from the modern aspect, and has shown that in respect of both the cuckoo and the fact that cow-pox is smallpox of the cow, Jenner was right and Creighton was wrong. A film has been taken of the cuckoo carrying out the ejection; and the work of Monckton Copeman and of Mervyn Gordon proved the analogy of smallpox and cow-pox.

The two pages of "Contents", in Creighton's handwriting, of his own bound copy of reprints of his early papers.

Creighton's work was microscopic and did not involve animal experiments. Hence he had no hesitation in accepting the assistance offered.

(b) *Writings on tuberculosis*.—Creighton's early writings had dealt to a considerable extent with the pathology of bovine tuberculosis. In the tuberculosis field he was a heretic, out and out. His theories are now as dead as the dodo, but in any study of Creighton the man they are significant. Perhaps the best short statement of his early views is found in the *Encyclopædia Britannica* article on pathology. In referring to experiments to produce tuberculosis by inoculating or feeding tuberculous matter, he says that a suggestive proportion of all such experiments have succeeded. Then he goes on: "It has been boldly alleged by Koch that the active agent in the inoculative production of tubercle is not the tuberculous matter from a previous case, but a minute rod-like living parasite belonging to the order of schizomycetes. According to this view tubercle is from first to last an affair of a parasite". He then says that the weak point is that one cannot be assured that the inoculated parasites have been completely freed from the original tuberculous matter! This is a very good rock for a heretic to take his stand on.

This article was published in 1885, and twenty-three years later Creighton was still fighting a magnificent rearguard action—though he would not have admitted, or even realized, that it was a rearguard action. It was a case of everyone else being out of step but himself. In 1908 he published his *Contributions to the Physiological Theory of Tuberculosis*. In this work he acknowledged the assistance of William Bulloch in obtaining for him inoculation material and the brains of patients who had died from tuberculous meningitis. He carried out a series of injections of tubercle bacilli into rabbits, and from the histological features he concluded that the resulting neoplasm was formed to get rid of the waste of disintegrated old blood corpuscles. He thought that bovine tuberculosis was a chronic disorder of nutrition, to which breeding might predispose in a very high degree. The same applied to a large part of human tuberculosis. As a cause of the tuberculosis of infants he suggested the absorption of milk from anæmic cows, which produced a state of the blood favouring the formation of minute multiple thrombi in the meningeal arterioles. There was nothing specifically infective common to human and bovine tuberculosis. He denied that tuberculosis was of the nature of a specific fever. Though cases of acute miliary tuberculosis often ran the course of a specific fever, it differed from other forms of tuberculosis only "in the insidiousness of the prodromata (in a scrofulous constitution) and the suddenness with which the actual crisis arises".

A man who could assert such views on experimental evidence in 1908, and have them published by a reputable publisher, must have been a very extraordinary character indeed.

(c) *Cow-pox and smallpox*.—Creighton's first work on this subject, *The Natural History of Cow-pox and Vaccinal Syphilis*, was published in 1887. There is no preface, and it is not clear when or for what reason he first embarked on the Jennerian question. In this work Creighton discusses the origin of vaccine lymph from the first stocks. He implied that Jenner had no justification for calling cow-pox "smallpox of the cow", and asserted that cow-pox had stronger relations with "the great pox" (syphilis) than it had with smallpox. He differentiated what he called "vaccinal syphilis" from "venereal syphilis" in the infant. In the following year Creighton's article on "Vaccination" appeared in the ninth edition of the *Encyclopædia Britannica*. Creighton re-emphasized his views on the identity of "vaccinal syphilis" with vaccinia of a severe type, and he regarded various sequelæ of vaccination—such as erysipelas, jaundice, skin eruptions, ulcers, and "vaccinal syphilis"—not as evidence of secondary infection, but as a reversion to type of certain manifestations produced by primary inoculation from the cow. Holding as he did such views regarding the nature of vaccinia and of vaccine matter, it was inevitable that Creighton should have cast doubt upon the practice of vaccination. This article, appearing in an authoritative publication which should, as a reviewer pointed out, have stood for a generation, raised much adverse comment in the medical press, and one reviewer stigmatized Creighton's views on the pathogenesis of cow-pox and of smallpox as "pathological transcendentalism". In the following year (1889) Creighton returned to the attack with his book on *Jenner and Vaccination: a Strange Chapter of Medical History*. Creighton was a tactician of a high order, and at the start of the book he proceeded to discredit Jenner's observational acumen. He suggested that Jenner's observation of the young cuckoo ejecting its foster brothers from the nest is a "tissue of inconsistencies and absurdities". Creighton then discussed the history of the whole question of vaccination in this country and in Germany, France and Italy. His concluding chapter summed up his views and gave more fuel to those who had called him an anti-vaccinationist. Greenwood [8] has reviewed the position from the modern aspect, and has shown that in respect of both the cuckoo and the fact that cow-pox is smallpox of the cow, Jenner was right and Creighton was wrong. A film has been taken of the cuckoo carrying out the ejection; and the work of Monckton Copeman and of Mervyn Gordon proved the analogy of smallpox and cow-pox.

(d) *Historical epidemiology: Hirsch*.—The *Handbuch der historisch-geographischen Pathologie* was planned by August Hirsch about 1856, and the first edition appeared five years later. Though it was a monumental work a great mass of material was published in the following twenty years so that the second edition was a very large book. The first volume appeared in 1881, and Creighton was asked to undertake the translation of the whole three volumes for the New Sydenham Society. It was a Herculean task. The first volume of the translation appeared in 1883, and the second and third volumes in 1885 and 1886 respectively. Apart from indices the whole work in translation takes up over 2,100 closely printed pages. The volumes are heavily documented. Creighton must have learned a great deal in making this translation—but at a cost! He once told Bulloch that it occupied him for twelve hours a day for three years. If Creighton had done nothing else but this translation, he would still have placed the world of scholarship in his debt.

(e) *The History of Epidemics in Britain*.—The first volume of this great work appeared in 1891, and the second volume three years later. The whole work consists of over 1,500 pages; but even this number gives only a partial idea of the depth of its contents, and of the knowledge and labour which were essential for its compilation. Bulloch said that Creighton read and spoke every European language, alive or dead, and here we see the fruits of his remarkable ability.

The first volume covers the period from 664 to 1666, and deals with the following subjects in this order: Pestilences Previous to the Black Death; Leprosy in Mediæval Britain; The Black Death, 1348–49; Epidemics 1349–1485; The Sweating Sickness, 1485–1551; Plague in the Tudor Period; Gout Fevers and Influenzas in the Tudor Period; The French Pox; Smallpox and Measles; Plague and Fevers from James I to the Restoration; Sickness of Early Voyages and Colonies; The Great Plague of London.

The second volume covers the period 1666–1893, and has the following contents: Typhus and Other Continued Fevers; Fever and Dysentery in Ireland; Influenzas and Epidemic Agues; Smallpox; Measles; Whooping Cough; Scarletina and Diphtheria; Infantile Diarrhoea, Cholera Nostras and Dysentery; and lastly Asiatic Cholera.

It should be said that Creighton's peculiar views on the ætiology of infective diseases in no way impair the value of the work as a discussion of history. We meet these views very early in the book. On page 7 of the first volume he says that the nature of the plagues of 664 can only be guessed. "They have the look of having been due to some poison in the soil, running hither and thither, as the Black Death did seven centuries after". Somewhat further on he wonders whether the so-called psychopathies of the mediæval and more recent periods "may not have had a beginning, at least, in some toxic property of the staple food". These two factors keep recurring throughout the work, right up to the last outbreak of cholera. The stand which he takes sometimes leads him into a rather curious situation. For example, in discussing the plague-spots of the world, he gives six long quotations, dating between 1851–1882, from writers who had been to these places. In four out of the six there is *specific* mention of the mortality among rats, and even the results of post-mortems on rats. Two pages later he notes—correctly of course—that observations of rats leaving their holes during an outbreak are found in the plague books of London and Edinburgh during the Tudor period. He then says that this is only one of many proofs that the virus of plague has its habitat in the soils, although it may be carried long distances clinging to other things.

But such matters are extraneous. Among the great things in Creighton's work are his descriptions of the Black Assizes, his notable account of the history of variolation, his brilliant description of the results of the Black Death, and his numerous etymological references which indicate the true scholar. Among the latter is an interesting note on the derivation of the term "measles".

Of the two volumes of the work the first volume deals with a field which was practically untilled when Creighton entered it. His opening chapter is a most learned account of the famine fevers which were rampant in mediæval England, and in this chapter he embodied a mass of learning much of which had previously been available only in the original sources. There has been little research on this material since Creighton's day. His remarks on ergotism are especially interesting. The same may be said of his chapter on leprosy, in which he exposed a number of the misleading opinions of the day. The chapter on sweating sickness is of great importance. It was—and still is—the only comprehensive discussion of this strange malady. Creighton was able to discover a new document which fixed the date of first onset of this disease and which consequently had an important bearing on our knowledge of the sources of the disease.

Although the second volume, treating of the history of fevers since 1666, dealt with material which had already been written up in various forms, there is a mastery about Creighton's handling of the data which has so far discouraged all serious competition. There is too much important material in this volume to warrant selection for a short paper, but his

accounts of typhus fever and of influenza and epidemic agues are packed with information which is of practical interest to the modern epidemiologist.

The reviews of these volumes were uniformly good, but nearly all reviewers pointed out that, while Creighton's scholarship was almost beyond criticism, his views on the ætiology of infectious diseases must be disregarded. The *Lancet* said that it was a work which would without doubt "take the first rank, not only in medical, but in general literature". The reviewer concluded that "it is a great work—great in conception, in learning, in industry, in philosophic insight". To-day—more than fifty years after these words were written—modern scholarship can do nothing but endorse this view.

LATER LIFE AND INTERESTS

The controversy over cow-pox and vaccination was the great tragedy of Creighton's life. Although he must have been deeply hurt by the manner in which his professional colleagues received his views, he apparently did not show it. The years immediately following the start of the ostracism were of course full years: the great mass of historical material which he had accumulated during his years of reading in the British Museum was being arranged and the book written. He must at this time have been engaged also in writing the brilliant chapters on the history of Public Health which appeared in the volumes of Traill's *Social England*. These chapters still merit careful study. After the second volume of the *History* appeared in 1894 he wrote practically nothing in the medical field until 1896, when the first volume of his glycogen studies came out. The second volume appeared three years later. It would seem therefore that Creighton devoted five good years of his life to the prosecution of rather futile studies—handicapped as he was by the impracticability of carrying out experimental work on animals. I do not know where he had his laboratory, or where his microscopic work was carried out. Bulloch says that Creighton knew all about the latest methods of section-cutting and staining, and yet himself preferred sections cut with a razor from tissue embedded in a "penny dip", and stained with ink.

It was during these years in London that he made a habit, from about 1905 onwards, of looking in at the Bacteriology Department of the London Hospital about once every two months. Bulloch was of course the attraction. Professor Greenwood [9] tells me that Creighton was asked to give a series of lectures on the History of Medicine, and these were a great success. I have made enquiries at the London Hospital, and no record of this series is now in existence. Sir Paul Fildes [10] also knew him at the London Hospital at this period. He tells me that, though Creighton was a man who did not suffer fools gladly, he was in no way cantankerous. A brilliant conversationalist, he gave his juniors the impression that he was a friendly and unassuming man. Creighton must have been very lonely during these years, and he probably came to the London Hospital partly for that reason. His conversation during these visits would range over a variety of topics, but he was easily drawn on the subject of spontaneous generation, or on the tubercle bacillus. He professed great satisfaction in the fact that infectious disease was due to a miasma, and he was quite satisfied in his own mind that the tubercle bacillus, though present, was not the cause of tuberculosis. Professor Turnbull also knew him at this period, and he tells me that "however fantastic Creighton's views on some subject might appear to be at first, only a fool would not treat them with the greatest consideration. When they were carefully considered, it required very strong evidence to enable one to satisfy oneself that they were impossible" [11].

Creighton had a tall, commanding presence, and he was always meticulously dressed, with a turned-down Eton collar and a black satin tie passed through a ring.

SHAKESPEAREAN STUDIES AND OTHER LITERARY WORK

Creighton had been a student of literature all his life, and his immense learning and wonderful memory enabled him to range profitably over a wide field. He was deeply read in the Bible and in Shakespeare, and it was in this period—1904 to 1913—that his three books of Shakespearean criticism were published. *Shakespeare's Story of his Life* was published in 1904; *An allegory of Othello* in 1912; and *An allegory of King Lear* in 1913. In order to show the width of Creighton's learning and interests I propose to say a few words about the first of these books.

In 1900 Samuel Butler gave Creighton a copy of his book on Shakespeare's Sonnets, and Creighton soon disagreed—as he would do!—with Butler's identification of a key character in the sonnets. From the line in Sonnet 20 "a man in hew, all Hews in his controlling" Creighton identified Lord Herbert, and professed to confirm from other sources. He then said that the Sonnet series on the Rival Poet was occasioned by the death of Spenser, the Poet Laureate. The Rival Poet had been identified by Boaden as Samuel Daniel. Creighton agreed, and showed that though Daniel himself believed that he was the new Poet Laureate, he never got the patent for the office. The whole point is that Shakespeare, the greatest poet of his age, had been passed over, and the reasons are obscure. An answer is presumably

given in the next series of sonnets beginning "Farewell, thou art too dear for my possessing". Thomas Tyler had guessed that the lady addressed was Mary Fitton, a favourite maid-of-honour to the Queen, and Creighton proved this from other sources.

Creighton then found that from Sonnet 100 onwards there is an attempt to persuade Lord Pembroke to father an impending infant which is not his. Shakespeare was apparently impeached of the paternity—falsely as he alleged. Creighton followed this impeachment in various plays, and he devotes a special study to *The Tempest*, which is the story of Prospero's life. Creighton alleged that Lord Southampton had a hand in the early plays, and that Southampton was by way of being a poet. The plays had at first been anonymous, but while Southampton was abroad Shakespeare had begun to put his own name on the title pages. When Southampton returned he thought that he had been treated ill. Meanwhile Spenser died, and in Sonnet 94 Shakespeare discovers who had been plotting against him with reference to the succession.

Over a period of years up to 1892 Creighton contributed forty-seven biographies to the *Dictionary of National Biography*, and he had also historical articles in *Janus*. He was described as a voluminous writer, and it is quite probable that he had articles in non-medical journals which I have not yet traced.

LAST YEARS

Creighton had always been poor, and he lived frugally. Bulloch approached Mr. Asquith while he was Prime Minister, requesting a Civil Pension for Creighton. Professor Turnbull [11] tells me that when Bulloch mentioned the matter to Asquith, and named the *History of Epidemics*, Asquith replied: "Oh yes! I have read that". He was granted a pension of £140 a year and this he enjoyed until his death.

In 1917 a German bomb fell in Great Ormond Street, and thereafter Creighton had difficulty in sleeping. He decided to remove from London, and he was able to buy a small cottage and garden—"The Yews"—at Upper Boddington. There, at peace with the world, this great scholar passed his remaining years, and there he died. I have been in touch with the Vicar of the Parish, who knew Creighton well and who officiated at the funeral. The main point which he emphasizes is that Creighton never referred to his previous life or acquaintances.

I leave till a later occasion a fuller study of Creighton's merits as a scholar and a historian. Of Creighton as a man there appears to be a problem unsolved. No one seems to know why he did not ultimately grace a university chair. It is understandable that, once embarked on the vast sea of historical research, he would desire to be free of all administrative commitments. But when the *History* was finished, things might have been different. The answer seems to be that the cow-pox controversy probably upset all his plans. This is suggested by a letter which he wrote to the *Lancet* on December 22, 1894 [12]. Mr. (later Sir) Shirley Murphy, in his Presidential Address to the Epidemiological Society, had complimented Creighton on an excellent translation of a German word used by Hirsch in the preface to his comparative study of disease in all climates. The word was "eine Doctrin", meaning a body of knowledge which justifies for itself a place among the medical sciences. Creighton says that the best illustration of the rightness of Hirsch's claim for academic recognition in his own subject is the fact that he was called from being a general practitioner at Danzig "to represent his subject in the Berlin Faculty of Medicine when he had published only one-half of his work". Creighton no doubt felt in his heart that his subject, narrower in scope perhaps, but no less deep and exacting, should have had the same recognition. There is every reason to believe that if it had, and if bacteriological implications could have been kept out of the curriculum, Creighton would have been a great and inspiring teacher.

The Evolution of the Auditory Conducting Apparatus

A New Synthesis Based on Functional Considerations

By A. TUMARKIN, F.R.C.S.Ed.

DEFINITION

THE auditory conducting apparatus comprises all those structures that enable an animal to pick up acoustic energy from its environment and to apply that energy to the auditory neuro-epithelium of the inner ear. It follows from the definition that any theory of the evolution of this apparatus must account not only for the auditory mechanism of the mammals, but also for the cruder structures found in lower animals to-day.

Mechanically, the conducting mechanism of the middle ear may be subdivided into:

(a) The collecting component (in mammals this comprises pinna, external auditory canal and tympanic membrane).

(b) The transmitting component (in mammals this comprises malleus, incus and stapes).

(c) The terminal component (the oval window and perilymphatic duct and fluid). Component (c) is dealt with elsewhere (Tumarkin [6]).

This paper deals with the evolution of components (a) and (b) and is based on an analysis of the conditions found in animals to-day.

Six main types may be distinguished:

(1) *V.Sq.*—*Vestibulo-Squamosal* (fig. 1A).—This is found in urodeles (i.e. the tailed Amphibia, e.g. newts, salamanders, &c.). The columella stretches from oval window to the squamosal. It is a bone-conducting mechanism. The animal picks up vibrations by direct contact between the skull and the substrate (i.e. ground or other vibrating material). There is no tympanic membrane and no middle-ear cavity.

FIG. 1A.

FIG. 1B.

FIG. 1C.

FIG. 1D.

1A.—V.Sq. A primitive bone-conducting mechanism.

1B.—V.Q. A primitive bone-conducting mechanism.

1C.—V.S. An intermediate bone-cond. mechanism.

1D.—V.H. A primitive air-conducting mechanism.

(2) *V.Q.*—*Vestibulo-Quadrate* (fig. 1B).—Found in snakes—some lizards and many extinct reptiles. This resembles V.Sq. but the columella is attached externally to the quadrate. Vibrations are transmitted via the lower jaw and articulo-quadrate joint.

(3) *V.S.*—*Vestibulo-Scapular* (fig. 1C).—This remarkable mechanism is only found in urodeles and Anura (i.e. the jumping Amphibia, e.g. frogs and toads). It consists of an operculum, i.e. a plaque of cartilage lying in the oval window posterior to the true stapes. The musculus opercularis runs from the operculum to the scapula. Vibrations in the substrate pass via the fore-paw to the scapula and thence via the opercular structures to the vestibule. This is also a B.C. mechanism.

(4) *V.H.*—*Vestibulo-Hyoid* (fig. 1D), i.e. hearing via the buccal cavity and the hyoid bone. In amphisbaenids the stapes is continuous with the hyoid bone. These animals listen by opening the mouth. This is a crude form of air-conducted hearing. The floor of the mouth acts as a tympanic membrane and the hyoid acts as an intermediate ossicle comparable with the incus and malleus of the mammal.

given in the next series of sonnets beginning "Farewell, thou art too dear for my possessing". Thomas Tyler had guessed that the lady addressed was Mary Fitton, a favourite maid-of-honour to the Queen, and Creighton proved this from other sources.

Creighton then found that from Sonnet 100 onwards there is an attempt to persuade Lord Pembroke to father an impending infant which is not his. Shakespeare was apparently impeached of the paternity—falsely as he alleged. Creighton followed this impeachment in various plays, and he devotes a special study to *The Tempest*, which is the story of Prospero's life. Creighton alleged that Lord Southampton had a hand in the early plays, and that Southampton was by way of being a poet. The plays had at first been anonymous, but while Southampton was abroad Shakespeare had begun to put his own name on the title pages. When Southampton returned he thought that he had been treated ill. Meanwhile Spenser died, and in Sonnet 94 Shakespeare discovers who had been plotting against him with reference to the succession.

Over a period of years up to 1892 Creighton contributed forty-seven biographies to the *Dictionary of National Biography*, and he had also historical articles in *Janus*. He was described as a voluminous writer, and it is quite probable that he had articles in non-medical journals which I have not yet traced.

LAST YEARS

Creighton had always been poor, and he lived frugally. Bulloch approached Mr. Asquith while he was Prime Minister, requesting a Civil Pension for Creighton. Professor Turnbull [11] tells me that when Bulloch mentioned the matter to Asquith, and named the *History of Epidemics*, Asquith replied: "Oh yes! I have read that". He was granted a pension of £140 a year and this he enjoyed until his death.

In 1917 a German bomb fell in Great Ormond Street, and thereafter Creighton had difficulty in sleeping. He decided to remove from London, and he was able to buy a small cottage and garden—"The Yews"—at Upper Boddington. There, at peace with the world, this great scholar passed his remaining years, and there he died. I have been in touch with the Vicar of the Parish, who knew Creighton well and who officiated at the funeral. The main point which he emphasizes is that Creighton never referred to his previous life or acquaintances.

I leave till a later occasion a fuller study of Creighton's merits as a scholar and a historian. Of Creighton as a man there appears to be a problem unsolved. No one seems to know why he did not ultimately grace a university chair. It is understandable that, once embarked on the vast sea of historical research, he would desire to be free of all administrative commitments. But when the *History* was finished, things might have been different. The answer seems to be that the cow-pox controversy probably upset all his plans. This is suggested by a letter which he wrote to the *Lancet* on December 22, 1894 [12]. Mr. (later Sir) Shirley Murphy, in his Presidential Address to the Epidemiological Society, had complimented Creighton on an excellent translation of a German word used by Hirsch in the preface to his comparative study of disease in all climates. The word was "eine Doctrin", meaning a body of knowledge which justifies for itself a place among the medical sciences. Creighton says that the best illustration of the rightness of Hirsch's claim for academic recognition in his own subject is the fact that he was called from being a general practitioner at Danzig "to represent his subject in the Berlin Faculty of Medicine when he had published only one-half of his work". Creighton no doubt felt in his heart that *his* subject, narrower in scope perhaps, but no less deep and exacting, should have had the same recognition. There is every reason to believe that if it had, and *if* bacteriological implications could have been kept out of the curriculum, Creighton would have been a great and inspiring teacher.

The next stage was also determined by a biological accident.

FIG. 3.—Cartilaginous fish skull showing five processes of hyomandibular. 1. Ventral process. 2. Dorsal process. 3. Opercular process. 4. Hyoid process. 5. Quadrate process.

the auditory capsule thinned out to form an oval window and the perilymphatic duct was laid down. The history of the auditory conducting mechanism really starts with the appearance of these two structures.

In addition to a ventral process the hyomandibular possessed:

A dorsal process extending up to the dermal skull bone (especially the squamosal).

A quadrate process extending to the quadrate.

A hyoid process extending to the hyoid.

The opercular process extending to the operculum. [This operculum is a scale-like bone overlying the gill-slits of the fish. It has no relation at all to the cartilaginous operculum of the amphibian oval window.]

It follows that vibrations would reach the auditory capsule along the following routes:

(a) Via the dermal skull bones and the dorsal process as the animal thrust its head in the mud.

(b) Via the lower jaw and articulo-quadrate joint and the quadrate process when the jaw was resting on the ground.

(c) Via the opened mouth and the hyoid and the hyoid process.

(d) Furthermore these animals were not *completely* deaf to sound waves impinging directly on the body surface. A small fraction of the sound striking the gill area would enter and pass via the opercular process to the ventral process.

(e) Lastly vibrations passing from the substrate into the manus and pectoral girdle would proceed via the crano-scapular muscles to the auditory capsule without the intermediation of the hyomandibular. Thus the primitive Amphibia received faint auditory sensations via five distinct routes, of which the first three were the most efficient.

Then followed a process of specialization in which one or other route was perfected at the expense of the others. Route (a) gave rise to the V.Sq. mechanism of modern urodeles. This is obviously an unambitious mechanism only suited to completely prostrate animals. Even the lowly urodeles have found it inadequate for the obvious reason that it ceases to function as soon as the head is lifted off the ground. They have therefore developed the next available route for detecting substrate vibrations, i.e. via the fore-paw. It appears therefore that the V.S. mechanism developed phylogenetically after the V.Sq. mechanism in response to the functional demands of a more erect posture. Generally speaking modern urodeles possess both V.Sq. and V.S. but the relative importance of the two mechanisms varies greatly. In the completely prostrate types V.Sq. predominates and V.S. may not be present at all. On the other hand in the more erect types V.S. predominates and V.Sq. tends to disappear entirely.

The primitive Amphibia flourished throughout the Devonian and Carboniferous but in the Permian they were being thrust into the background by the newly evolved reptiles.

For our present purpose it will suffice to describe the main stem reptiles (the cotylosaurs) branching off into the archosaurs the pro-squamata and the premammalians (see fig. 15).

The archosaurs gave rise to the mighty dinosaurs who dominated the earth all through the Mesozoic era. They became extinct in the Cretaceous but early offshoots are represented

(5) *V.T.*—*Vestibulo-Tympanic*, i.e. hearing via a perfected drum and a single ossicle. In the highest Amphibia, i.e. frogs and in most reptiles, e.g. crocodiles, turtles, and many lizards, the stapes (usually called the columella) is a delicate spicule of bone lying freely mobile in a middle-ear cavity. Its inner extremity fits into the oval window—its outer extremity is continuous with a cartilaginous extra columella, which is inserted into a perfected trilaminar drumskin.

(6) *V.O.*—*Vestibulo-Ossicular*.—This is the mammalian triple ossicle system.¹

In addition to these clear-cut mechanisms, certain transitional types must be included. *Sphenodon*—a primitive New Zealand lizard shows the transition from *V.H.* to *V.T.* The stapes in this animal is still continuous with the hyoid—but in addition it sends a process to a plaque of fibrous tissue which lies subjacent to the pharyngeal mucosa. This plaque is largely overlain by the *musculus depressor mandibulae*, so that it can hardly pick up external sounds, nevertheless we shall see that certain primitive animals, starting with *V.H.* evolved *V.T.* and in the process passed through a stage similar to *Sphenodon* (see fig. 5).

It appears that other lizards have evolved from *V.Q.* to *V.T.* and so it is still possible to find amongst the various agamid and iguanid lizards all stages in this transition. In some the stapes is firmly attached to the quadrate. In others a rudimentary drum has formed but it is still overlain by muscles. In others the muscles have receded but the drum is still overlain by scales. *Pari passu* with this evolution of the drum goes the development of the middle-ear cavity. The stapes itself becomes thinner, and instead of being enveloped by muscles and connective tissue, it gradually becomes airborne being merely suspended by a thin mesentery of mucous membrane (fig. 6).

THE SYNTHESIS

It remains to correlate these data with each other and with the known facts of paleo-biology.

We start therefore at the Devonian era with the evolution of the amphibia. At that time the climate was torrid. The earth was covered with steamy lagoons which were liable to dry up periodically. Under those circumstances, the fish in them died. Gradually in response to such periodic disasters the stegocephalian Amphibia emerged, able to breathe air when necessary and provided with four limbs which enabled them to crawl off in search of water.

The very earliest Amphibia such as *Eogyrinus* (fig. 2) closely resembled the fishes except

FIG. 2.—*Eogyrinus*, a Carboniferous embolomere amphibian; estimated length about 15 ft. (After Gregory, modified from Watson.) (Reproduced by permission.)

that they had four flabby little paws in place of fins. They lived mostly in water, only venturing on to land when the shallow lagoons dried up. In water the animal was enveloped by an environment of almost identical characteristics. A sound wave traversing the water easily entered the skull. On land, however, it was surrounded by air. But sound waves in a gaseous medium like air when they encounter a dense medium like a fish are almost completely reflected. Therefore the amphibian was very deaf to airborne sounds. There was, however, another avenue for sound transmission, the ground. These primitive Amphibia were prostrate and sound waves in the ground easily entered their bodies. At that time there was no specialized acoustic receptor. The utricle and saccule were purely organs of static equilibrium. It is clear however that these structures—primarily acting as gravity receptors—would also respond to the periodic vibrations of a sound wave. It was this biological accident which evolved an acoustic receptor out of the primitive gravity receptor.

¹In (1) (2) (4) (5) and (6) the nomenclature is based on the attachments of the stapes. The internal attachment in each case is to the vestibule (i.e. the oval window). The external attachment completes the titles. *V.O.* for instance indicates that externally the stapes articulates with an ossicle, i.e. the incus. In (3) the operculum determines the nomenclature.

The next stage was also determined by a biological accident.

FIG. 3.—Cartilaginous fish skull showing five processes of hyomandibular. 1. Ventral process. 2. Dorsal process. 3. Opercular process. 4. Hyoid process. 5. Quadrate process.

the auditory capsule thinned out to form an oval window and the perilymphatic duct was laid down. The history of the auditory conducting mechanism really starts with the appearance of these two structures.

In addition to a ventral process the hyomandibular possessed:

A dorsal process extending up to the dermal skull bone (especially the squamosal).

A quadrate process extending to the quadrate.

A hyoid process extending to the hyoid.

The opercular process extending to the operculum. [This operculum is a scale-like bone overlying the gill-slits of the fish. It has no relation at all to the cartilaginous operculum of the amphibian oval window.]

It follows that vibrations would reach the auditory capsule along the following routes:

(a) Via the dermal skull bones and the dorsal process as the animal thrust its head in the mud.

(b) Via the lower jaw and articulo-quadrate joint and the quadrate process when the jaw was resting on the ground.

(c) Via the opened mouth and the hyoid and the hyoid process.

(d) Furthermore these animals were not *completely* deaf to sound waves impinging directly on the body surface. A small fraction of the sound striking the gill area would enter and pass via the opercular process to the ventral process.

(e) Lastly vibrations passing from the substrate into the manus and pectoral girdle would proceed via the cranio-scapular muscles to the auditory capsule without the intermediation of the hyomandibular. Thus the primitive Amphibia received faint auditory sensations via five distinct routes, of which the first three were the most efficient.

Then followed a process of specialization in which one or other route was perfected at the expense of the others. Route (a) gave rise to the V.Sq. mechanism of modern urodeles. This is obviously an unambitious mechanism only suited to completely prostrate animals. Even the lowly urodeles have found it inadequate for the obvious reason that it ceases to function as soon as the head is lifted off the ground. They have therefore developed the next available route for detecting substrate vibrations, i.e. via the fore-paw. It appears therefore that the V.S. mechanism developed phylogenetically after the V.Sq. mechanism in response to the functional demands of a more erect posture. Generally speaking modern urodeles possess both V.Sq. and V.S. but the relative importance of the two mechanisms varies greatly. In the completely prostrate types V.Sq. predominates and V.S. may not be present at all. On the other hand in the more erect types V.S. predominates and V.Sq. tends to disappear entirely.

The primitive Amphibia flourished throughout the Devonian and Carboniferous but in the Permian they were being thrust into the background by the newly evolved reptiles.

For our present purpose it will suffice to describe the main stem reptiles (the cotylosaurs) branching off into the archosaurs the pro-squamata and the premammalians (see fig. 15).

The archosaurs gave rise to the mighty dinosaurs who dominated the earth all through the Mesozoic era. They became extinct in the Cretaceous but early offshoots are represented

FIG. 4.—*Saltoposuchus*, a lightly built Triassic thecodont, about 3½ ft. in length. (From von Huene.) This animal obviously rarely had its skull or fore-paw on the ground. Therefore it had no use for V.Sq., V.Q. or V.S. hearing. It almost certainly had airborne hearing comparable to that of *Sphenodon*—or it may even have achieved perfect V.T. hearing. (Reproduced by permission.)

to-day by crocodiles, turtles and birds. Fig. 4 shows a thecodont, the immediate forerunner of the archosaur. Its bi-pedal stance means that V.Sq., V.Q. and V.S. would be useless to it. In the writer's opinion these animals probably used route (c) (i.e. V.H.) but they were probably well on the way to V.T. Certainly the archosaurs had perfect V.T.—the transition taking place as shown in fig. 5. *Sphenodon* is living evidence of this very transition.

The pro-squamata apparently started off with route (b) (i.e. V.Q.) and in fact snakes still use that route. Most lizards have evolved V.T. out of V.Q. as shown in fig. 6 but certain species have not advanced as far as others. It is in fact possible to demonstrate in modern lizards all stages of evolution from the primitive V.Q. to the perfected V.T.

Stage I.—V.H. as found in amphibienids. The stapes is a solid conical mass overlain by muscles and articulating with the hyoid. Arrows indicate path of sound conduction (a).

Stage II.—V.H. + rudimentary V.T. Present in *Sphenodon*. The stapes has become smaller. It is still connected with the hyoid but it also sends a process to a plaque of fibrous tissue in the overlying muscles. The animal still mainly hears via the mouth but the plaque is faintly sensitive to external airborne sounds (b).

Stage III.—Perfected V.T. The stapes is extremely delicate and airborne. A true tympanic membrane is present. The middle ear opens widely on to the pharynx (c).

Vestibulo-quadrato.—Note massive stapes overlain by muscles and articulating firmly with quadrate. Arrows indicate path of sound conduction (a).

V.Q. + rudimentary V.T. as in *Lyriocephalus*. Note the rudimentary tympanic membrane in the masticatory muscles. The stapes is smaller. The epipharynx sends a pouch towards it (b).

Perfected vestibulo-tympanic. The muscles have receded. The drum has reached the surface. The stapes is delicate and airborne (c).

FIG. 5.—The transition from vestibulo-hyoid to vestibulo-tympanic hearing.

FIG. 6.—The transition from vestibulo-quadrato to vestibulo-tympanic hearing.

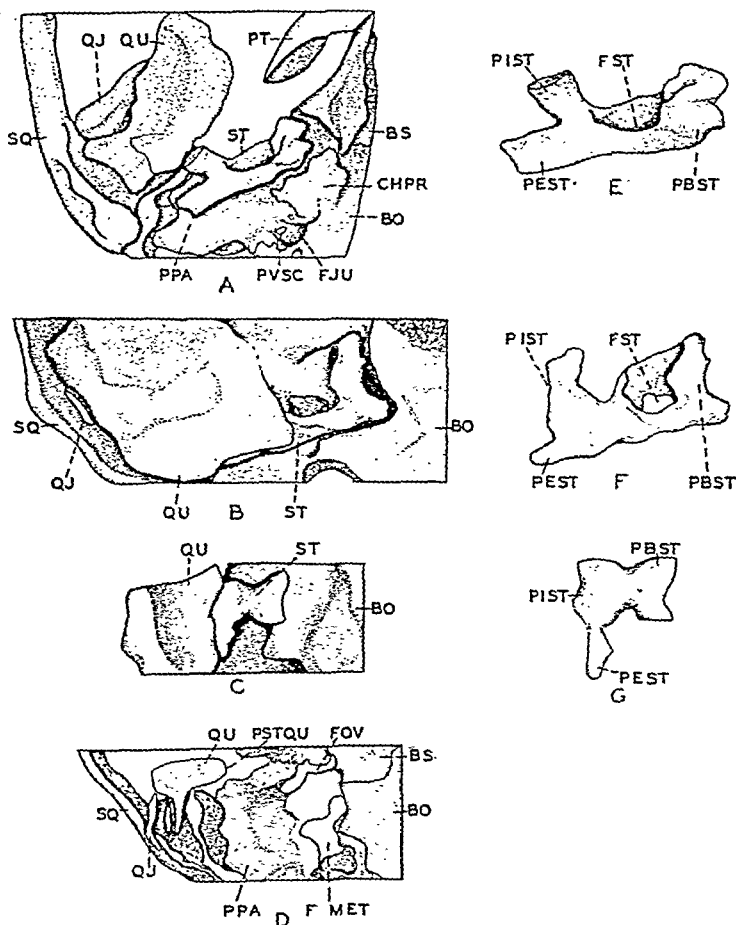

FIG. 7.—The therapsid stapes. Ventral views of right tympanic regions and stapes of selected therapsids. Reconstructed from wax models and from sections. A. Therocephalian B, *Tapinocephalus* zone. B. Gorgonopsian B, *Cistecephalus* zone. C. Anomodont E, *Endothiodon* zone. D. Cynodont B, horizon uncertain. Right stapes of three therapsids in ventral aspect. Drawn from wax models which were reconstructed from sections. E.—Therocephalian B. F.—Gorgonopsian B. G.—Anomodont E.

Note the relatively enormous size of the stapes. In each case the bone is so firmly locked to adjacent bones—especially the quadrate—that a tympanic membrane would have been entirely useless. (From *Spec. Papers Geol. Soc. Amer.*, 1944, No. 55, p. 40, by permission.)

The pre-mammalian reptiles utilized V.Q. also. Fig. 7 shows the skulls of some typical therapsids. The stapes is a massive structure firmly articulating with adjacent bones—in particular with the quadrate. It is obviously impossible for such a stapes to have been energized by the feeble flapping of a tympanic membrane and we must deduce that the pre-mammalian reptiles utilized V.Q. bone-conducted hearing, just as the pro-squamata did. Nevertheless they did not evolve in the same way, the fact being that the modern mammalian middle ear differs from the reptilian in possessing three ossicles in place of the single columella of the reptile.

The explanation of the mammalian triple ossicle system is to be found in the amazing metamorphosis of the jaw-joint. The mammalian lower jaw consists of a single bone—the dentary, which articulates with the squamosal. In all other terrestrial vertebrates the lower jaw consists of 6 or more elements—the dentary, splenial, angular, surangular, articular, &c. This complex bone articulates with the quadrate at the articular and we have to consider how the primitive articulo-quadrate joint became supplanted in the mammal by the squamoso-dental joint. The reasons why this change occurred are not clearly understood, but one

FIG. 4.—*Saltoposuchus*, a lightly built Triassic thecodont, about 3½ ft. in length. (From von Huene.) This animal obviously rarely had its skull or fore-paw on the ground. Therefore it had no use for V.Sq., V.Q. or V.S. hearing. It almost certainly had airborne hearing comparable to that of *Sphenodon*—or it may even have achieved perfect V.T. hearing. (Reproduced by permission.)

to-day by crocodiles, turtles and birds. Fig. 4 shows a thecodont, the immediate forerunner of the archosaur. Its bi-pedal stance means that V.Sq., V.Q. and V.S. would be useless to it. In the writer's opinion these animals probably used route (c) (i.e. V.H.) but they were probably well on the way to V.T. Certainly the archosaurs had perfect V.T.—the transition taking place as shown in fig. 5. *Sphenodon* is living evidence of this very transition.

The pro-squamata apparently started off with route (b) (i.e. V.Q.) and in fact snakes still use that route. Most lizards have evolved V.T. out of V.Q. as shown in fig. 6 but certain species have not advanced as far as others. It is in fact possible to demonstrate in modern lizards all stages of evolution from the primitive V.Q. to the perfected V.T.

Stage I.—V.H. as found in amphisbæuids. The stapes is a solid conical mass overlain by muscles and articulating with the hyoid. Arrows indicate path of sound conduction (a).

Stage II.—V.H. + rudimentary V.T. Present in *Sphenodon*. The stapes has become smaller. It is still connected with the hyoid but it also sends a process to a plaque of fibrous tissue in the overlying muscles. The animal still mainly hears via the mouth but the plaque is faintly sensitive to external airborne sounds (b).

Stage III.—Perfected V.T. The stapes is extremely delicate and airborne. A true tympanic membrane is present. The middle ear opens widely on to the pharynx (c).

FIG. 5.—The transition from vestibulo-hyoid to vestibulo-tympanic hearing.

Vestibulo-quadrato.—Note massive stapes overlain by muscles and articulating firmly with quadratus. Arrows indicate path of sound conduction (a).

V.Q. + rudimentary V.T. as in *Lyriocephalus*. Note the rudimentary tympanic membrane in the masticatory muscles. The stapes is smaller. The epipharynx sends a pouch towards it (b).

Perfected vestibulo-tympanic. The muscles have receded. The drum has reached the surface. The stapes is delicate and airborne (c).

FIG. 6.—The transition from vestibulo-quadrato to vestibulo-tympanic hearing.

THE ORTHODOX THEORY

Excellent reviews of the accepted theory on the development of the auditory conducting mechanism have been recently published by Gerrie [3] and Westoll [9].

It is believed that soon after floundering on to land the Amphibia acquired a perfected vestibulo-tympanic mechanism, complete with a tympanic membrane and an airborne stapes. Fig. 10A shows this mechanism as described by Westoll. A tympanic membrane is envisaged attached to the tabulo-squamosal notch (fig. 11A). Modern Anura are supposed to have directly inherited this arrangement.

FIG. 10.—Attempted reconstructions (schematic) of tympanic diverticula in fossil tetrapods.

A, the stegocephalian *Benthosuchus*, adapted from Bystrow and Efremov. B, the cotylosaur *Dimetrodon*, adapted from Captorhinus, adapted from Sushkin, Price and others. C, the pelycosaur *Lycedops*, adapted from Romer and Price. D, the therapsalian *Lycedops*, adapted from Broom. In each figure the columella auris or stapes is shown on the left side, the tympanic diverticulum on the right. Col—St—Columella (or stapes). Ty.d.—Tympanic diverticulum. ty—Tympanic membrane. Qu—Quadrate. Sq—Squamosal. (From T. S. Westoll, *Proc. roy. Soc. B.*, 1943, 131, 393.)

The tabulo-squamosal notch, however, is not found in the reptilian skull (see fig. 11B). It has been obliterated by a downspreading of the tabular and squamosal and therefore a new site has to be found for the reptilian tympanic membrane. In the cotylosaurs the drum is envisaged low down towards the posterior extremity of the lower jaw although no precise bony attachments are specified. Fig. 10B shows how the stapes has changed direction.

From the cotylosaurs diverged the three main groups, viz. pro-Squamata, archosaurs and the pre-mammals. It seems to be assumed that the cotylosaurian V.T. mechanism was handed on to the reptiles in general and indeed little attention is paid to that aspect of the problem. Speculation is concentrated almost entirely on the phylogeny of the mammalian ossicles. It is believed that the reptilian middle-ear cavity continued to spread around the articulo-quadrate joint during the evolution of the mammals and that when the squamoso-dental joint began to function the stapes somehow came adrift from the original reptilian tympanic membrane and resumed contact with the quadrate whilst a new mammalian tympanic membrane developed in the immediate vicinity of the articular.

Certain general features of this theory merit special attention. For example no attention whatsoever is paid to any type of auditory mechanism other than V.T. and V.O. The usual procedure is to locate the stapes and then to assume it was enveloped in a middle-ear cavity, placing a drum at whatever spot is available, without any regard to the mechanical efficiency of the system. This preoccupation with the tympanic membrane is probably anthropocentric and it leads to a dismissal of all other forms of hearing as "degenerate": V.Sq. of the urodeles, V.Q. of the snakes and lizards, V.H. of the amphibians and Sphenodon are all thus stigmatized. Even V.S. is regarded in some way as degenerate.

THE THEORIES CONTRASTED

Turning now to a more detailed analysis we consider first the stegocephalian "tympanic membrane". The only evidence in support of it is the fact that the stegocephalian stapes

important factor was the development of powerful masticatory muscles descending from the squamosal to the dentary. In response to functional stress on the bone, outgrowth occurred at these muscle insertions, and finally the outgrowth on the dentary reached almost to the squamosal.

FIG. 8.—Lower jaw of *Cynognathus*—internal aspect. ar—articular. a—angular. d—dentary. sa—surangular. pa—pre-articular. (Reproduced by permission.)

Fig. 8.—shows the inside of the lower jaw of cynognathus. It still articulates at *ar*, the articulo-quadrate joint, but obviously the dentary is reaching upwards towards the base of the skull. It is easy to envisage a stage at which a squamosal-dentary bursa would develop externally to the primitive joint, the jaw, actually rocking on a double articulation. Subsequently the squamoso-dental-joint took over full function and the articulo-quadrate joint was completely superseded. The subsequent transition may be described in a few words (fig. 9). The ossicles became progressively lighter and at the same time the pharyngeal mucosa pushed outwards whilst the skin pushed inwards.¹ The two layers approximated to form the typical trilaminar drum. In the process the articular was trapped together with the adjacent fibrous tissue and that explains how the handle of the malleus (which is derived from the articular) persists in the substance of the tympanic membrane. Similarly, the tympanic annulus would develop out of the posterior jaw-bone element to which the fibrous tissue in question was attached, i.e. the angular. Thus the tympanic membrane of the mammal has developed along completely different lines from either that of the Squamata or of the archosaurs.

There is still another type of tympanic membrane to be discussed, that of the Anura. We left the urodeles at the stage of the V.S. mechanism having noted that in some types (e.g. Triton) the hyomandibular columella has completely disappeared, the animal depending solely on V.S. The Anura seem to have travelled functionally along a similar path to that of the Urodela.² Some toads, like Bombinator, only possess an opercular mechanism; like Triton, they have no columella whatsoever. We assume, therefore, that the Anura in general passed through a stage in which only V.S. was present, but the more progressive frogs went further and developed a V.T. mechanism as well. If, however, the hyomandibular columella had by that time completely disappeared it would not be available to produce the anuran columella. Therefore the latter must have developed out of some other structure. In other words it is not homologous with the hyomandibular-derived columella of the urodele. Evidence in support of this will be adduced later (see fig. 13).

I call this stage vestibulo-mandibular (V.M.). Mechanically it closely resembles V.H. No living animal shows V.M. but recent research [10] has confirmed its presence in the bauriamorphs, i.e. the most advanced therapsids.

²Although they are both Amphibia they diverged from the common stem very early on. Nevertheless their opercular mechanisms are practically identical so that either they inherited their auditory apparatus from a common ancestor or they have travelled along the same functional lines. In either case the argument holds.

FIG. 9.—The development of the triple ossicle system.

The C.N.S. towers above the ear and bellies out external to it. The oval window sinks inwards. The jaw still hinges at the articulo-quadrate joint which has become delicate. Note the massive dentary extending upwards in the muscles towards the squamosal.

Vestibulo - quadrate hearing in *Cynognathus*.

The dentary has reached the squamosal to form the mammalian joint. The reptilian joint is superseded. The ossicles are shrinking in size. The animal opens its mouth to listen.

Vestibulo - mandibular hearing in the earliest mammals.

The ramus of the mandible has been excised to show the ossicles still shrinking in size. The outer ear and the eustachian tube begin to form and as they approximate the articular is trapped in the intervening fibrous layer and becomes the malleus.

THE ORTHODOX THEORY

Excellent reviews of the accepted theory on the development of the auditory conducting mechanism have been recently published by Gerrie [3] and Westoll [9].

It is believed that soon after floundering on to land the Amphibia acquired a perfected vestibulo-tympanic mechanism, complete with a tympanic membrane and an airborne stapes. Fig. 10A shows this mechanism as described by Westoll. A tympanic membrane is envisaged attached to the tabulo-squamosal notch (fig. 11A). Modern Anura are supposed to have directly inherited this arrangement.

FIG. 10.—Attempted reconstructions (schematic) of tympanic diverticula in fossil tetrapods. A, the stegocephalian *Benthosuchus*, adapted from Bystrow and Efremov. B, the cotylosaur *Captorhinus*, adapted from Sushkin, Price and others. C, the pelycosaur *Dimetrodon*, adapted from Romer and Price. D, the therapsid *Lyceodops*, adapted from Broom. In each figure the columella auris or stapes is shown on the left side, the tympanic diverticulum on the right. Col—St—Columella (or stapes). Ty.d.—Tympanic diverticulum. ty—Tympanic membrane. Qu—Quadrate. Sq—Squamosal. (From T. S. Westoll, *Proc. roy. Soc. B.*, 1943, 131, 393.)

The tabulo-squamosal notch, however, is not found in the reptilian skull (see fig. 11B). It has been obliterated by a downspreading of the tabular and squamosal and therefore a new site has to be found for the reptilian tympanic membrane. In the cotylosaurs the drum is envisaged low down towards the posterior extremity of the lower jaw although no precise bony attachments are specified. Fig. 10B shows how the stapes has changed direction.

From the cotylosaurs diverged the three main groups, viz. pro-Squamata, archosaurs and the pre-mammalians. It seems to be assumed that the cotylosaurian V.T. mechanism was handed on to the reptiles in general and indeed little attention is paid to that aspect of the problem. Speculation is concentrated almost entirely on the phylogeny of the mammalian ossicles. It is believed that the reptilian middle-ear cavity continued to spread around the articulo-quadrate joint during the evolution of the mammals and that when the squamoso-dental joint began to function the stapes somehow came adrift from the original reptilian tympanic membrane and resumed contact with the quadrate whilst a new mammalian tympanic membrane developed in the immediate vicinity of the articular.

Certain general features of this theory merit special attention. For example no attention whatsoever is paid to any type of auditory mechanism other than V.T. and V.O. The usual procedure is to locate the stapes and then to assume it was enveloped in a middle-ear cavity, placing a drum at whatever spot is available, without any regard to the mechanical efficiency of the system. This preoccupation with the tympanic membrane is probably anthropocentric and it leads to a dismissal of all other forms of hearing as "degenerate": V.Sq. of the urodeles, V.Q. of the snakes and lizards, V.H. of the amphisbaenids and *Sphenodon* are all thus stigmatized. Even V.S. is regarded in some way as degenerate.

THE THEORIES CONTRASTED

Turning now to a more detailed analysis we consider first the stegocephalian "tympanic membrane". The only evidence in support of it is the fact that the stegocephalian stapes

important factor was the development of powerful masticatory muscles descending from the squamosal to the dentary. In response to functional stress on the bone, outgrowth occurred at these muscle insertions, and finally the outgrowth on the dentary reached almost to the squamosal.

FIG. 8.—Lower jaw of *Cynognathus*—internal aspect. ar—articular. a—angular. d—dentary. sa—surangular. pa—pre-articular. (Reproduced by permission.)

Fig. 8.—shows the inside of the lower jaw of cynognathus. It still articulates at ar, the articulo-quadrato joint, but obviously the dentary is reaching upwards towards the base of the skull. It is easy to envisage a stage at which a squamosal-dentary bursa would develop externally to the primitive joint, the jaw, actually rocking on a double articulation. Subsequently the squamoso-dental-joint took over full function and the articulo-quadrato joint was completely superseded. The subsequent transition may be described in a few words (fig. 9). The ossicles became progressively lighter and at the same time the pharyngeal mucosa pushed outwards whilst the skin pushed inwards.¹ The two layers approximated to form the typical trilaminar drum. In the process the articular was trapped together with the adjacent fibrous tissue and that explains how the handle of the malleus (which is derived from the articular) persists in the substance of the tympanic membrane. Similarly, the tympanic annulus would develop out of the posterior jaw-bone element to which the fibrous tissue in question was attached, i.e. the angular. Thus the tympanic membrane of the mammal has developed along completely different lines from either that of the Squamata or of the archosaurs.

There is still another type of tympanic membrane to be discussed, that of the Anura. We left the urodeles at the stage of the V.S. mechanism having noted that in some types (e.g. Triton) the hyomandibular columella has completely disappeared, the animal depending solely on V.S. The Anura seem to have travelled functionally along a similar path to that of the Urodela.² Some toads, like Bombinator, only possess an opercular mechanism; like Triton, they have no columella whatsoever. We assume, therefore, that the Anura in general passed through a stage in which only V.S. was present, but the more progressive frogs went further and developed a V.T. mechanism as well. If, however, the hyomandibular columella had by that time completely disappeared it would not be available to produce the anuran columella. Therefore the latter must have developed out of some other structure. In other words it is not homologous with the hyomandibular-derived columella of the urodele. Evidence in support of this will be adduced later (see fig. 13).

¹I call this stage vestibulo-mandibular (V.M.). Mechanically it closely resembles V.H. No living animal shows V.M. but recent research [10] has confirmed its presence in the bauriamorphs, i.e. the most advanced therapsids.

²Although they are both Amphibia they diverged from the common stem very early on. Nevertheless their opercular mechanisms are practically identical so that either they inherited their auditory apparatus from a common ancestor or they have travelled along the same functional lines. In either case the argument holds.

THE ORTHODOX THEORY

Excellent reviews of the accepted theory on the development of the auditory conducting mechanism have been recently published by Gerrie [3] and Westoll [9].

It is believed that soon after floundering on to land the Amphibia acquired a perfected vestibulo-tympanic mechanism, complete with a tympanic membrane and an airborne stapes. Fig. 10A shows this mechanism as described by Westoll. A tympanic membrane is envisaged attached to the tabulo-squamosal notch (fig. 11A). Modern Anura are supposed to have directly inherited this arrangement.

FIG. 10.—Attempted reconstructions (schematic) of tympanic diverticula in fossil tetrapods. A, the stegocephalian *Benthosuchus*, adapted from Bystrow and Efremov. B, the cotylosaur *Captorhinus*, adapted from Sushkin, Price and others. C, the pelycosaur *Dimetrodon*, adapted from Romer and Price. D, the therapsid *Lyceodops*, adapted from Broom. In each figure the columella auris or stapes is shown on the left side, the tympanic diverticulum on the right. Col—St—Columella (or stapes). Ty.d.—Tympanic diverticulum. ty—Tympanic membrane. Qu—Quadrate. Sq—Squamosal. (From T. S. Westoll, *Proc. roy. Soc. B.*, 1943, 131, 393.)

The tabulo-squamosal notch, however, is not found in the reptilian skull (see fig. 11B). It has been obliterated by a downspreading of the tabular and squamosal and therefore a new site has to be found for the reptilian tympanic membrane. In the cotylosaurs the drum is envisaged low down towards the posterior extremity of the lower jaw although no precise bony attachments are specified. Fig. 10B shows how the stapes has changed direction.

From the cotylosaurs diverged the three main groups, viz. pro-Squamata, archosaurs and the pre-mammals. It seems to be assumed that the cotylosaurian V.T. mechanism was handed on to the reptiles in general and indeed little attention is paid to that aspect of the problem. Speculation is concentrated almost entirely on the phylogeny of the mammalian ossicles. It is believed that the reptilian middle-ear cavity continued to spread around the articulo-quadrate joint during the evolution of the mammals and that when the squamoso-dental joint began to function the stapes somehow came adrift from the original reptilian tympanic membrane and resumed contact with the quadrate whilst a new mammalian tympanic membrane developed in the immediate vicinity of the articular.

Certain general features of this theory merit special attention. For example no attention whatsoever is paid to any type of auditory mechanism other than V.T. and V.O. The usual procedure is to locate the stapes and then to assume it was enveloped in a middle-ear cavity, placing a drum at whatever spot is available, without any regard to the mechanical efficiency of the system. This preoccupation with the tympanic membrane is probably anthropocentric and it leads to a dismissal of all other forms of hearing as "degenerate": V.Sq. of the urodeles, V.Q. of the snakes and lizards, V.H. of the amphibians and *Sphenodon* are all thus stigmatized. Even V.S. is regarded in some way as degenerate.

THE THEORIES CONTRASTED

Turning now to a more detailed analysis we consider first the stegocephalian "tympanic membrane". The only evidence in support of it is the fact that the stegocephalian stapes

points to the otic notch. It is difficult to avoid the conclusion that morphologists have merely assumed that a drum and tympanic cavity must have been present. Having located the stapes they quite uncritically postulate a middle-ear cavity and drum to go with it. The tabulosquamosal notch at first sight is a suitable situation for a drum but actually there is strong evidence that it did *not* house a tympanic membrane. This notch is quite prominent in very early Amphibia (e.g. *Ichthyostega*) in which the oval window had not yet evolved. The writer has shown [7] that in the absence of an oval window a tympanic membrane could have had no possible function. Thus on functional grounds it must be stated that the otic notch did not house a tympanic membrane. It has been argued that the slender nature of the stegocephalian columella is evidence that it was airborne. This is entirely fallacious. Fig. 12 shows the stapes of *Lyriocephalus*, a modern lizard. It is a long slender stylus (with a small cartilaginous extra columella) strongly reminiscent of the stegocephalian. *Lyriocephalus* possesses no true tympanic membrane or cavity and there is no reason to believe that the *Stegocephalia* did. Certainly the mere appearance of the bony structures does not justify the assumption.

FIG. 11.—A: Lateral view of skull of *Ichthyostega* showing otic notch. B: Lateral view of skull of *Captorhinus* showing absence of otic notch.

(From J. Gerrie, Mammalian Tympanic Cavity and Auditory Ossicles, *J. Laryng. Otol.*, 1948, 62, 350, after Romer.)

FIG. 12.—Hind view of skull of *Lyriocephalus scutatus*. This modern lizard has no drum or middle-ear cavity. The dorsal process (D.P.) and ventral process (V.P.) are attached to the quadrate. A small cartilaginous extra columella enters the superjacent muscles. The arrangement closely resembles fig. 10 and illustrates the fallacy of assuming the existence of a drum or middle-ear cavity solely from the appearance of the bony skeleton. (From *Evolutionary Changes in the Middle Ear of Certain Agamid and Iguanid Lizards*, by Malcolm A. Smith, *Proc. zool. Soc. Lond. Ser. B*, 1938, Part 3, 1938, by permission.)

Septicism as to the otic notch is, if anything, increased by a consideration of the cotylosaurs. These stem reptiles more or less supplanted the Amphibia and gave rise subsequently to the mighty radiation of the Mesozoic reptiles. One would expect them in general to have improved on the Amphibia, but actually the cotylosaurian stapes is a massive bone bound firmly to adjacent structures, in particular the quadrate. It seems unquestionable that the cotylosaurs heard by V.Q. Despite this, orthodox theory persists in ascribing to them a middle-ear cavity and a drum as in fig. 10b. The precise situation of the drum is unspecified. As shown in fig. 11b the otic notch has disappeared and it is apparently presumed that the cotylosaurian drum lay somewhere in the soft tissues near the jaw-joint. This is a remarkable transition. Mechanically speaking the otic notch would have been an excellent situation for a drum. If the *Stegocephalia* had really achieved such an excellent tympanic annulus it seems incredible that the cotylosaurs could have abandoned it. Yet this is implicit in the orthodox theory which states that the otic notch was obliterated by a downspreading of the adjacent bones—without considering the functional implications.

Passing on to the three branches of the stem reptiles, we consider the pre-mammals first. We have already seen from fig. 7 that the therapsids inherited with little modification the V.Q. mechanism of the cotylosaurs, but orthodox theory persists in attributing to them a tympanic membrane and cavity (see fig. 10b). This results in a further paradox. The therapsids gave rise directly to the mammals and it has been shown conclusively that the mammalian annulus tympanicus is homologous with the therapsid angular. [The angular is one of the posterior elements in the reptilian lower jaw.] Therefore it appears as if the therapsids' tympanic membrane must have been directly adjacent to the angular. It is even

widely held that it was closely attached to the reflected lamina of the angular. This theory has been criticized devastatingly by Romer and Price [5] but unfortunately the dilemma persists. If the therapsids possessed a tympanic membrane at all it *must* have been closely related, if not directly attached to, the lower jaw where it would be twitched and pulled by every snap of the jaws. This precarious situation is in striking contrast with the otic notch of the Stegocephalia and we are entitled to protest that evolution is unlikely to have worked in such a retrograde manner.

In the writer's theory these difficulties and dilemmas do not arise. It is recognized that a tympanic membrane of sorts may have existed in close relation with the lower jaw of the therapsids—but it was not the delicate trilaminar drumskin of the orthodox theory. It was merely the fibrous tissues which enveloped the obsolescent articulo-quadrate joint. The later therapsids had vestibulo-mandibular hearing and not V.T. It is true that this "tympanic membrane" was at the mercy of the mandibular muscles just as is that of *Sphenodon* to-day. It was indeed a crude structure, nevertheless it was more efficient than the V.Q. mechanism of the pelycosaurs, cotylosaurs and Stegocephalia which preceded it. Thus, in the writer's theory, the transition from amphibian to reptile was accompanied by a process of improvement such as would be normally expected to occur and there was no disastrous migration from otic notch to lower jaw such as is implicit in the orthodox theory.

Next we consider the archosaurian middle ear. Orthodox theory is strangely silent on this subject. This is partly due to an anthropocentric pre-occupation with the mammalian ear. Most work is devoted to a consideration of the transition from amphibian to cotylosaur, and thence via pelycosaur and therapsid to mammal. In the case of the archosaurs, however, little is said because in fact practically nothing is known. It is remarkable that the stapes of a dinosaur has *never* been located, despite the fact that these reptiles achieved colossal dimensions, and many species in excellent preservation have been minutely studied. Compared to the therapsids—bulk for bulk some dinosaurs should have possessed stapes a foot or more in length. On this fascinating mystery of the missing dinosaur stapes orthodox theory is silent whereas the functional theory provides the following simple and plausible explanation. The outstanding characteristic of the dinosaurs was their bipedal stance which meant that they could not have utilized V.Sq., V.Q. or V.S. If they heard at all it can only have been via V.H. or V.T. In the writer's opinion they heard by V.T. The fact being that for true V.T. the columella must be airborne and extremely delicate and a columella of this fragile nature *will not survive the process of fossilization*—at any rate it would escape the palaeontologist in search of a stapes comparable with that of the pre-mammalian.¹ It might be countered that the absence of a dinosaurian stapes is susceptible to an even simpler explanation—namely that they had no stapes. This, however, will not bear examination. These were the dominant animals throughout the Mesozoic. They reigned for over fifty million years—having almost wiped out the therapsids in the Triassic.² It is difficult to believe that this enormous group can have been uniformly stone deaf, the more so as birds and crocodiles—descendants from the common dinosaurian stem possess perfect V.T. mechanisms to-day. In the writer's opinion the dinosaurs were the *first* animals ever to evolve a true V.T. mechanism and it is not improbable that that master patent accounts for their success in supplanting the therapsids all through the Mesozoic.

With regard to the Squamata, little need be said. In the writer's opinion the pro-Squamata had V.Q. hearing which has persisted in the snakes and certain of the lizards. A transition to V.T. has taken place with varying velocity in the different species of lizards so that all stages of perfection can be demonstrated. According to orthodox theory, precisely the opposite has happened. The pro-Squamata possessed V.T. and snakes, chameleons, &c., show varying degrees of degeneration. No valid evidence for the tympanic membranes of the pro-Squamata is vouchsafed and no valid reasons are given for the widespread "degeneration" in their descendants.

We now pass on to the mammalian triple ossicle system. It may perhaps be asked why the pre-mammals, starting with V.Q., did not simply evolve V.T. just as the archosaurs did. The answer has already been partially provided by the account given of the transformation of the articulo-quadrate joint. A further suggestion was made by Dabelow [1] who pointed out that despite their diminution in size the therapsids possessed relatively large brains. The central nervous system expanding upwards and outwards thrust the squamosal before it so that the oval window sank relatively inwards. Thus the stapes was nowhere near the surface.

¹The fact that the stapes of other orders (e.g. therapsids) was *not* of this fragile nature has already been adduced as evidence that the corresponding mechanism was *not* V.T.

²The pelycosaurs and therapsids dominated the thecodonts in the Permian. Then the dinosaurs overwhelmed the therapsids throughout the Mesozoic. They suddenly disappeared at the end of the Cretaceous. The cause is unknown. They were not overwhelmed by the mammals. The latter appeared first in the mid-Jurassic but were tiny furtive creatures. Their descendants proliferated to fill the vacuum left by the receding dinosaurs.

points to the otic notch. It is difficult to avoid the conclusion that morphologists have merely assumed that a drum and tympanic cavity must have been present. Having located the stapes they quite uncritically postulate a middle-ear cavity and drum to go with it. The tabulosquamosal notch at first sight is a suitable situation for a drum but actually there is strong evidence that it did *not* house a tympanic membrane. This notch is quite prominent in very early Amphibia (e.g. *Ichthyostega*) in which the oval window had not yet evolved. The writer has shown [7] that in the absence of an oval window a tympanic membrane could have had no possible function. Thus on functional grounds it must be stated that the otic notch did not house a tympanic membrane. It has been argued that the slender nature of the stegocephalian columella is evidence that it was airborne. This is entirely fallacious. Fig. 12 shows the stapes of *Lyriocephalus*, a modern lizard. It is a long slender stylus (with a small cartilaginous extra columella) strongly reminiscent of the stegocephalian. *Lyriocephalus* possesses no true tympanic membrane or cavity and there is no reason to believe that the *Stegocephalia* did. Certainly the mere appearance of the bony structures does not justify the assumption.

(From J. Gerrie, Mammalian Tympanic Cavity and Auditory Ossicles, *J. Laryng. Otol.*, 1948, 62, 350, after Romer.)

FIG. 12.—Hind view of skull of *Lyriocephalus scutatus*. This modern lizard has no drum or middle-ear cavity. The dorsal process (D.P.) and ventral process (V.P.) are attached to the quadrate. A small cartilaginous extra columella enters the superjacent muscles. The arrangement closely resembles fig. 10 and illustrates the fallacy of assuming the existence of a drum or middle-ear cavity solely from the appearance of the bony skeleton. (From *Evolutionary Changes in the Middle Ear of Certain Agamid and Iguanid Lizards*, by Malcolm A. Smith, *Proc. zool. Soc. Lond. Ser. B*, 108, Part 3, 1938, by permission.)

Scepticism as to the otic notch is, if anything, increased by a consideration of the cotylosaurs. These stem reptiles more or less supplanted the Amphibia and gave rise subsequently to the mighty radiation of the Mesozoic reptiles. One would expect them in general to have improved on the Amphibia, but actually the cotylosaurian stapes is a massive bone bound firmly to adjacent structures, in particular the quadrate. It seems unquestionable that the cotylosaurs heard by V.Q. Despite this, orthodox theory persists in ascribing to them a middle-ear cavity and a drum as in fig. 10b. The precise situation of the drum is unspecified. As shown in fig. 11b the otic notch has disappeared and it is apparently presumed that the cotylosaurian drum lay somewhere in the soft tissues near the jaw-joint. This is a remarkable transition. Mechanically speaking the otic notch would have been an excellent situation for a drum. If the *Stegocephalia* had really achieved such an excellent tympanic annulus it seems incredible that the cotylosaurs could have abandoned it. Yet this is implicit in the orthodox theory which states that the otic notch was obliterated by a downspreading of the adjacent bones—without considering the functional implications.

Passing on to the three branches of the stem reptiles, we consider the pre-mammals first. We have already seen from fig. 7 that the therapsids inherited with little modification the V.Q. mechanism of the cotylosaurs, but orthodox theory persists in attributing to them a tympanic membrane and cavity (see fig. 10D). This results in a further paradox. The therapsids gave rise directly to the mammals and it has been shown conclusively that the mammalian annulus tympanicus is homologous with the therapsid angular. [The angular is one of the posterior elements in the reptilian lower jaw.] Therefore it appears as if the therapsids' tympanic membrane must have been directly adjacent to the angular. It is even

widely held that it was closely attached to the reflected lamina of the angular. This theory has been criticized devastatingly by Romer and Price [5] but unfortunately the dilemma persists. If the therapsids possessed a tympanic membrane at all it *must* have been closely related, if not directly attached to, the lower jaw where it would be twitched and pulled by every snap of the jaws. This precarious situation is in striking contrast with the otic notch of the Stegocephalia and we are entitled to protest that evolution is unlikely to have worked in such a retrograde manner.

In the writer's theory these difficulties and dilemmas do not arise. It is recognized that a tympanic membrane of sorts may have existed in close relation with the lower jaw of the therapsids—but it was not the delicate trilaminar drumskin of the orthodox theory. It was merely the fibrous tissues which enveloped the obsolescent articulo-quadrate joint. The later therapsids had vestibulo-mandibular hearing and not V.T. It is true that this "tympanic membrane" was at the mercy of the mandibular muscles just as is that of Sphenodon to-day. It was indeed a crude structure, nevertheless it was more efficient than the V.Q. mechanism of the pelycosaurs, cotylosaurs and Stegocephalia which preceded it. Thus, in the writer's theory, the transition from amphibian to reptile was accompanied by a process of improvement such as would be normally expected to occur and there was no disastrous migration from otic notch to lower jaw such as is implicit in the orthodox theory.

Next we consider the archosaurian middle ear. Orthodox theory is strangely silent on this subject. This is partly due to an anthropocentric pre-occupation with the mammalian ear. Most work is devoted to a consideration of the transition from amphibian to cotylosaur, and thence via pelycosaur and therapsid to mammal. In the case of the archosaurs, however, little is said because in fact practically nothing is known. It is remarkable that the stapes of a dinosaur has *never* been located, despite the fact that these reptiles achieved colossal dimensions, and many species in excellent preservation have been minutely studied. Compared to the therapsids—bulk for bulk some dinosaurs should have possessed stapes a foot or more in length. On this fascinating mystery of the missing dinosaur stapes orthodox theory is silent whereas the functional theory provides the following simple and plausible explanation. The outstanding characteristic of the dinosaurs was their bipedal stance which meant that they could not have utilized V.Sq., V.Q. or V.S. If they heard at all it can only have been via V.H. or V.T. In the writer's opinion they heard by V.T. The fact being that for true V.T. the columella must be airborne and extremely delicate and a columella of this fragile nature *would not survive the process of fossilization*—at any rate it would escape the palaeontologist in search of a stapes comparable with that of the pre-mammalian.¹ It might be countered that the absence of a dinosaurian stapes is susceptible to an even simpler explanation—namely that they had no stapes. This, however, will not bear examination. These were the dominant animals throughout the Mesozoic. They reigned for over fifty million years—having almost wiped out the therapsids in the Triassic.² It is difficult to believe that this enormous group can have been uniformly stone deaf, the more so as birds and crocodiles—descendants from the common dinosaurian stem possess perfect V.T. mechanisms to-day. In the writer's opinion the dinosaurs were the *first* animals ever to evolve a true V.T. mechanism and it is not improbable that that master patent accounts for their success in supplanting the therapsids all through the Mesozoic.

With regard to the Squamata, little need be said. In the writer's opinion the pro-Squamata had V.Q. hearing which has persisted in the snakes and certain of the lizards. A transition to V.T. has taken place with varying velocity in the different species of lizards so that all stages of perfection can be demonstrated. According to orthodox theory, precisely the opposite has happened. The pro-Squamata possessed V.T. and snakes, chameleons, &c., show varying degrees of degeneration. No valid evidence for the tympanic membranes of the pro-Squamata is vouchsafed and no valid reasons are given for the widespread "degeneration" in their descendants.

We now pass on to the mammalian triple ossicle system. It may perhaps be asked why the pre-mammalians, starting with V.Q., did not simply evolve V.T. just as the archosaurs did. The answer has already been partially provided by the account given of the transformation of the articulo-quadrate joint. A further suggestion was made by Dabelow [1] who pointed out that despite their diminution in size the therapsids possessed relatively large brains. The central nervous system expanding upwards and outwards thrust the squamosal before it so that the oval window sank relatively inwards. Thus the stapes was nowhere near the surface.

¹The fact that the stapes of other orders (e.g. therapsids) was *not* of this fragile nature has already been adduced as evidence that the corresponding mechanism was *not* V.T.

²The pelycosaurs and therapsids dominated the thecodonts in the Permian. Then the dinosaurs overwhelmed the therapsids throughout the Mesozoic. They suddenly disappeared at the end of the Cretaceous. The cause is unknown. They were not overwhelmed by the mammals. The latter appeared first in the mid-Jurassic but were tiny furtive creatures. Their descendants proliferated to fill the vacuum left by the receding dinosaurs.

It was closer to the pharyngeal mucosa and naturally joined the obsolescent articulo-quadrate complex to form an acoustic transmitter.

The functional theory thus postulates a progressively improving mechanism—the transition being from V.Q. to V.M. and so to V.O. In this transition the obsolescent articulo-quadrate structures play a useful part and their incorporation in the mammalian ossicular chain follows logically. Orthodox theory on the contrary provides no explanation for the incorporation, and indeed the usual account involves a retrogression as disastrous as that of the stegocephalian-therapsid transition. We are asked to believe that the therapsids enjoyed adequate V.T. hearing which they had inherited from the cotylosaurs and that somehow the obsolescent articulo-quadrate structures forced themselves between the stapes and the tympanic membrane. This means that at some stage the stapes became dissociated from the tympanic membrane. No suggestion is made as to why this should have happened.¹ It seems to be a most unnatural conception involving grave loss of efficiency.

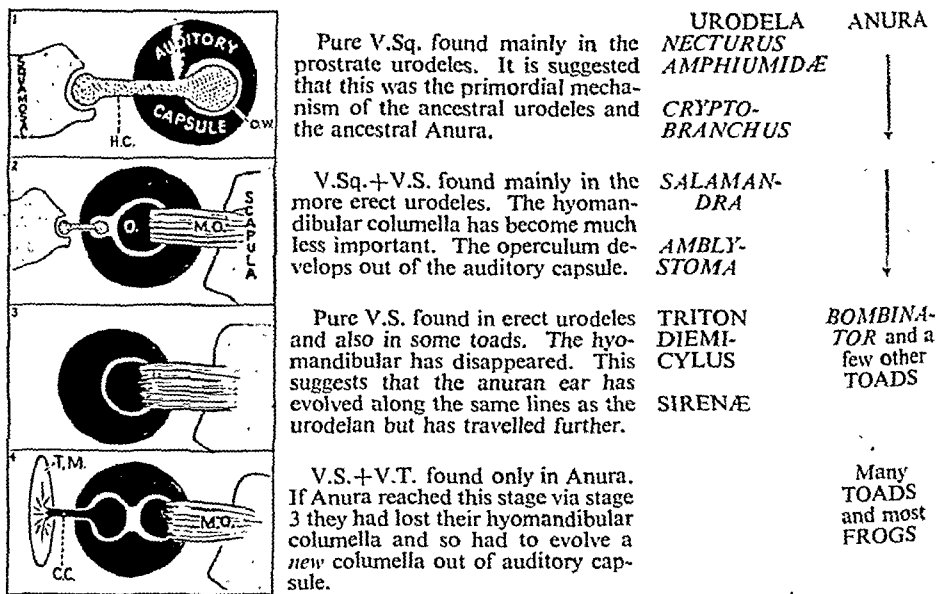

FIG. 13.—The auditory mechanism of modern amphibia.—V.Sq., V.S. and V.T. (Functional theory).

Functional theory suggests that modern Amphibia represent various stages in evolution. Orthodox theory declares that modern Amphibia represent various stages of degeneration.

O. Operculum.

T.M. Tympanic membrane.

Lastly we return to the Anura. Orthodox theory ascribes to them a tympanic membrane directly derived from the Stegocephalia. Functional theory denies this. First because the Stegocephalia had no drum to bequeath. Second because (fig. 13) functional considerations lead to the transition V.Sq. → (V.Sq. + V.S.) → V.S. → (V.S. + V.T.). The argument being that by the time the Anura came to add V.T. to their V.S. the hyomandibular had disappeared and they were reduced to evolving a columella out of a bit of auditory capsule just as they had evolved the opercular cartilage. Appealing to embryology we find the greatest authorities (Gaupp [2]; Villy [8] &c.) reporting that in the frog the columella, like the operculum, develops out of the auditory capsule. Thus, it cannot have descended from the hyomandibular which evolves out of the hyoid arch—an entirely different embryonic anlage.

The functional theory is further confirmed by the embryological order of appearance of these various structures. If it is correct to declare that the phylogenetic order was urodele columella first, then operculum, then anuran columella, we expect to find that order preserved in ontogeny. On the other hand orthodox theory, identifying the urodele columella with the anuran, requires them both to appear embryologically before the operculum. Kingsbury and Reed have shown quite definitely that the urodele columella precedes the operculum, whilst the anuran columella succeeds it.

The urodele columella is derived from the hyomandibular although even so it is not to be regarded as identical with the columella either of the Squamata or of the archosaurs.

¹It should be noted that physically speaking the triple ossicle mechanism is in no way superior to the monossicular system so that nothing was gained from the interpolation.

THE PHYLOGENY OF THE AUDITORY CONDUCTING MECHANISM (ORTHODOX THEORY)

FIG. 14.—A tympanic membrane is postulated in the stegocephalian "otic notch". Modern frogs have inherited it. Urodeles, amphisbaenids, snakes, Sphenodont and many lizards are degenerate. The cotylosaurs modified the stegocephalian mechanism by transferring the drum from the otic notch to the articulo-quadrato region. Mammals separated the drum from the columella and thrust the articulo-quadrato complex into the gap. See fig. 15 for details of primitive reptilian groups.

THE PHYLOGENY OF THE AUDITORY CONDUCTING MECHANISM (FUNCTIONAL THEORY)

FIG. 15.—The Stegocephalia started with rudimentary V.Sq., V.Q. and V.H. V.S. was also "potentially" present. Urodeles specialized in V.Sq. and later added V.S. Anura went on to add their own special type of V.T.

Cotylosaurs had V.Q. + V.H.

Archosaurs show the transition V.H.→V.T.

Squamata show the transition V.Q.→V.T.

Mammalia show the transition V.Q.→V.O.

Acknowledgments.—Figs. 2, 4 and 8 are reproduced by permission from "Vertebrate Paleontology" by A. S. Romer, 2nd ed., 1945, Chicago. Figs. 7, 10, 11 and 12 are reproduced from other sources, details of which will be found below the illustrations concerned.

It was closer to the pharyngeal mucosa and naturally joined the obsolescent articulo-quadrate complex to form an acoustic transmitter.

The functional theory thus postulates a progressively improving mechanism—the transition being from V.Q. to V.M. and so to V.O. In this transition the obsolescent articulo-quadrate structures play a useful part and their incorporation in the mammalian ossicular chain follows logically. Orthodox theory on the contrary provides no explanation for the incorporation, and indeed the usual account involves a retrogression as disastrous as that of the stegocephalian-therapsid transition. We are asked to believe that the therapsids enjoyed adequate V.T. hearing which they had inherited from the cotylosaurs and that somehow the obsolescent articulo-quadrate structures forced themselves between the stapes and the tympanic membrane. This means that at some stage the stapes became dissociated from the tympanic membrane. No suggestion is made as to why this should have happened.¹ It seems to be a most unnatural conception involving grave loss of efficiency.

Pure V.Sq. found mainly in the prostrate urodeles. It is suggested that this was the primordial mechanism of the ancestral urodeles and the ancestral Anura.

V.Sq. + V.S. found mainly in the more erect urodeles. The hyomandibular columella has become much less important. The operculum develops out of the auditory capsule.

Pure V.S. found in erect urodeles and also in some toads. The hyomandibular has disappeared. This suggests that the anuran ear has evolved along the same lines as the urodele but has travelled further.

V.S. + V.T. found only in Anura. If Anura reached this stage via stage 3 they had lost their hyomandibular columella and so had to evolve a new columella out of auditory capsule.

O.W. Oval window.

O. Operculum.

M.O. Musc. opercularis.

C.C. Capsular columella.

T.M. Tympanic membrane.

Lastly we return to the Anura. Orthodox theory ascribes to them a tympanic membrane directly derived from the Stegocephalia. Functional theory denies this. First because the Stegocephalia had no drum to bequeath. Second because (fig. 13) functional considerations lead to the transition V.Sq. → (V.Sq. + V.S.) → V.S. → (V.S. + V.T.). The argument being that by the time the Anura came to add V.T. to their V.S. the hyomandibular had disappeared and they were reduced to evolving a columella out of a bit of auditory capsule just as they had evolved the opercular cartilage. Appealing to embryology we find the greatest authorities (Gaupp [2]; Villy [8] &c.) reporting that in the frog the columella, like the operculum, develops out of the auditory capsule. Thus, it cannot have descended from the hyomandibular which evolves out of the hyoid arch—an entirely different embryonic anlage.

The functional theory is further confirmed by the embryological order of appearance of these various structures. If it is correct to declare that the phylogenetic order was urodele columella first, then operculum, then anuran columella, we expect to find that order preserved in ontogeny. On the other hand orthodox theory, identifying the urodele columella with the anuran, requires them both to appear embryologically before the operculum. Kingsbury and Reed have shown quite definitely that the urodele columella precedes the operculum, whilst the anuran columella succeeds it.

The urodele columella is derived from the hyomandibular although even so it is not to be regarded as identical with the columella either of the Squamata or of the archosaurs.

¹It should be noted that physically speaking the triple ossicle mechanism is in no way superior to the monossicular system so that nothing was gained from the interpolation.

INDEX

The differences may be tabulated as follows:

Functional theory		Orthodox
Urodele columella	Ventral + dorsal processes of hyomandibular	} VENTRAL PLUS OPERCULAR PROCESS OF HYOMANDIBULAR
Archosaurs columella	Ventral + hyoid processes of hyomandibular	
Squamata columella	Ventral + quadrate processes of hyomandibular	
Anuran columella	Auditory capsule	

In seeking for further evidence to enable us to choose between the two theories we turn to the neural relations. The facial nerve is closely related to the primitive hyomandibular. It emerges from the auditory capsule between the ventral and dorsal processes. Orthodox morphologists regarding all columellæ as identical expect to find them preserving identical relations with the facial nerve. Unfortunately this is far from being the case. Whereas in urodeles the main trunk of the nerve is *below* the columella, in all other animals it is *above*. Textbooks offer no explanation of this paradox, but the functional theory explains it quite simply. It is exactly what we should expect when we observe that V.Sq. of urodeles utilizes the dorsal process of the hyomandibular, i.e. the only process which is dorsal to the nerve. All the other processes are below it.

Again the chorda tympani in the Anura is post-tympanic—in all other animals it is pre-tympanic. This paradox has never been satisfactorily explained by the orthodox theory. On the functional theory it simply does not arise. The anuran columella is a totally different structure from all other columellæ and there is no reason to expect it to maintain identical relations. Figs. 14 and 15 show the two theories diagrammatically.

SUMMARY

The orthodox theory of the evolution of the middle ear is criticized for the following reasons:

- (1) It is based too exclusively on palæontological and ontological evidence.
- (2) In virtually ignoring the functional implications it accepts hypotheses which are "unreasonable" on physical and physiological grounds.
- (3) It labels organs as homologous on inadequate evidence and in the face of much evidence to the contrary.

(4) It adheres to the outdated conception that homologous organs must of necessity be inherited from a common ancestor.

(5) It is exclusively preoccupied with the airborne type of middle ear. Much standard work is devoted to the problem of locating the site of the tympanic membrane. Such work is doomed to failure because the tympanic membrane in many cases did not exist as such. The drum is phylogenetically a comparatively late development and was preceded by at least 5 other auditory mechanisms.

(6) These other mechanisms (V.Q., V.Sq., V.S., V.H. and V.M.) are mechanically comparatively crude but biologically they must be placed on a par with the air-conducting mechanisms V.T. and V.O. They are alternative solutions to the problem of picking up acoustic vibrations which confronted the primitive amphibian when it first floundered on to land.

(7) Orthodox theory has no place for these alternative mechanisms and is reduced to dismissing them as "degenerate."

(8) An alternative theory is proposed in which due regard is paid to the functional implications. This leads to many deductions which are diametrically opposed to orthodox theory. It appears that this functional theory not only conforms satisfactorily to all the available ontogenetic and phylogenetic data but it also disposes quite easily of the various paradoxes which render the orthodox theory so unacceptable.

I am very glad to acknowledge the stimulating criticism and very real help which I have received from Professor J. Harris, F.R.S., of Bristol, and from Professor F. Wood Jones, F.R.C.S., F.R.S., of the Royal College of Surgeons.
